to the standard Heaviside-Kelvin Bessel-function formulas, within
of experimental error.

skin-effect resistance ratio of a copper conductor formed of seven
parallel round bare strands (six surrounding a central seventh),
to be the same as that of the equisectional solid round wire up to
cles per second, within the limits of observational error. It is there-
ed that the subdivision of a round wire into a round cable of uninsu-
acting strands does not alter the skin effect.

effect of simple spiraling of strands in the same direction increased
nce ratio.

resistance ratio of a subdivided wire, with parallel insulated strands,
that of the equisectional solid wire, and diminished rapidly with the
r degree of strand separation.

braiding of strands, so as to effect their transposition in the cross-
frequent intervals, was found to diminish the skin effect.

skin effect in copper strips was found to be usually, but not invariably,
that of equisectional round wires.

easing the width of a copper strip within the limits reported was found
e the skin-effect resistance ratio; owing to what may be called "edge

ir of parallel going and returning flat strips, separated by a thin insu-
er, was found to have a skin effect depending only on the strip thick-
t is, without perceptible edge effect.

ng a flat strip into the form of a slit tube destroyed the edge effect,
ed the resistance ratio to a minimum dependent only on the strip

ting longitudinal slits with a sharp knife in a thin flat copper strip,
not appreciably to affect its skin effect resistance ratio.

order to employ a stranded wire of minimum skin effect at radio-fre-
seems desirable to employ thick insulation on the strands, such as
tton, to transpose the strands by braiding, and to avoid spirality in
he same direction.

order to employ a flat strip conductor most effectively, it is necessary
lling it out laterally when the increasing edge effect more than offsets
ion in skin effect.

hollow tubular form seems to be the most efficient type of radio-
metallic conductor, since, with proper mechanical internal support,
ffect can be indefinitely diminished by diminishing the wall thickness,
dge effect is absent.

SMOKE PREVENTION. — The direct cause of smoke from boiler furnaces is that the gases distilled from the coal are not completely burned in the furnace before coming in contact with the surface of the boiler, which chills them below the temperature of ignition.

Smoke may be prevented from forming if each particle of gas, as it is made by distillation from coal, is immediately mixed thoroughly with hot air. Even if smoke is formed by the absence of conditions for preventing it, it may afterwards be burned if it is thoroughly mixed with air at a sufficiently-high temperature. It is easy to burn smoke when it is made in small quantities, but when made in great volumes it is difficult to get the hot air mixed with it unless special apparatus is used. In boiler firing the formation of smoke must be prevented, as the conditions do not usually permit of its being burned.

Essential Conditions. — The essential conditions for preventing smoke in boiler fires may be enumerated as follows:

1. The gases must be distilled from the coal at a uniform rate.
2. The gases, when distilled, must be brought into intimate mixture with sufficient hot air to burn them completely.
3. The mixing should be done in a fire-brick chamber.
4. The gases should not be allowed to touch the comparatively-cold surfaces of the boiler until they are completely burned. This means that the gases shall have sufficient space and time in which to burn before they are allowed to come in contact with the boiler surface.

Every one of these four conditions is violated in the ordinary method of burning coal under a steam boiler. (1) The coal is fired intermittently and often in large quantities at a time, and the distillation proceeds at so rapid a rate that enough air cannot be introduced into the furnace to burn the gas. (2) The piling of fresh coal on the grate in itself chokes the air supply. (3) The roof of the furnace, or tubes of the boiler, is a cold shell instead of a fire-brick arch, as it should be, and the furnace is not of a sufficient size to allow the gases time and space in which to be thoroughly mixed with the air supply.

Methods of Prevention. — In order to obtain the conditions for preventing smoke it is necessary: (1) That the coal be delivered into the furnace in small quantities at a time. (2) That the draft be sufficient to carry enough air into the furnace to burn the gases as fast as they are distilled. (3) That the air itself be thoroughly heated either by passing through a bed of white-hot coke or by passing through channels in hot brickwork, or by contact with hot fire-brick surfaces. (4) That the gas and the air be brought into the most complete and intimate mixture, so that each particle of carbon in the gas meets before it escapes from the furnace its necessary supply of air. (5) That the flame produced by the burning shall be completely extinguished by the burning of every particle of the carbon into invisible carbon dioxide.

If a white flame touches the surface of a boiler, it is apt to deposit soot and to produce smoke. A white flame itself is the visible evidence of incomplete combustion.

Anthracite Coal. — The first remedy for smoke is to obtain anthracite coal. If this is not commercially practicable, then obtain, if possible, coal with the smallest amount of volatile matter. Coal of from 15 to 25 per cent of volatile matter makes much less smoke than coals containing higher percentages. Provide a proper furnace for burning coal. Any furnace is a proper furnace which secures the conditions named in the preceding paragraphs. Next, compel the firemen to follow instructions concerning the method of firing.

Bituminous Coal. — It is impossible with coal containing over 30 per cent of volatile matter and with a water-tube boiler, with tubes set close to the grate

l gas passages, as in an anthracite setting, to prevent smoke even by killful firing. This style of setting for a water-tube boiler should ly condemned. A Dutch oven setting, or a longitudinal setting with affle walls, is highly recommended as a smoke-preventing furnace ch a furnace it is necessary to use considerable skill in firing.

Jets and Mechanical Stokers. — Mechanical mixing of the gases by steam jets is sometimes successful in preventing smoke, but it iversal preventive, especially when the coal is very high in volatile en the firing is done unskillfully, or when the boiler is being driven normal capacity. It is essential to have sufficient draft to burn operly and this draft may be obtained either from a chimney or a e is no especial merit in forced draft, except that it enables a tity of coal to be burned and the boiler to be driven harder in case cy, and usually the harder the boiler is driven, the more difficult it ss smoke.

aft furnaces and mechanical stokers (q.v.) of many different kinds fully used for smoke prevention, and when properly designed and nd handled skillfully, and usually at a rate not beyond that for are designed, prevent all smoke. If these appliances are found ke, it is always due either to overdriving or to unskillful handling. ary, however, that the design of these stokers be suited to the quality l and the quantity to be burned, and great care should be taken to ufficient size of furnace with a fire-brick roof and means of introduc- nake them completely successful.

SPARK GAP FOR MEASURING HIGH VOLTAGES. — One of the simplest methods of obtaining a measure of the value (maximum value in case of an alternating voltage) of a high voltage is to determine the length of air gap between two electrodes across which the given voltage will just cause a spark to pass. The voltage (maximum value) required to break down such a gap depends upon: 1. the shape and size of the electrodes; 2. the presence of other conductors in the vicinity of the gap; 3. the time of application of the voltage; and 4. upon the temperature and pressure of the air. The dependence of the break-down voltage upon the shape and size of the electrode is due not only to the effect of these factors upon the potential gradient in the gap but also to the fact that the maximum potential gradient at which air breaks down is dependent upon the distribution of the electrostatic field in the gap (*see article on Corona*) and is greater for very short gaps (0.5 cm. or less) than for long gaps.

For the same *maximum* value of the voltage it has been found that the striking distance is independent of the wave shape and frequency, and is the same for direct as for alternating voltages.

Time of Application of Voltage. — Air (and other gases) will stand for a short period of time (i.e., a few seconds) a much larger potential than it will stand for an indefinitely long period of time; this phenomenon is known as dilatation. After a voltage has been applied to a gap for about one minute, the apparent dielectric strength becomes sensibly constant. When measurements must be made with great rapidity, dilatation may be prevented by illuminating the gap by an arc-lamp. This procedure reduces the value of the sparking voltage, but only to a slight extent. (The theory of the action is that the ultra-violet light from the arc-lamp ionizes the air in the gap, thereby enabling the spark to pass at once.)

NEEDLE SPARK GAP. — Steinmetz in 1898 (*Trans. A.I.E.E., Vol. 15, p. 281*) made a careful determination of the voltages required to produce a spark between spherical, cylindrical and pointed (needles) electrodes. Steinmetz concluded that the sparking voltage between needle points (a sine wave of potential being used) was especially constant for any given set of conditions and that after the curve connecting spark potential and distance between needle points had been carefully ascertained, the needle spark gap offered a very valuable means for measuring high voltages. Although the needle spark gap is less trustworthy than the sphere gap, the Standardization Rules of the A.I.E.E. state that the needle gap may be used for voltages between 10 and 50 kilovolts. At higher voltages it has been found difficult to duplicate conditions nearly enough for different observers to obtain results which are in agreement.

Needle Spark-gap and Spark-over Voltages. — The needle spark-gap shall be between new sewing needles, supported axially at the ends of linear conductors, which are at least twice the length of the gap. There must be a clear space around the gap for a radius at least twice the gap length.

The sparking distances in air between No. 00 double long sewing-needle points for various root-mean-square sinusoidal voltages shall be assumed to be as shown in Table I.

SPHERE SPARK-GAP. — In 1913, Farnsworth and Fortescue (*Trans. A.I.E.E., Feb., 1913*) showed that a spark-gap between two spheres is a much more reliable measure of high voltage than the gap between needle points. The sphere spark-gap is now (1922) generally recognized as standard.

Besides giving more consistent results the sphere spark-gap occupies much less space for high voltages than the needle-gap. In addition to this advantage the sphere spark-gap breaks down with a sharply-defined spark discharge

TABLE I.—NEEDLE-GAP SPARK-OVER VOLTAGES

(At 25° C. and 760 mm. barometer)

R. M. S. Kilovolts	Millimeters	R. M. S. Kilovolts	Millimeters

25	33	50	90
30	41		

The values in this table refer to a relative humidity of 80 per cent. Variaons from this humidity may involve appreciable variations in the sparking istance.

thout previous formation of corona, provided the distance of separation is s than the diameter of either sphere. For greater distances of separation e corona forms first and the sparking voltage for a given length of gap becomes ore or less variable. Another advantage of the sphere spark-gap is that the rminals do not have to be renewed after each discharge, as is the case with the edle-gap.

Construction of Sphere Spark-gap. — Fig. 1 shows the arrangement commended by Farnsworth and Fortescue. The top sphere is stationary it slightly adjustable in height as just to make contact with e lower sphere when it is set for ro separation. The lower sphere mounted on a piece of brass bing which carries a threaded ishing on its lower end. This ishing works on a carefully-readed rod having a pitch of 10 per centimeter. The bushing ing graduated to fiftieths on its rcumference, separation may be easured to the nearest $\frac{1}{500}$ cm. rectly, thus providing a micro-eter adjustment. This arrange-ent is mechanically strong and e spheres are kept in constant ignment. The frame work may be conveniently mounted on wheels, to render easily moved.

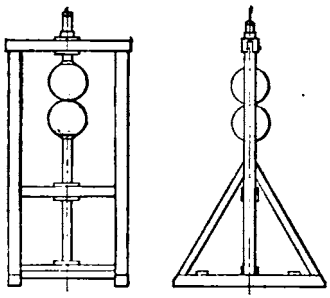

Fig. 1. Sphere Spark Gap.

A.I.E.E. Sphere Spark-gap and Spark-over Voltages. — The standard here spark gap shall be between two suitably mounted spheres. No extraneis body, or external part of the circuit, shall be nearer the spheres than rice their diameter. The shanks shall be not greater in diameter than $\frac{1}{8}$ the here diameter. Metal collars, etc., through which the shanks extend, shall be small as practicable and shall not, during any measurement, come closer to e sphere than the maximum gap length used in the measurement. The here diameter should not vary more than 0.1 per cent, and the curvature, easured by a spherometer, should not vary more than 1 per cent from that

a true sphere of the required diameter. When used as specified, the accuracy obtainable should be approximately 2 per cent.

The sparking distance between spheres for various r.m.s. sinusoidal voltages shall be assumed to be as shown in Table II, when the air density is that corresponding to a barometric pressure of 760 mm. mercury and a temperature

25° C. For any other air density the voltage at which the gap breaks down, any given spacing, is equal to the break-down voltage for this spacing at ındard pressure and temperature multiplied by the correction factor given Table III. The relative air density is found from the formula:

$$\text{Relative air density} = \frac{0.392b}{273+t}$$

ıere b = barometric pressure in mm. and t = temperature in degrees C.

It is important that the surface of the spheres be kept perfectly clean, i.e., ee from dust and moisture (*Marvin, R. H., Elec. W., 67, p. 649, 1916*).

The sphere-gap is more sensitive than the needle-gap to momentary rises of ltage and the voltage required to spark over the gap should be obtained by owly closing the gap under constant voltage, or by slowly raising the voltage th a fixed setting of the gap. Open arcs should not be permitted in proximity the gap during its operation, as they may affect its calibration.

ABLE III.—AIR DENSITY CORRECTION FACTORS FOR SPHERE-GAPS

SPECIFICATIONS AND CONTRACTS. — (*See also Standardization Rules and Standard Specifications; also under name of apparatus.*) Webster defines a specification as a written statement containing a minute description or enumeration of particulars, and a contract as a formal writing which contains the agreement of parties, with the terms and conditions, and which serves as a proof of the obligation. A "preliminary" specification is a description or enumeration of a purchaser's requirements when calling for bids. A "contract" specification is a description or enumeration of labor and material to be supplied under a contract of which the specification is an integral part. A "manufacturer's" specification is a description or enumeration of secondary details peculiar to the work of the individual manufacturer. This also is often made an integral part of a contract.

POLICY TO BE FOLLOWED. — When writing a specification the engineer should bear the following points in mind:

1. A preliminary specification is a commercial instrument designed to describe labor, material or results desired by a purchaser, with the object of enabling competitive bidders to estimate with equal facility upon the amount of a contract.

2. As a rule, contractors are as honest as the struggle for commercial existence permits them to be, and every unnecessary or unfair clause in a specification has its part in limiting competition and lowering the standard of honesty among contractors. A similar remark applies to requirements of which the purchaser cannot ascertain or enforce the fulfillment.

3. The standards of the national engineering societies should be followed unless local conditions prohibit them, and manufacturer's standards should be followed if low bids are to be expected.

4. No specification should contain a blanket clause covering the furnishing of unnamed contingencies unless all bidders are to have an equal opportunity to ascertain what such contingencies are likely to be. If such a clause is made very broad, it is unlikely that the courts would hold it valid.

5. Before drawing the specifications, determine to what extent the contractor is to be made responsible for the final results.

6. Avoid specifying proprietary articles or material as far as possible in order not to restrict competition.

7. Quality is an important factor in cost, hence unless the very best materials and workmanship are required, in spite of the higher cost, it is necessary to adopt some fair commercial standard.

8. There are many minor items in specifications which cannot be minutely described without making the specifications unduly long. In such cases it is good practice to specify that these items shall be made "to the reasonable satisfaction of the inspector," the word "reasonable" saving the contractor from arbitrary and unjustifiable actions of the inspector by enabling him to refer the reasonableness of such actions to the arbitrament of the courts.

FORM OF SPECIFICATIONS. — All specifications should be written in clear, concise language, free from ambiguity, and should be in convenient form for reference purposes.

It is desirable to number the paragraphs or clauses of all specifications to facilitate reference, and every item of the work should be alloted a separate clause.

There are two general classes of specifications. In one class results only are specified and all requirements should be rigorously exact. In the other class details of construction are specified and requirements can be stated in approximate terms only. Wherever practicable the former class of specification should be used. A combination of the two classes is also commonly adopted, but is

Digitized by Google

agreement as to results does not bind the contractor if the methods these results are also specified. (*See J. C. Wait, Eng. News;* . In either case considerable study should be given to securing a m between brevity and elaboration of details. The degree of detail verned very largely by the magnitude and importance of the work. ing is suggested as a suitable plan to follow in drawing up specifica- erials. It is the result of a study of this subject by a special com- American Society for Testing Materials.

form is adopted should be closely adhered to in writing all the for a given job.

ecification shall be divided into eight "Parts."

es of these Parts shall be in large upper-case type centered over the eded by a Roman numeral.

les of these Parts shall be as follows unless conditions necessitate on. In case a Part is omitted, the Roman numerals shall be con- unbroken sequence.

nufacture.

. The Contractor shall give these other contractors the privilege of
g his work in so far as it affects the acceptance of their work.
ontractor shall not drill or in any way impair the strength of buildings
ures except with the written consent of the Engineer.
l work shall conform to the requirements of the "National Board of
erwriters," and to all Government regulations.
ne Contractor shall obtain all necessary permits from the City or County.
l like parts shall be interchangeable as far as practicable.
ne Contractor shall install and maintain in his offices and at the site
rk such telephones as may be required by the Engineer, and shall place
he disposal of the Engineer or his representative for any purpose relating
ecution of the contract.
ne Standardization Rules of the A.I.E.E. and other similar documents
e followed wherever possible.
ne provisions of the preliminary specification and those subsequently
pon between Company and Bidder should be incorporated as part of
or contract specification.

TS TO BE COVERED IN CONTRACT. — In addition to items
above, the Engineer should make sure that the following points are
in the contract. The actual preparation of the contract, at least where
nt of money involved is large, should be left to a competent lawyer.

scription and value of bond and indemnity to be delivered by Con-
o Company.
tement of fire insurance to be secured by Contractor for Company.
otection of Company by Contractor against losses resulting from letters

e work to be performed in such a way as not to interfere with safety and
y of service.
sponsibility for damage to work from fire, floods, storm, earthquake,
her cause whatsoever.
ntiguous work by other contractors shall not be delayed.
tement of liquidated damages to be paid in the event of work not being
d on the date agreed.
e Contractor shall not transfer the contract without permission.
ne of commencement of work, rate of progress and date of completion.
ne character of the methods and appliances to be used and grade of
l to be employed.
ethod of payment, time of settlement and basis thereof.
rbitration and settlement of disputes.
xtras and claims therefor.
subject of Engineering contracts is more fully covered in the books by
nson and J. I. Tucker, cited in the Bibliography.)

AMERICAN ENGINEERING STANDARDS (*Secrtary, P. G. Agnew, 29 West 39th St., New York Cit*

Digitized by Google

serves as a national clearing house for engineering and industrial standardization. The Committee is made up at present (1922) of representatives of, and is maintained by, nine national engineering societies, five government departments, and fourteen national industrial associations. Its functions are: to unify methods of arriving at standards; to secure nationally recognized standards, through cooperation between various interested organizations, thus preventing duplication of work and promulgation of conflicting standards; and to act as a general bureau of information regarding standardization.

Standards covering eighteen different subjects have already (1922) been adopted and active work is now in progress on about sixty projects, including a number of industrial safety codes. Information on the organization and the work will be sent free upon request.

AMERICAN ELECTRIC RAILWAY ENGINEERING ASSOCIATION. — (*Secretary, E. B. Burritt, 8 West 40th St., New York City.*) This Association issues an *Engineering Manual*, which contains all standards set by the Association, all practices recommended by it, and those practices which, while they have not been formally adopted either as standards or recommended practice, have been discussed and put forward by the Association's various committees. The *Manual* is in loose-leaf form, and is revised each year by the Committee on Standards. The contents are grouped under the headings: Buildings and Structures; Power Distribution; Equipment; Power Generation; Block Signals; Way Matters. The price of the *Manual*, including all sections in a binder, is $5.00 to non-members.

AMERICAN RAILWAY ASSOCIATION. — (*General Secretary, J. E. Fairbanks, 75 Church St., New York City.*) This is a general association representing the steam railroads of the country. There are now incorporated in it several technical associations which were formerly distinct.

Mechanical Division (Master Car Builders; Master Mechanics). — (*Secretary, V. R. Hawthorne, 431 South Dearborn St., Chicago, Ill.*) The Division, with its predecessor organizations, has numerous specifications covering parts and details of cars and locomotives, practices, etc., which are now (1922) being unified for publication in a loose-leaf manual.

Signal Section. — (*Secretary, H. S. Balliet, 75 Church St., New York City.*) The Section publishes a loose-leaf *Manual* containing specifications for primary batteries, storage batteries, bells, insulated wires and cables for various kinds of signal use, conduit, interlocking devices, lightning protection devices, relays, and various other signal apparatus and supplies; and standard designs for a large number of devices, and parts used in railway signal work.

Telegraph and Telephone Division. — (*Secretary, W. A. Fairbanks, 75 Church St., New York City.*) The present specifications of the division, which include specifications for various kinds of conduits and conduit fittings, telephone and telegraph equipment, protection against electrolysis and against lightning, transpositions of circuits are published in a *Manual* (1922).

AMERICAN RAILWAY ENGINEERING ASSOCIATION. — (*Secretary, E. H. Fritch, 431 So. Dearborn St., Chicago, Ill.*) This Association, which is closely allied to the American Railway Association, issues a *Manual* containing the various committee reports which have been formally adopted by the Association. The following items are covered: Roadway; Ballast; Ties; Rail; Track; Buildings; Wooden Bridges and Trestles; Masonry; Signs, Fences and Crossings; Signals and Interlockings; Records and Accounts; Rules and Organization; Water Service; Yards and Terminals; Iron and Steel Structures; Economics of Railway Location; Wood Preservation; Electricity.

Digitized by Google

The last edition of the *Manual* (1915) is now out of print, but a new edition is in preparation (1922).

THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS. — (*Secretary, Calvin W. Rice, 29 West 39th St., New York City.*) The Boiler Code of this Society contains standard specifications for the construction, equipment and use of steam boilers ($1 to non-members). Official interpretations of the Code by the Boiler Code Committee are published separately. The Power Test Codes ($2 to non-members), are rules for the testing of boilers, engines, turbines, compressors, fans, power plants, locomotives, water-wheels, etc. The Standard Pipe Thread has been approved by the American Engineering Standards Committee as an "American Standard," the Society acting with the American Gas Association as joint sponsors. The work of committees of the Society on Shafting and on Pipe Flanges and Pipe Fittings is now being extended under the auspices of the American Engineering Standards Committee. A list of the publications of the Society will be sent free upon request to the Society.

AMERICAN SOCIETY FOR TESTING MATERIALS. — (*Secretary, C. L. Warwick, 1315 Spruce St., Philadelphia, Pa.*) This Society issues a triennial volume of "A.S.T.M. Standards," and annual supplements in intervening years. The last triennial volume was issued in September, 1921. The specifications and methods of tests cover a wide range, including Steel Rails, Structural Steel, Various Steel Objects, Steel Castings, Wrought Iron, Pig Iron, Iron Castings, Locomotive Material, Magnetic Tests of Iron and Steel (*see Magnetic Testing*), Various Kinds of Copper Wire and Wire Bars (*see Wires and Cables, Bare*), Spelter, Manganese Bronze Ingots, Cement, Lime, Clay Products, Preservative Coatings, Road Materials, Timber, Brass, Paints, Oils, and various other materials. The price of the 1921 Book of Standards is $11.00 to non-members. Single standards may be purchased for 25 cents.

BUREAU OF STANDARDS. — The Bureau of Standards at Washington is a branch of the U. S. Department of Commerce. It is the official custodian of the fundamental standards of measurement. In addition to making tests and comparisons of measuring apparatus, the Bureau carries on numerous researches related to the establishment and maintenance of the various standards and units of measurement, the development of measuring instruments and methods of measurement, the determination of physical constants and the properties of matter. The results of these investigations are published in pamphlet form issued in two separate series: (1) *Scientific Papers* and (2) *Technological Papers*. In addition, the Bureau issues a third series, *Circulars*, giving useful technical data, standard specifications for apparatus, description of the nature of the standard tests carried out at the Bureau, etc.

A complete list of the publications of the Bureau will be furnished by the Bureau upon request and free of charge; this list is contained in *Circular No. 21* which contains an index and a brief summary of each of the *Scientific* and *Technological Papers*, and *Circulars* most of which can be furnished by the Bureau upon request and free of charge. Others may be purchased from the Superintendent of Documents, Washington. D. C.

The *Bulletin of the Bureau of Standards* is a serial publication in which the *Scientific Papers* are published collectively. Each number of the *Bulletin* contains about 150 pages, the separate numbers being issued as material accumulates, at intervals of about three months. Four numbers constitute a volume. The bound volume is now (1921) issued under the title "Scientific Papers." Sixteen volumes had been issued at the beginning of 1921. The complete *Bulletin* is furnished free to educational and scientific institutions. Individuals may obtain separate numbers in paper covers (current or back num-

5 cents per copy, complete volumes bound in cloth at $1.50 per volume, subscribe in advance at the rate of $1.00 per volume to receive the four numbers as issued. Orders and payments for the *Bulletin* should be to the Superintendent of Documents, Washington, D. C., and *not* to u of Standards.

ncipal publications of the Bureau dealing primarily with specifications lards of interest to the electrical engineer are: Electrical Units and (Circular 60); Specifications for Incandescent Lamps (Circular 13); Wire Tables (Circular 31); Wire and Cable Terminology (Circular 37); National Electrical Safety Code" (Circular 54), which is a general ing with safety, covering electrical supply stations, electrical line on, electrical utilization equipment, and electrical operation.

TRIC POWER CLUB. — (*Secretary, C. H. Roth, 1410 West Adams go, Ill.*) This Club is an association of companies engaged in the manu- f electric power apparatus. Its standardization rules, which are the Handbook of the Club, deal with the industrial standardization s, generators, transformers, and electric power control apparatus. phlet referred to may be obtained from the Secretary of the Club cents).

MINATING ENGINEERING SOCIETY. — (*General Secretary, L. Law, 29 West 39th St., New York City.*) The Committee on Nomen- nd Standards of this Society published a report in 1918. The defini- his report are substantially the same as those incorporated in the *ization Rules of the A.I.E.E.* (1921 edition). The Society has also Automobile Headlighting Specifications, and a Code of Lighting for Mills and other Work Places.

TUTE OF RADIO ENGINEERS. — (*Secretary, Alfred N. Gold- llege of the City of New York, New York City.*) See the reports of the s Committee of this Institute. The standard nomenclature adopted stitute is included in the *Standardization Rules of the A.I.E.E.* bear- dio matter.

ONAL ELECTRIC LIGHT ASSOCIATION. — (*Executive Mana- . Aylesworth, 29 West 39th St., New York City.*) The Apparatus Com- this Association has published Transformer Standards; Methods of nsulating Oils; and Rules for the Installation and use of Motors on tation Distribution Systems. The Underground Systems Committee shed Specifications for Lead Covered Paper Cables. Other committee eal with Railway Rates, Transportation, Accounting, Prime Movers, Line Construction, Lamps, Electrical Apparatus, Meters, Termi- rounding Secondaries, Underground Construction, Electrical Measure- t Values and Street Lighting.

.E.L.A. issues the *Electrical Meterman's Handbook*, prepared by the ee on Meters. This book is intended primarily for practical meter he *Meterman's Handbook* deals with the subject of metering in great ntaining over 1000 pages. It may be had from the Secretary of the on for $5.00.

STARTERS, MOTOR. — (*See also Controllers; Motors, Alternating-Current; Motors, Direct-Current; Rheostats.*) An auxiliary resistance which is used with a motor, either d-c. or a-c., during acceleration is called a starter, or a starting rheostat. A compensator, or induction starter, consists of an auto-transformer and a switch, by the operation of which a reduced voltage is supplied to the terminals of an induction motor for starting.

STARTERS FOR DIRECT-CURRENT MOTORS. — The starters in use with constant speed d-c motors consist usually of a resistance to be inserted in the armature circuit, this resistance being gradually cut out by the movement of a contact arm over a face plate as the motor comes up to speed. Such rheostats connect the motor field in circuit at the first step and are provided with various safeguards such as low-voltage release, overload release, etc.

Resistance Steps for D-C. Starters. — The resistance is designed to limit the starting current to about 1½ times full load current with enough steps to limit the voltage between contacts. Motors of 10 horsepower or less usually are brought up to speed in about 15 seconds and larger motors in about 30 seconds. Resistors should carry full load current for two minutes starting cold with an average temperature rise not exceeding 250° C. Resistors will withstand 500° C. without deterioration.

Fig. 1 shows the connections of a typical d-c. starter with low-voltage release. If the rheostat arm is moved from the off position shown in the cut to the contact $R-1$. current will flow from $L+$ to the arm; from this to contact $R-1$. through the regulating resistance to $R-11$, thence through the armature and series field of the motor to $L-$. The shunt field is connected from $R-1$ to $L-$. As the rheostat arm is being moved from $R-1$ to $R-11$ there is a small drop in voltage across the shunt-field circuit due to the field current flowing through the starting resistor but this is so small that it may be neglected and the field can be considered as having full voltage impressed upon it. The rheostat arm is provided with a spring which returns it to the off position when the handle is released during the starting of the motor. After the motor has been brought up to speed and the rheostat arm rests upon contact $R-11$ the low-voltage release magnet holds the arm in this position. Brush B bridges between the terminals M and N so that in the running position the current passes from $L+$ to terminal M, through the brush B to the terminal N, thence to the armature of the motor and through the series field to $L-$.

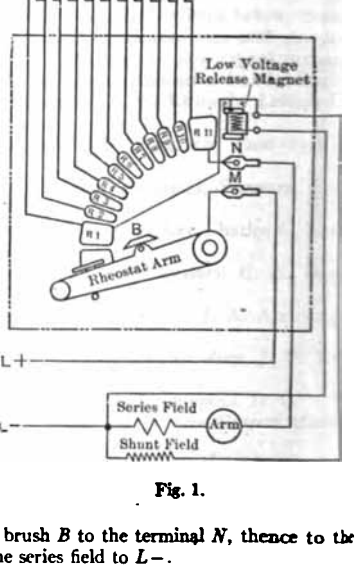

Fig. 1.

Overload Release. — An overload release is often furnished, especially with motors of large capacity. This device consists essentially of a solenoid which is connected in series with the motor armature and which, in case of a predeter-

ned overload, opens the circuit of the low-voltage coil. This action releases e contact arm and thus stops the motor.

Mounting of Starting Boxes. — Starting rheostats are occasionally mounted a small panel, together with the line switches and fuses or circuit breaker quired for the complete protection of the motor circuit.

Multiple Switch Starters. — With the larger d-c. motors, where the start-g conditions are severe, the face type of starter is not found satisfactory; course is therefore had to multiple switch starters, drum controllers, or con-ctors. Multiple switch starters consist essentially of a number of switches ounted on a panel and a separate resistor usually of cast-iron grids. The itches are mechanically interlocked so that it is necessary to close them in quence.

The type of starter shown diagrammatically in Fig. 2 is used with 110-volt otors up to 300 h.p. and with 220- and 500-volt motors up to 600 h.p. The st switch on the right of the dia-am is provided with magnetic blow-t-coils and acts as a circuit breaker. also has voltage release device. rotection against inadvertently leav-g part of the switches open when arting is provided by means of an uxiliary push-button switch that ust be held closed until the last witch on the left is closed, thus nergizing the coil of the low-voltage elease.

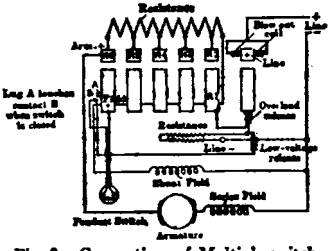

Fig. 2. Connections of Multiple-switch Starter

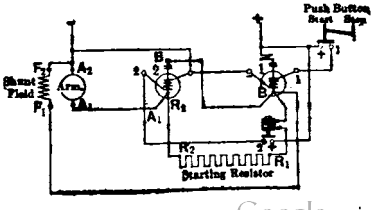
Starters with Automatically-perated Contactors. — In starting motor the energy required to over-ome the inertia of the motor and the apparatus it is driving must be admitted radually, which is accomplished by introducing resistance into the armature ircuit. If the time taken in starting is too long the resistor may be injured y overheating; if the time is too short the motor may be damaged, the sup-ly circuits seriously disturbed, or gears stripped on the driven machine. For his reason a motor starter that will automatically take care of the proper ate of acceleration presents many advantages. Such a starter can be devised y means of contactors and suitable relays, which are operated either by the ariation of the voltage drop across a resistor as the motor speeds up, or by he decrease in current that permits a solenoid to drop its core, or by other means of acceleration.

Contactor Starter with Series Relay Control (Fig. 3). — Acceleration by series relay control is satisfactory where the voltage does not vary more than 12½ per cent either way from a constant value. Fig. 3 shows the connections of a shunt motor controlled by means of two contactors, a push button station, and a series relay. When the push button is closed in the starting position, the coil of contactor No. 1 is energized, closing the contactor and completing the circuit through the series relay, the starting resistor,



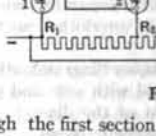


Fig. 3.

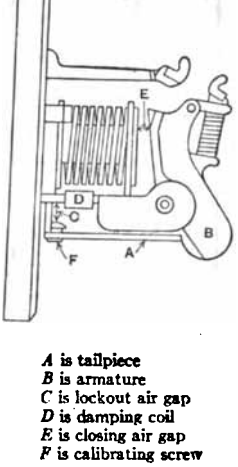
and the armature of the motor. When the starting cu certain value the current in the series relay is no longe the contacts so that connection is automatically mad of contactor No. 2 closing that contactor and short resistors. With large motors several contactors with se

A Contactor with Counter E.M.F. Control is s this method of starting, the operating coils of the thr side connected to the motor brush farthest away from the starting resistor. The other sides of the operating coils are connected to the taps on the starting resistor, the coil on contactor 1, being connected to R_2 on the resistor. The voltage on this coil is equal to the line voltage less the drop in voltage through the first section speed of the motor increases the counter e.m.f., causes a ture current. This reduces the drop to the first section The voltage on the operating coil of contactor 1, is gr this closes. Contactor 2 has its operating coil connect ing resistor. The voltage on this coil is increased by th The increase in current causes a considerable drop i the starting resistor. As this current gradually decrea speed of the motor, contactor 2 closes. Contactor 3 motor armature and closes when the counter e.m.f. of th to the line voltage. The main contactors for closing cuits are not shown in the diagram.



Series Lockout Contactor Method. — Another s frequently used is the series lockout method. With magnetic contactor is provided with a series coil and d rate relay for controlling it. The closing of the magn upon the saturation of the iron in one portion of the can be understood from the diagram of a contactor o Fig. 5. The flux or magnetism in the iron is caused through the operating coil. This flux passes through th ture of the contactors. Part of this flux passes from th armature brackets to the magnetic yoke and thence to the part of the flux passes from the armature through the t yoke. The flux through this last circuit exerts a pull w tactor from closing. The magnetic path through the a small cross-section so that when the current flowing thr exceeds a certain value it becomes saturated and forces through the tail piece holding the contactor open. As the flux in the saturated armature bracket remains through the tail piece decreases until it is not sufficient open. The switch can be adjusted to close at a predeter ing the air gaps between the tail piece and the magne calibrating screw.

The success of starters with acceleration control such depends largely on the contactors or contactor switches. or circuit breakers which are held in the closed position b such as a solenoid or compressed air. A typical conta the lockout contactor shown in Fig. 5, using a shunt c coil and omitting the damping coil and similar features shunt coil is energized the contactor is closed against th

'ontactors are built both for d-c. and a-c. operation and are made single ole and multiple, single throw and double throw, in various capacities. The ıain arcing contacts are usually protected by ıeans of a magnetic blowout.

These contactors are ordinarily used in conection with a master switch or controller and rotective relays of various kinds to insure the erformance of various functions, such as the utomatic cutting in and out of resistance in he secondary of an induction motor to mainain constant input to a flywheel set or any imilar feature that may be desired such as verload, low voltage and field protection reays limit and sequence switches, etc.

Fig. 5.

STARTERS FOR INDUCTION MOTORS may be divided into two classes: 1) those used with motors having a squirrel cage or short-circuited secondary, and (2) those or motors having a wound secondary. In the ormer case the starting is done by impressing on the primary a voltage sufficient to induce n the short-circuited secondary the current equired to develop the proper starting torque, nd then transferring the primary connections o full voltage. With induction motors having hase-wound secondaries the method of startng is to connect the primary circuit directly o the line, with the secondary winding hort-circuited through a resistance which is cut out in one or more steps.

With squirrel-cage motors up to about 7½ horsepower it is usually feasible to connect the primary immediately to the full line voltage without drawing an abnormal current from the line. The limiting feature is the power disturbance and its effect on other loads, particularly lighting. With larger squirrel cage motors this is not feasible and consequently there have been developed various means of reducing the voltage impressed on the motor. Motors with special windings and all leads brought out, can be arranged for series parallel grouping of coils, delta-star connections for three phase, and other similar schemes but these are not used to any appreciable extent in America.

Starting Compensators. — Under normal conditions the most satisfactory means of obtaining the reduced voltage for starting induction motors with squirrel-cage secondaries is by the use of auto-transformers or compensators (q.v.). The auto-transformers supplied for starting induction motors are provided with taps permitting the choice of any one of several voltages. The auto-transformers are designed for starting service only and are not intended to be left permanently in circuit.

Connections of Starting Compensator (Fig. 6). — The connections of the starting compensator for a two-phase motor are shown diagrammatically in Fig. 6, the switching mechanism being omitted for the sake of simplicity. Two auto-transformers are used with a two-phase motor; with a three-phase motor there would be used either three Y-connected or two V-connected auto-transformers. In the starting position the voltage at the motor primary which is connected to the auto-transformer is cut down by the auto-transformers from 200 to 130 in this particular case.

Digitized by Google

The auto-transformers are provided with taps giving 50 of line voltage for starting, though it is usually found that gives the proper conditions for average service. With the

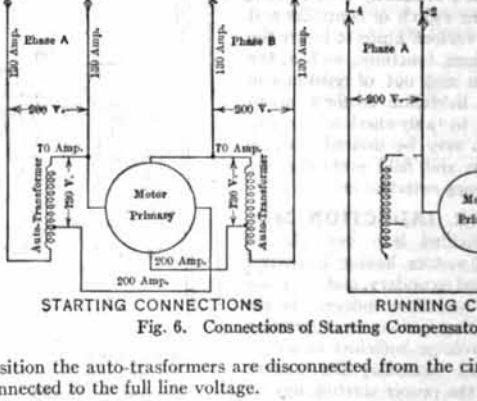

Fig. 6. Connections of Starting Compensato

position the auto-trasformers are disconnected from the ci connected to the full line voltage.

Switch Mechanism. — The auto-starter switches or made of various types, with contacts suitable for the cur The equivalent of a double throw switch is usually furnished ing auto-transformers and connecting the motor to low-volt and the second throw connecting the motor directly to full The second throw always disconnects enough circuits so t through any part of the winding of the transformer and so disconnects the auto-transformers from the circuit. The has three positions and locks automatically in the off an but has to be held in the starting position. In starting a first moved very quickly to the starting position and held t gets up to speed; the handle is then moved quickly past th running position where it becomes locked. A mechanical de ing the handle to the switch from the off position to the runn moving first to the starting position.

Automatic protection with auto-starters is usually secure load trip coils, either connected directly in the circuit or op transformers. Usually the overload protection is only in t With certain types of auto-starter switches the overload r of two solenoids with plungers in two different phases and on each solenoid plunger gives an inverse time element f contacts usually trip independently of the handle so that t held closed on an overload.

Resistance Starters for Induction Motors. — With mo secondary it is customary to connect the primary to full lin and to short-circuit the secondary through a resistor. As t this secondary resistance is cut out in one or more steps u secondary is short-circuited. By properly designing the r ous service instead of for intermittent service, this type of for speed regulation as well as for starting purposes (*see Co*

Digitized by Google

With constant-speed induction motors up to 200 h.p. output it is sometimes possible to mount the starting resistor upon the rotor spider, and to control it by butt-contact switches operated by a rod which passes through the hollow rotor shaft. By moving this rod out or in by means of a knob at its outer end the resistance may be connected into the secondary circuit for starting or be disconnected therefrom after the motor has come up to speed. With large motors the terminals of the secondary windings are connected by means of slip rings and a drum controller to the resistor, which in this case consists of three resistors mounted separately from the motor. Each resistor has one terminal connected with one of the three phases of the motor secondary.

The other terminals of the resistors are usually connected in star but sometimes in delta, depending on the current in the motor secondary, the capacity of the resistors, etc. When in star, the neutral is usually grounded to the frame of the controller. The drum of the controller short-circuits the various sections of the resistor by steps.

Resistance Steps for Induction Motor Starters. — Wound secondary motors at standstill act as transformers and the resistance in the secondary circuit has to absorb practically the entire input to the motor; as the motor speeds up, the secondary voltage drops off and resistance is cut out of circuit at such a rate that the motor draws from the line about 50 per cent more than full load primary current. Grid resistors for starting service will rise about 250° F. in two minutes. Grid resistors for speed regulation are designed for the same rise on continuous service.

Starters for "Self-starting" Synchronous Motors. — Where self-starting synchronous motors are used they are provided with a squirrel-cage winding on the rotor in addition to the usual field poles and field coils. Owing to this squirrel-cage winding they are started up as induction motors and controlled by the same type of starting devices. Suitable auxiliary apparatus, such as field rheostats and field switches, must be provided.

CALCULATION OF STEPS FOR RESISTANCE STARTERS.* — (*See also Rheostats.*) Resistance starters usually have from four steps for small motors to seven or ten for large sizes. The number of steps used is commonly somewhat larger than the computed values as a safeguard against excessive starting currents due to improper handling by inexperienced operators. Starters for motors starting under heavy loads are frequently designed with two or three extra steps by which it is permitted to switch the loaded machine on the line with a low current and to raise the current step-by step. On the other hand, in stations where experienced operators are available, large motors and synchronous converters are often started on three or four steps.

Calculation for Shunt-motor Starters. — The design is usually based on a fixed maximum current on each step of the starter, as well as on a fixed minimum current for each step. The minimum current must not be taken as less than the load current required for the maximum load with which the motor is to be started.

Let

I_m = the maximum current on each step of the starting rheostat,
I_0 = the lowest current for which the steps are to be designed,
E = the fixed line voltage,
$C = I_m + I_0$.

Let $K - 1$ be the number of steps required in the rheostat, and let R_1, R_2, . . . R_k be the total resistances in the circuit, including the resistance of the motor, for the successive positions of the contact arm. K is the number of working

contacts over which the contact arm moves, the first c
the resistance of the rheostat is in the circuit and the Kth
to all the resistance of the rheostat cut out; whence R_K
ance and $R_1 = E \div I_m$. This equation does not take into a
of the motor resistor.

It can be shown that the successive resistances form a
the ratio C, whence

$$K = 1 + \frac{\log\left(\frac{E}{rI_m}\right)}{\log C}, \qquad \text{and} \qquad R_1 = \frac{E}{I_m}, \quad R_2 = \frac{R_1}{C},$$

The value of C must be so chosen that K is a whol
motors which are likely to start under load, the value of
For machines which are started with no load, a larger value
the limiting value being determined by the ratio of maxi
at starting to current at no load. The maximum allowabl
limited to 1.5 times full-load current. Occasionally twi
taken, but the lower value is preferable, particularly if bo
services are connected to the same feeders.

Design of Series Motor Starters. — An algebraic me

STARTING AND LIGHTING SYSTEMS FOR A

— (*See also Batteries, Storage; Generators, Direct-current; Ign. Incandescent; Motors, Direct-current.*) The items com starting and lighting equipment of a gasoline automobile a (2) storage battery, (3) starting motor, (4) lamps, (5) cut-outs, and fuses. In the so-called "single unit" syste starting motor are combined in a single unit. The batter supply energy for starting and lighting but also for ignition (

GENERATOR. — The generator employed is almo wound, and is driven directly by the engine through suit The purpose of the generator is to charge the storage ba nected across its terminals. In order to keep the termina erator substantially constant, which condition is requi charging of the battery, some auxiliary controlling device i wise the terminal voltage of the generator would vary direct engine.

Battery Cut-out. — The generator must of cour to the battery until its voltage is equal to that of the batt taken care of by means of an automatic switch which cl reaches a speed corresponding to a car speed of about 10 opens when the speed falls below this value.

Common Types of Voltage Control. — Numerous de posed and tried out for keeping the generator voltage s after the battery cut-out closes, but at the present time control are in common use, viz., (1) outside regulation, (2 tion, (3) reverse series-field regulation.

Outside Regulation. — A simple form of outside in Fig. 1, which embodies the principle of the Bijur reg resistance is included in the field circuit, which resistance is short circuited when the vibrator is in contact with the contact *C*. When the vibrator is pulled away from the contact *C* by the electromagnet the resistance is inserted in the field circuit and the field current is thereby reduced. As long as the vibrator is operating, the field current will vary between maximum and minimum values, and its average value will depend upon the rate of vibration. The turn will depend upon the voltage across the winding and a very small increase in this voltage will cause a relati the rate of vibration, and therefore make a substantial de value of the field current. Consequently, as the speed thereby tending to produce a varying voltage at the gene tendency is counteracted by the reduction in the field terminal voltage of the generator remains substantially c of the speed.

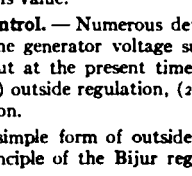

Fig.

A modification of this type of control is used by the We In the Westinghouse regulator, the position of the contact electromagnet connected across the terminals of the genera is actuated by an eccentric coupled to the armature shaf

eases, the contact *C* is drawn away from the vibrator, with the re- resistance is inserted in the field circuit for a greater length of time. orm of outside regulation which is coming into favor on vehicles is hat of the train lighting systems (*see Lighting of Trains*). The machine is used and regulation is accomplished by passing the arma- through a solenoid which in turn controls a plunger linked to a of a small rheostat.

Brush Regulation. — In this system use is made of the distort- armature reaction (*see Generators, Direct-current*). When current h the armature, the resultant flux is skewed around in the direction ee Fig. 2), with the result that the number of lines of force entering from the leading pole- ed and a corresponding the number of lines of place at the trailing nsequently, referring to vident that the electro- generated between the d the third brush *C*, hown, will decrease as through the armature f the shunt field is con- een the brushes *A* and nt through the shunt refore decrease as the e main circuit increases, rn will reduce the electromotive force between *A* and *C* still nsequently, if the battery is connected across the main brushes *A* tendency for the current to the battery to increase when the generator increases is counteracted by the decrease in the field ch a generator when connected to a storage battery will tend to stant current machine, irrespective of the speed. As a matter of the effect of the short-circuit current in the coil passing under the ich current is practically proportional to the speed and which demagnetizing action, the current to the battery actually reaches value at a definite speed and then falls off.

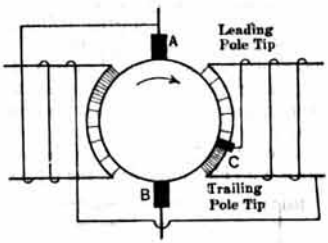

Fig. 2

m of regulation has come into extensive use, due to its simplicity. m current supplied to the generator is readily controlled merely the position of the intermediate brush. For a full treatment of f third brush regulation, see Langsdorf's *Principles of Direct-current*

rse Series-field Regulation. — In this system of regulation a com- d generator is employed, with the series field connected so as to shunt field, i.e., differentially compounded. Up to the present has found but little favor, on account of the inability to control It gives neither a constant voltage nor a constant current char- e current output rising rather rapidly to a maximum and then opping off, due chiefly to the cross magnetization of the armature

Y. — The lead-acid type of storage battery is almost invariably tteries, *Storage*). Batteries of from 6 to 24 volts are employed, 6-volt (3 cell) battery is rapidly becoming the standard. To starting requirements, an ampere-hour capacity of from 60 to 120 depending upon the size of car. A 60-ampere-hour, 6-volt bat-

Digitized by Google

tery weighs about 45 pounds, and a 120-ampere-hour, 70 pounds.

STARTING MOTOR. — The conditions under whic operates are widely different from those encountered in c extremely high initial torque is required to overcome the There is also a constant variation in load, due to the and suction of the engine. As the service periods are motor is designed to give its maximum output for only a therefore relatively small compared with a motor desig maximum torque continuously.

The motor is compact and rugged to withstand vibra relatively large size and fitted with large bearings, to wi sudden engagement. Starting motors are usually designe voltage, although there are a few 12- and 24-volt systems average size engine an initial current of about 200 amperes At cranking speed this current drops to about 80 amperes

The torque required to start an engine is dependent upo the compression, the clearances, and the lubricant use above zero have little effect on the starting torque, but there is a decided increase in the torque required. Fig. 3

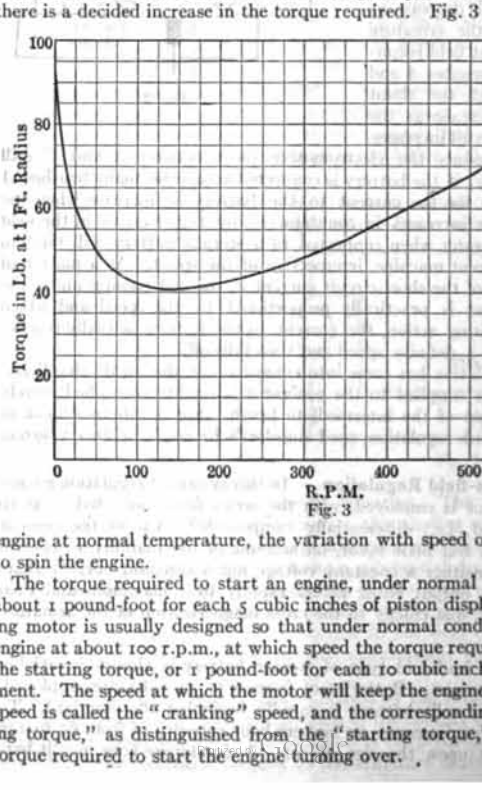

Fig. 3

engine at normal temperature, the variation with speed to spin the engine.

The torque required to start an engine, under normal about 1 pound-foot for each 5 cubic inches of piston displ ing motor is usually designed so that under normal cond engine at about 100 r.p.m., at which speed the torque requ the starting torque, or 1 pound-foot for each 10 cubic inch ment. The speed at which the motor will keep the engine speed is called the "cranking" speed, and the correspondi ing torque," as distinguished from the "starting torque, torque required to start the engine turning over.

ed of the starting motor when developing its cranking torque ranges to 3000 r.p.m., depending upon the design. The gear reduction emges from 8 to 1 to upwards of 25 to 1.

S. — There are two common types of lamps, namely, focusing and ng. In the focusing type, used for head and spot lights, the filament nto a compact spiral, which brings the source of light as near a point e. The non-focusing lamps are usually constructed with a looped ent. Lamps of this type are used for tail lights, cowl lights, and side

n filament lamps are now used almost exclusively. Both the vacuum the nitrogen filled type are employed, the former consuming about candle-power and the latter about ¾ watts per candle-power. The e lamps ranges from 100 to 300 hours under ordinary service condi-

ING SWITCH AND FUSES.— Switches used on starting sysf two types, viz., (1) those completing the circuit directly and (2) a solenoid to complete the circuit.

rst, the so-called harpoon type is most generally used, consisting of onnections to laminated copper sections at either side of the switch ovable member extends through the cover and is held extended by a ow. Depressing this plunger completes the circuit. The solenoid ts of a plunger closing the main circuit to the motor after the coil xcited.

ile fuses are now made of standard capacity for maximum currents o amperes. Two sizes of fuses are used, namely,

1¼ in. length overall with ferrules ¼ in. in diameter,
1½ in. length overall with ferrules $\frac{13}{32}$ in. in diameter.

fuses are usually of the sight type.

G. — There are two common systems of wiring in use, i.e., the and the double-wire systems. The single-wire system is the more aving the advantage of cheapness and simplicity. In this system, ortions of the chassis are used to complete the circuit.

ple-wire system is used when leads are not located adjacent to the of the chassis. It has the disadvantages of being more expensive, nger from open circuits is twice as great as in the single wire.

ing circuits and connections between battery and switch, wires of 4 to No. 10 B and S. Gauge are generally used. It is well to use as it costs but little more, and there is a decided saving in electrical o. 14 stranded copper wire, rubber covered and cotton wrapped

10 stranded copper wire, rubber covered and cotton wr
for the lines where heavier currents are carried, e.g., fr
switch to head lights, horn, etc.

The size of starting motor cable in general use range
and S. Gauge. The length should always be kept as sh
come excessive losses in voltage. A good rule is to use
for the length required the voltage drop in the cable wh
will not exceed 0.3 volt.

**SPECIFICATIONS FOR INSTALLING E
MENT.** — The following specification for electrical in
from the S.A.E. specification.

Insulation Requirements. — Electrical apparatus
be capable after installation of withstanding 500 volts
between conducting circuit and ground. Tests of t
entire circuit.

Exception. — Batteries will not be subjected to any in
working potential.

Use of Conduit. — Insulated conductors must be p
non-metallic conduit outside of insulation, except wh
from the elements or where out of contact with metal s

Metallic conduit ends must be provided with ferrule
and having a fit sufficiently tight to exclude free entran

Where wires are not protected by conduit, they are to
not exceeding 10 inches. Cleats may be of metal w
interposed between cleats and wire.

Clearance. — Where no conduit is used, as on wo
shall be at least two inches from exhaust pipe.

Connectors. — All connectors shall be so made th
the section which is alive will have all live parts recessed
end of shell of connector.

Springs used in connectors shall not be relied upon to

Protection against Accidental Short-Circuits. —
fuse and junction block or on instruments, generators
which must have live parts exposed, shall be so constructe
that an accidental short-circuit cannot be effected by met
minor repairs or adjustments.

Bulb Sockets. — Bulb sockets must be so made tha
return path is not impaired when lamp is subjected to v

In lamps, hinges shall not be relied upon to carry cur
tions must be either permanent or so spring held that
tight under vibration.

Protective Devices. — The current to all lighting a
be passed through protective devices.

Protective devices shall be on battery side of switches

Temperature Test. — All insulating material used
sockets, and similar devices for electrical apparatus for
mobiles shall be capable of withstanding for 30 minutes a

— (*See also Boilers; Calorimeters, Steam; Pipes and Piping; Steam am Turbines; etc.*) Steam at a given pressure and at a temperature ay decrease in temperature, the pressure being kept constant, will lensation of water, is said to be "saturated." When the tempera- that a decrease of temperature, the pressure being kept constant, ce without the formation of water, the steam is said to be "super- d the number of degrees that the temperature can be lowered before n of water takes place is called the "degrees of superheat." Saturated contain fine particles of water in the form of spray or mist, in which am is said to be "wet," while if there is no such moisture present said to be "dry." (When the steam produced by a boiler is wet also said to be "primed," and the amount of moisture is called the priming.") Superheated steam is always dry. The weight of the steam in a pound of wet steam (steam and moisture) is called of the steam." The temperature of saturated steam at a given he same whether the steam be dry or wet, and is the same as the of water at that pressure. The temperature of saturated steam, g point, depends solely upon the pressure of the steam.

HEAT OF STEAM. — The amount of heat required to change f water at 32° F. into steam at any pressure, p, is called the "total saturated steam at this pressure. The number of B.t.u. required temperature of one pound of water from 32° to the temperature of d steam at the given pressure is called the "heat of the liquid." ce between the total heat and the heat of the liquid is called the poration."

e of superheated steam, heat is also required to raise the temper- steam from the temperature corresponding to saturation to the of the superheated steam. The total number of B.t.u. required e pound of water at 32° F. into superheated steam is given in the below.

Y OF STEAM. — (*See also Thermodynamics, Principles of.*) ith steam the change in entropy resulting from adding to one e water at 32° F. an amount of heat necessary to raise its temper- boiling point is called the "entropy of the water," the change in ng evaporation, i.e., the heat of evaporation divided by the abso- ture of the boiling point, is called the "entropy of evaporation," ropy of the water plus the entropy of evaporation is called the the steam." The entropy of the water is approximately the he heat added to 1 lb. from 32° to the boiling point divided by of these two temperatures above absolute zero.

TABLES. — Tables giving the values of the various properties the range of temperatures and pressures met with in practice have recomputed by Marks and Davis, using the latest experimental basis for their calculations. The following tables are condensed iven in their *Steam Tables and Diagrams* (N.Y., 1909).

Steam. — Using the symbols at top of the table:

Gage pressure in lb. per square in.	$= p - 14.7$
Vacuum, inches of mercury,	$= 29.92 - 2.036\, p$
Entropy of evaporation	$= N - n$
Pounds per cubic foot	$= \frac{1}{v}$.

V OF STEAM THROUGH A NOZZLE. — The rate of flow of rough a nozzle increases as the difference in the pressures on the two the nozzle increases, until the absolute pressure p_0 of the atmosphere ch the nozzle discharges reaches 58 per cent of the initial absolute p of the steam. For greater differences in pressure, i.e., for $\frac{p_0}{p} < 0.58$, of flow through a given nozzle depends only upon the initial absolute of the steam. For $\frac{p_0}{p} < 0.58$ the percentage change in the volume of the it passes through the nozzle also remains constant, the ratio of initial o expanded volume being 1.624. The following formulas have been the authorities stated for the flow of steam through a nozzle when 3. The notation is P = initial absolute pressure in pounds per square = smallest cross section of nozzle in square inches; W = flow in pounds te; x = quality of steam = $\frac{100 - y}{100}$ where y is the per cent of moisture; rheat in degrees F.

	Dry saturated	Moist	Superheated
.....	$W = 0.857 A P$		
.....	$W = A P^{0.97}$	$\frac{A P^{0.97}}{x}$	$A P^{0.97} (1 + 0.00065 D)$

V OF STEAM THROUGH PIPES, VALVES, AND BENDS. — *s and Piping.*)

OGRAPHY. — Marks and Davis, *Steam Tables and Diagrams: Steam Tables;* Ennis, W. D., *Applied Thermodynamics.* See also phies in the articles on *Boilers, Steam,* and *Steam Engines.*

Digitized by Google

STEAM ENGINES. — (*See also Condensers; Power Turbines.*) A steam engine is a machine in which the verted into mechanical energy by means of the pressu more parts of the machine. This article treats of the r steam turbines (q.v.) are treated in a separate article.

CLASSIFICATION. — The principal classificatio gines are the following:

Single- and Double-acting Engines. — If the ste of the piston it is a single-acting engine; if on both si

Throttling and Automatic Engines. — A throttlin the speed of the engine is governed by a throttle valve i vary the pressure of the steam admitted to the engine engine is one in which steam is always admitted at ful by a valve or valves at different points in the stroke a point at which the cut-off takes place being autom governor.

Throttling as a means of governing is seldom emplo engines. It affords a simple and reliable means of sp etc. Automatic regulation of cut-off is capable of clos permits higher ratios of expansion.

Condensing and Noncondensing Engines. — A c in which the steam is exhausted into a condenser, by me is reduced usually to within 1 to 3 pounds per square inch A non-condensing engine is one whose exhaust steam i atmospheric pressure. Any engine can be operated co ing, but certain minor modifications are usually made i when it is to be operated normally condensing.

Binary-vapor Engine. — This is a very spec engine. Sulphur dioxide, instead of water, is used as surface condenser. The sulphur dioxide in condensin itself vaporized and this vapor, under a pressure of abou inch, is used expansively in a secondary reciprocating sulphur dioxide is discharged into a surface condenser i cooling water, much the same as in refrigerating prac over again. This type of engine has never come into

High- and Low-speed Engines. — This classific (fly wheel) speed only; engines having a rotative spee minute or less are usually classified as low-speed engi speed is greater than 150 revolutions per minute the speed engine. A high-speed engine may have a lo low-speed engine; the relation between piston speed pends solely on the length of stroke.

Compound and Multiple-expansion Engines. — one in which the steam is partially expanded in a sm carried to one or more larger cylinders in which it is fu cylinders are in line with each other, using a common tandem compound; if the smaller and larger, or high-p cylinders are side by side it is called a cross-compoun simpler, lighter, cheaper and more compact, and serv ancing and uniform crank effort are not essential. vertical or horizontal. Vertical engines take up less fl costly than horizontal engines.

Digitized by Google

ine in which the total expansion of the steam is divided into three gh-, intermediate- and low-pressure, is a triple-expansion engine; if stages, a quadruple-expansion engine. Multiple-expansion engines n compound) are seldom used for driving electric generators.

cation According to Valve Gear. — Engines are also classified to their valve gear (*see Valve Gear, below*), as Corliss engines, slide- nes, piston-valve engines and poppet-valve engines.

N AND CONSTRUCTION. — For a more complete treatment of and construction of steam engines see Kent's *Mechanical Engineers' ok.* A brief discussion of valves and governors is given below.

and Valve Gear. — Three types of valves are used to control the and exhaust of the steam to and from the cylinder, namely the slide liss valve and poppet valve.

de Valves. — Fig. 1 shows a cylinder with a plain slide valve of the type. The valve rests in a V-shaped groove in the bottom of the st, and is held up seat by pressure eam. The valve asses through a the back of the shown by the section of the and steam chest, ows the valve to nst its seat with- ging the valve

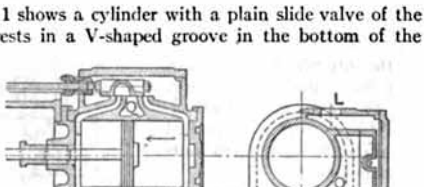

Fig. 1. Plain Slide Valve

lrawing, the valve is shown moved over to the left so as to allow the steam chest to pass into the head end of the cylinder and force toward the left. Steam from the crank end of the cylinder can flow cavity in the valve to the exhaust space *Q*. Steam enters by the

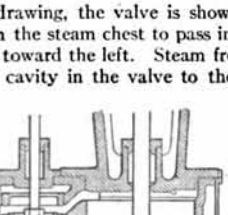

Fig. 2. Piston Valve

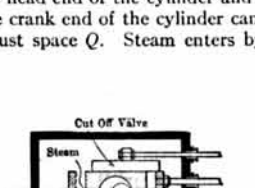

Fig. 3. Riding Cut-off Slide Valve

(transverse section) and escapes through the exhaust space *Q*. As moves toward the end of the forward stroke, the valve is moved by ric to the right, and it first shuts off the supply of steam from the head he exhaust from the crank end of the cylinder, and then opens the steam for the crank end and the exhaust for the head end just before stroke is begun.

ypes of slide valves are the piston valve and the riding cut-off valve. mer. Fig. 2, is used a piston filling an auxiliary cylinder which takes

Digitized by Google

the place of the steam chest used with the common type. The riding cut-off slide valve, Fig. 3, is essentially a double slide valve. The riding cut-off controls the point of cut-off only, the points of admission, release and compression being controlled by the main valve. (*See Fig. 3 below.*)

Any adjustment of the simple slide valve changes all four events of the stroke, namely admission, cut-off, release and compression. With the riding cut-off slide valve the cut-off can be varied independent of the other events.

Corliss Valve. — To make all four events of the stroke independently adjustable, four separately controlled valves are necessary, One of the first successful four-valve engines was invented by George Corliss in 1848. Various modifications of the original Corliss valve gear have since been made, but the same general principle of operation is embodied in practically all modern four-valve engines.

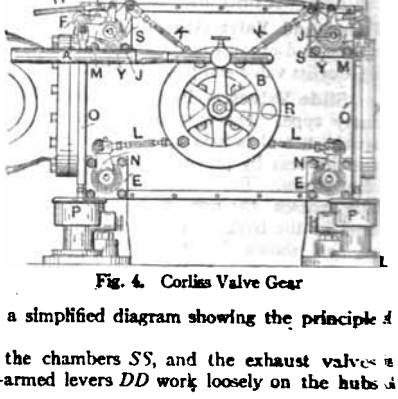

Fig. 4. Corliss Valve Gear

Fig. 4 shows the general external appearance of a simple Corliss valve gear and Fig. 5 is a simplified diagram showing the principle of operation.

"The steam valves work in the chambers *SS*, and the exhaust valves in the chambers *EE*. The double-armed levers *DD* work loosely on the hubs of the steam bonnets; they are connected to the wrist plate *B* by the rods *KK*; the levers *MM* are keyed to the valve stems *JJ*, and are also connected by the rods *OO* to the dashpots *PP*. The double-armed levers *D* carry at their outer ends steam hooks *FF*, these being provided with hardened-steel catch plates which engage with arms *MM*, making the arm *M* and the hook *F* work in unison until steam is to be cut off. At this point another set of levers or cams *GG*, connected by the cam rods *HH* to the governor, come into play, causing the catch plates on the hooks *F* to release the arms *MM*, the outer ends of which are then pulled downwards by the dashpot plunger, causing the steam valves to rotate on their axis and thus cut off steam. The exhaust valve arms *N* are connected to the wrist plate by the rods *LL*, and it is seen that all the valves receive their motion from the wrist plate *B*; the latter receives its motion from the hook rod *A*. This rod is attached to a rocker arm; to this arm the eccentric rod is also attached.

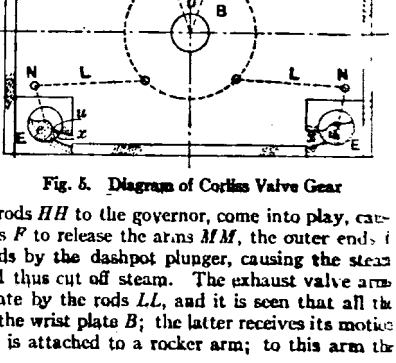

Fig. 5. Diagram of Corliss Valve Gear

"In order to obtain a greater range of cut-off in Corliss engines, a separate steam and exhaust eccentric is used. With two eccentrics the admission and

Digitized by Google

valves can be adjusted independently, and steam may be cut off anyearly to the end of the stroke." (*From Types of Modern Engines and ve Setting, by M. C. Myers, Boston, 1910.*)

ppet Valves. — This type of valve for engine cylinders is largely urope, but only to a limited extent in this country. Fig. 6 illustrates of poppet valve and valve gear, known as the Sulzer valve gear.

mparison of Different f Valves. — Multi-valve re more expensive than ve types, but give better due to the independent of cut-off and other the stroke, and to the equirements of clearance space. Rotary valves are icult to make and keep t when used with superam than the poppet and ypes. The erosive action evere temperature strains superheat add much to lty of maintaining a good but the difficulties are in the best designs.

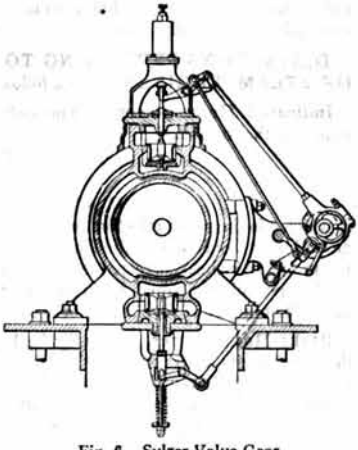

Fig. 6. Sulzer Valve Gear

ors. — Two types of govused, viz., the pendulum nd the flywheel types.

ndulum Governor.—The on of the pendulum governor is too well known to need description. of governor can be made to control the quantity of steam admitted nder either by opening or closing a throttle valve, or by varying f cut-off. In the latter case a suitable link motion (*see below*) must d.

wheel or Shaft Governor. — This type of governor is now largely ially for high-speed automatic engines

es governor, Fig. 7, one of the commonest forms of flywheel gov-

f the single-weight or inertia type. The ravity of the weight is located approxi-. The governor is shown in position for ff; the rotation is in the direction of the y increase in speed tends to make the avity of the weight seek a position further the center of the shaft and causes the wing on its pivot in a direction opposite to wheel; the eccentric is attached to the this movement brings the center of the arer the center of the shaft, and increases advance, thus effecting an earlier cut-off.

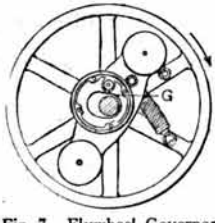

Fig. 7. Flywheel Governor

other types of shaft governors are described in detail in a small *ft Governors* (*Hill Pub. Co., 1908*).

tion. — Link motions, of which the Stephenson link is the most sed, are designed for two purposes: first, for reversing the motion e, and second, for varying the point of cut-off by varying the travel

of the valve. The Stephenson link motion is a combi called forward and back eccentrics, with a link conne the eccentric rods, so that by varying the position o may be put in direct connection with either eccentric ment controlled in part by one and in part by the oth link is moved by the reversing lever into a position such the valve rod is attached is at either end of the link, th imum travel, and when the link is in mid-gear the trav takes place early in the stroke.

DEFINITIONS PERTAINING TO RATING A OF STEAM ENGINES. — The following terms are

Indicated Horse-power. — The indicated horse-p found by the formula

$$P = \frac{pLAN}{33{,}000},$$

in which p is the mean effective pressure, in pounds per an indicator (*see below*), L the length of the stroke in fe ton in square inches (corrected for area of the piston rod) strokes per minute, equal to the number of revolutio twice the number of revolutions of a double-acting engi

Brake Horse-power. — The brake horse-power of delivered by its shaft as determined by a dynamomete equal to the indicated horse-power minus the power ab engine. In well-designed engines working under nor usually from 8 to 12 per cent of the indicated power; t in friction is nearly a constant at all loads, so that its 100 as the load decreases to zero, when the whole of the absorbed in overcoming friction.

Rated Horse-power. — When an engine is comme horse-power it is understood that it will deliver that those conditions for which it is designed, such as spee pressure, etc., and cutting off at that fraction of the s best economy. Its rated overload capacity is the po the same speed, steam pressure and back pressure, and point which the design of the valve motion will permit.

Indicator Diagram. — An indicator diagram is a showing the steam pressure in the engine cylinder at e Such a diagram may be actually obtained by means of a steam-engine indicator, which is an instrument which causes a pencil to record on paper the pressure in the cylinder at every point of the stroke. The diagram drawn by the pencil shows whether the valves are properly adjusted, and it is also used in figuring the power developed in the cylinder, and approximately the steam consumption. A diagram of a noncondensing engine in which the steam is cut off at about one-quarter of the stroke is shown in Fig. 8.

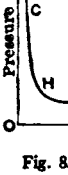

Fig. 8

The lines and points have the following significance.

Point of Admission, C, is the point at which t

Digitized by Google

ssion Line, *CD*, shows the rise of pressure due to the admission of cylinder by opening the steam valve.

n Line, *DE*, is drawn when the steam valve is open and steam itted tc the cylinder.

of Cut-off, *E*, is the point where the admission of steam is the closing of the valve. It is often difficult to determine the t which the cut-off takes place. It is usually located where the e diagram changes its curvature from convex to concave.

nsion Curve, *EF*, shows the fall in pressure as the steam in the nds doing work.

of Release, *F*, shows when the exhaust valve opens.

ust Line, *FG*, represents the change in pressure that takes place aust valve opens.

-pressure Line, *GH*, shows the pressure against which the piston ts return stroke.

of Exhaust Closure, *H*, is the point where the exhaust valve annot be located definitely, as the change in pressure is at first radual closing of the valve.

ression Curve, *HC*, shows the rise in pressure due to the com- he steam remaining in the cylinder after the exhaust valve has

l Pressure is the pressure acting on the piston at the beginning of

inal Pressure is the pressure above the line of perfect vacuum xist at the end of the stroke if the steam had not been released s found by continuing the expansion curve to the end of the

Definitions. — In addition to the terms defined above, the fol- mmonly employed:

tle Pressure is the pressure in the steam pipe at the entrance to valve.

Effective Pressure is that equivalent constant pressure which ame amount of work on the piston per stroke as is done by the sure shown by the indicator card. This may be calculated by area of the card by the length and multiplying by the scale of the n the indicator.

ance. — The portion of the cylinder volume, including the steam wept through by the piston but which is nevertheless filled with admission occurs is called the clearance volume. It ranges from 1 he piston displacement in very large engines to 10 per cent or more -speed engines.

of Expansion is the ratio of the piston displacement (in low- nder in case of a multiple-expansion engine) to the volume of dmitted through the throttle valve at each stroke (or half stroke double-acting engine), the volume being that corresponding to the the engine side of the throttle valve.

Drawing, as applied to steam, is the reducing of its pressure, wing through restricted pipes and passages.

NCY OF A STEAM ENGINE. — By the thermal efficiency of ne is meant the quotient of the B.t.u. per hour equivalent to the

Digitized by Google

indicated horse-power divided by the total number of B.
per hour; or, putting

W = pounds of steam supplied per hour per indicate
x = quality of the steam supplied (= lb. of dry ste
see article on *Steam*),
L = heat of evaporation per pound of steam at throt
pound,
h = heat of the liquid at throttle pressure, B.t.u. pe
h_0 = heat of the liquid of feed water, B.t.u. per
perature corresponding to the pressure in the exh
(*See A.S.M.E. code, 1913.*)

Then the thermal efficiency for saturated steam is

$$E_t = \frac{2546.5}{W(xL + h - h_0)}.$$

If the steam is superheated, let

H = total heat of superheated steam at throttle pres
heat, in B.t.u. per pound.

Then the thermal efficiency is

$$E_t = \frac{2546.5}{W(H - h_0)}.$$

The above formulas are also applicable to the calcul
ciency, including friction losses, if W is taken as the pou
hour per brake horse-power.

Efficiency of Rankine Cycle. — The maximum p
is that of an engine performing the ideal Carnot's cy
Principles of), but this cycle is not very closely simula
even when the losses are neglected. Instead the effi
cycle" is employed as a standard of reference. This
assumes that the work done by the engine is equal t
(*see Thermodynamics*) corresponding to an adiabatic
pressure to exhaust pressure and an isothermal cond
steam and a compression of the condensed water to thr

Rankine Efficiency for Dry Saturated Ste

H_1 = total heat, B.t.u. per pound, of dry saturated st
H_2 = total heat, B.t.u. per pound, of dry saturated st
h_2 = heat of the liquid, B.t.u. per pound, at exhaust t
T_2 = temperature of exhaust steam, in ° F.,
N_1 = total entropy of 1 pound of dry saturated steam
N_2 = total entropy of 1 pound of dry saturated stean

Then the efficiency is

$$E_r = \frac{H_1 - H_2 + T_2(N_2 - N_1)}{H_1 - h_2}.$$

Rankine Efficiency for Wet Steam. — In ad
bols let

H_w = total heat, B.t.u. per pound, of wet steam at th
N_w = total entropy of 1 pound of wet steam at throtl
T_1 = temperature of steam at throttle pressure, in °F

Then the efficiency is

$$E_r = \frac{H_w - H_2 + T_2(N_2 - N_w}{H_w - h_2}$$

Digitized by Google

ankine Efficiency for Superheated Steam.—In addition to the
bols let

otal heat, B.t.u. per pound, of superheated steam at throttle pressure,
otal entropy of 1 pound of superheated steam at the given degree of
superheat at throttle.
efficiency is

$$E_r = \frac{H_s - H_2 - T_2 (N_s - N_2)}{H_s - h_2}.$$

cy Ratio Referred to the Rankine Cycle.—This is the ratio of
l efficiency of the actual engine (referred to indicated or brake horse-
he case may be) to the efficiency of the Rankine cycle between the
s of temperature and pressure as those observed in the actual engine.
e of steam turbines the thermal efficiency is referred to the brake
r. In the case of reciprocating engines it is usually referred to the
orse-power.

TEAM ENGINE EFFICIENCIES—SATURATED STEAM.

al thermal efficiencies of multiple expansion engines using superheated
e from about 19 to 23 per cent.

Losses. — The actual efficiencies of steam engines are necessarily
than the efficiency of the Rankine cycle due to the thermal and
losses. These losses consist chiefly of (1) cylinder condensation,
eakage, (3) incomplete expansion and compression on return stroke,
, (5) clearance loss, (6) radiation and (7) the admission of wet

nder Condensation is due to the chilling of steam by the cooler
lls during admission and early expansion, thus reducing the active
expansion. Condensation increases with the range of expansion
and with the duration of the cycle. The condensation loss is

Digitized by Google

augmented by the formation of a water film on the cylinder walls. It is successfully reduced by expanding the steam in several stages, thus reducing the range of temperature in each cylinder and rendering the heat carried to the exhaust in that cylinder available in succeeding cylinders. Other remedies for condensation are: increasing the rotative speed; steam jackets about the cylinders; and reheaters to dry the steam between cylinders. The most positive and effective remedy is superheat sufficient to keep the steam dry at least during admission.

Steam Leakage past valves, pistons and packing increases with the pressure difference. It is an important element of loss in all piston engines and tends to increase with the wear of moving parts. Leakage is especially serious in cylinders employing a wide range of pressures. Flow of steam through orifices, in pounds, increases directly as the pressure (Napier's rule), and through pipes as $\sqrt{\text{density}}$. (*p. 845* Kent's *Mechanical Engineers' Pocket-Book.*)

Incomplete Expansion and Compression. — As a rule the release occurs before the piston reaches the end of the stroke and the point of closure comes before the piston reaches the end of the back stroke. There is a consequent loss of expansion on the forward stroke. The piston also has to do work in compressing the steam remaining in the cylinder on the reverse stroke. These two features are, as a rule, necessary; the first to reduce cylinder condensation, and the second for its cushioning effect. The first always, and the second usually, results in a net loss.

Friction varies with the type and condition of the engine, is greater in compound engines than in simple engines, and is nearly independent of the load, increasing but slightly as the load increases. It ranges from 4 to 20 per cent of the rated output.

Losses Due to Radiation, Clearance and Moisture. — With well-lagged cylinders radiation losses are small. Some clearance is necessary in every engine, but the amount is much greater for high speeds than for low speeds. The loss due to it is trifling in slow-speed engines of long stroke. Moisture dilutes the steam admitted but has little effect on the consumption of *dry* steam; the consumption of the fluid (steam and moisture) is of course increased in proportion to the percentage of moisture present.

ECONOMY OF STEAM ENGINES.* — The performance of a steam engine is frequently expressed in terms of the number of pounds of steam per hour required per indicated horse-power, per brake horse-power or per kilowatt (if used to drive an electric generator). The number of pounds of steam per unit of output is called the "economy" of the engine or of the combined engine and generator unit.

Such data may be very misleading unless comparisons are based on identical conditions of steam pressure, superheat, vacuum, etc. A true measure of economy applicable to all conditions may be expressed in net heat units consumed per unit of output, as B.t.u. per kilowatt-hour. In such determinations of economy all heat returned from the exhaust to the boiler should be credited to the engine or turbine.

The commonest means of gaining good engine economy are: raising the initial pressure, compounding, condensing and superheating.

Effect of Steam Pressure on Economy and Capacity. — There can be no universal rule connecting initial pressure and working economy. Compound

ngines are better adapted to high pressures than simple engines. Experience ndicates that the following gauge pressures are desirable:

Simple, condensing engine without steam jackets	60 lb.
Simple, condensing engine with steam jackets.....	80 lb.
Simple, non-condensing engine without steam jackets .	100 lb.
Compound, non-condensing engines	175 lb.
Compound, condensing engines	150 lb.
Triple-expansion, condensing engines	175 to 200 lb.
Quadruple-expansion condensing engines	200 lb.

An important advantage from the use of high pressures is the greater capacity which can be developed from a given engine. The ratio of pressure and capacity s nearly a direct one. High pressures tend to improve economy but not to the extent theoretically available, due to the counteracting effects of condensation and steam leakage with increasing pressure ranges. High steam pressures, however, usually add to the expense of piping and its maintenance. From an examination of a large number of engine performances Stevens and Hobart give the general relation of pressure and economy as shown in Fig. 9.

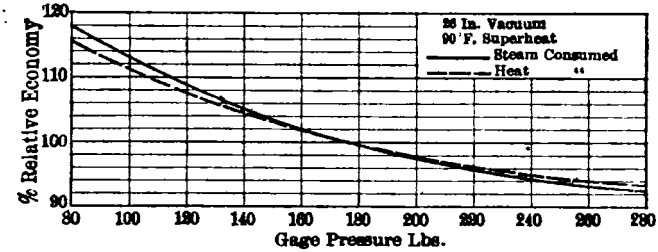

Fig. 9. Effect of Steam Pressure on Economy of Compound Piston Engines

Effect of Multiple Expansion on Economy. — The loss due to cylinder condensation increases with an increase of the difference of temperature of the steam during admission and exhaust, and therefore tends to become greater as the initial pressure is higher. By dividing the total range of expansion into two or more stages, the range of temperature in any one cylinder is decreased, and this lessens the total loss due to cylinder condensation.

Triple and quadruple expansion afford substantial economies with constant load as in pumping and marine service, but have little advantage with the variable loads of electric service to compensate for their great weight, complexity, bulk and cost. Compound engines with high cylinder ratios permit more complete expansion, but have less overload capacity than engines of smaller ratios. For electric service more than 18 expansions is seldom profitable. A cylinder ratio of 1 : 2.5 is well adapted to a pressure of 100 pounds; 1 : 3 to 125 pounds; 1 : 3.5 to 150 pounds and 1 : 4 to 175 pounds or above. Compound engines are relatively uneconomical at light loads, but have a greater economical range of overloads than simple engines. Compound engines, with a moderate cylinder ratio, usually give their best economy at ¼ cut-off in the high-pressure cylinder and will safely carry an overload of 50 per cent.

Effect of Condensing on Economy. — Condensing serves to increase both the capacity and economy of engines. The theoretical gain from condensing to various back pressures is indicated in Fig. 10. Actual engines can avail themselves of but a part of this gain, the proportion falling as the vacuum is increased due to the added condensation and leakage. Expansion to very

low pressures requires cylinders of excessive volume. Condensing equipment, especially that for high vacuum, adds much to the first cost of a plant and hence

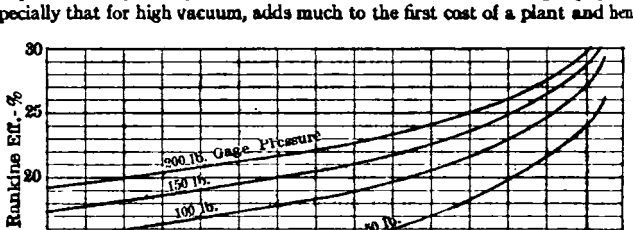

Fig. 10. Effect of Vacuum on Theoretical Efficiency

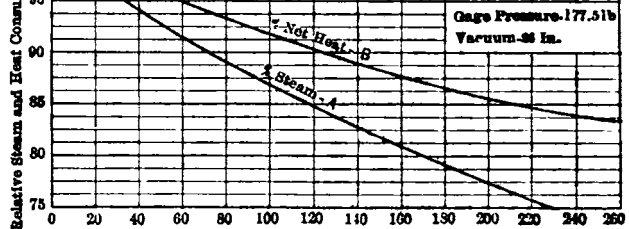
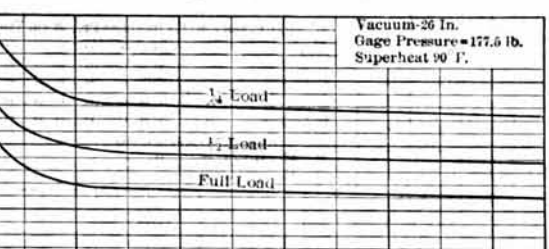
to its burden of fixed charges. (*See article on Condensers.*) Condensers require from one to three pumps and the thermal gain is reduced by the amount of their heat consumption. The temperature of the exhaust steam is lowered as the vacuum increases and so reduces the heat which can be reclaimed in the feed water. It is of great importance that the net gain rather than the apparent gain be considered in determining the economics of various vacua. Reduced steam consumption lessens the necessary investment in steam-generating equipment and piping, and this tends to somewhat counterbalance the investment in condensing apparatus. (*See article on Power Stations.*)

Effect of Superheating on Economy. — Superheating the steam is more effective than using steam jackets and reheaters as a preventive of cylinder condensation under the usual central-station conditions. With proper valve structures there is a decided net saving in heat consumption as the superheat is increased within reasonable limits, but this procedure usually adds to the





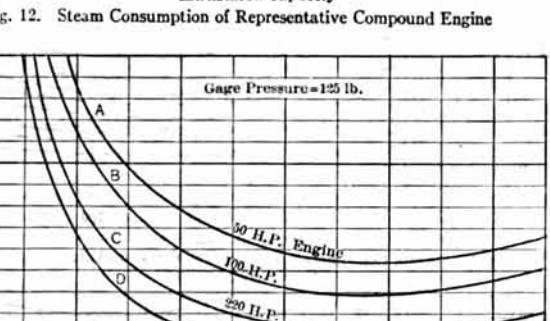


Fig. 11. Effect of Superheat on Piston-engine Economy

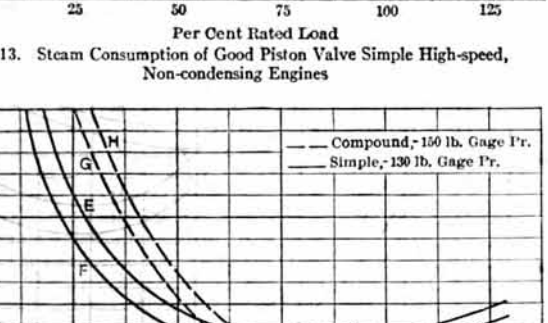

cost of piping, fittings and their upkeep. Stevens and Hobart report the mean relationship between superheat and economy in compound and multiple expansion engines, as shown in Fig. 11. It is especially important that economic comparison be based on the heat unit consumption as in Curve B. Additional advantages from superheating are the reduction of condensation, radiation losses and pressure drop in steam pipes.

Variation of Economy with Load. — Other factors affecting the economy of engines are the size of the unit, the speed, the mode of governing and the uniformity of load. Stevens and Hobart give the relations between engine sizes, loads and economy shown in Fig. 12 as averages for compound piston engines. Simple engines as a rule show smaller variation in economy with partial loads than compound engines. Typical economy curves for simple and compound engines with saturated steam and compound engines with superheated steam are shown in Figs. 13 to 16. The curves in Fig. 16 correspond to like lettered curves in the other figures.

Economy of the Binary-vapor Engine. — With this type of engine there has been obtained an economy of only 8.36 pounds of steam per indicated horse-power-hour, corresponding to a heat consumption of 158.3 B.t.u. per minute. This was the best recorded performance in steam-engine practice at the time of the report (1907) and has not been noticeably exceeded since (1913).

DIMENSIONS AND WEIGHT OF ENGINES depend so largely upon the type, speed, etc., that it is impossible to give representative figures in the space available. The following table from the *Elec. World*, (*Sept., 1902*), gives the dimensions of some very large engines in New York City.

DIMENSIONS OF SOME LARGE RECIPROCATING ENGINES

Name of station.....	Metropolitan	Manhattan	Kingsbridge	Rapid Transit	Edison
Type of engine.....	Vert. cross-comp.	Double 2 hor. 2 vert. cyls.	Vert. cross-comp.	Double, 2 hor. 2 vert. cyls.	3-cyl. vert.
Rated horse-power.....	4500	8000	4500	8900	5200
Cylinders, all 60-in. stroke, in.....	46, 86	44, 88	46, 86	42, 86	43½, 2–75½
Piston rods, diam., in.....	9, 10	8	9, 10	8, 10	9
Crank pins, in.....	14×14	18×18	14×14	20×18	22 & 16×14
Wrist pins, in.....	14×14	12×12	14×14	12×12	14×14
Shaft length	27 ft. 4 in.	25 ft. 3 in.	27 ft.	25 ft. 3 in.	35 ft.
max. diam.....	37 in.	37 in.	39 in.	37 in.	29⅝ in.
bearings, in.....	34×60	34×60	34×60	34×60	26×60

The shafts are hollow, with a 16-inch hole, except the Edison which have a 10-inch hole. The speed of all the engines is 75 revolutions per minute, or 750 feet per minute. The crank pins of the Manhattan and Rapid Transit engines are each attached to two connecting rods, side by side, horizontal and vertical, each rod having a bearing 9 inches long on the pin. The crank pins of the Edison engine are 16 inches in diameter for the side cranks, and 22 inches for the center crank.

TESTING OF STEAM ENGINES. — The actual work done by an engine may be tested by a brake or friction dynamometer, or in the case of engines driving electric generators by measuring the electric energy delivered, correction being made for the efficiency of the generator. The work done in the cylinder is obtained by taking numerous indicator diagrams and calculating

from them the mean effective pressure and the horse-power. The steam consumption is tested by condensing all the steam discharged by the engine and weighing the water of condensation. When a condenser is not available the feed water delivered to the boilers may be weighed instead, precautions being taken to insure that all of the steam made by the boiler is used by the engine. For directions for making steam-engine tests see A.S.M.E. Codes.

Plant Tests. — In the introduction to the report above referred to the Committee says:

The heat consumption of a steam-engine plant is ascertained by measuring the quantity of steam consumed by the plant, calculating the total heat of the entire quantity, and crediting this total with that portion of the heat rejected by the plant which is utilized and returned to the boiler. The term "engine plant" as here used should include the entire equipment of the steam plant which is concerned in the production of the power, embracing the main cylinder or cylinders; the jackets and reheaters; the air, circulating, and boiler-feed pumps, if steam driven; and any other steam-driven mechanism or auxiliaries necessary to the working of the engine. It is obligatory to thus charge the engine with the steam used by necessary auxiliaries in determining the plant economy, for the reason that it is itself finally benefited, or should be so benefited, by the heat which they return, it being generally agreed that exhaust steam from such auxiliaries should be passed through a feed-water heater, and the heat thereby carried back to the boiler and saved.

SPECIFICATIONS. — (*See also article on Specifications.*) In obtaining bids for steam engines the prospective purchaser or his engineer usually furnishes only general specifications, stating the kind of work to be done by the engine, such as driving a cotton mill, or an electric power plant, and the following requirements: (1) Indicated horse-power required, (*a*) Maximum, (*b*) Average; (2) Steam pressure available at engine; (3) Maximum absolute back pressure; (4) Number of revolutions; (5) Required steam consumption.

The bidders then furnish with their bids complete detailed specifications with guarantees of the engines they propose to supply, with drawings, when these are required. The bidders are usually prepared to contract for the installation, erection and starting of the engine, especially if it is of a large size.

FOUNDATIONS FOR STEAM ENGINES. — Engine foundations may be built of brick or concrete; the latter is more commonly employed in modern practice. The concrete is made with proportions of one barrel of Portland cement, three of sand, and five of crushed stone.

If the foundation is to be of concrete a wooden box is built in the ground, the inside of the box being the shape of the foundation. Over the top of this box are a number of pieces of joist, from which the anchor bolts or holding-down bolts are hung. Most engine builders furnish drawings giving location of foundation bolts and size of foundation required. The nuts at the top of these bolts are blocked up to the height they are to be when the engine is in place.

The heads of the bolts are at the bottom. A cast-iron plate eight inches by eight inches by one inch, with a square recess for the bolt head, is at the bottom of each rod. Around each bolt a piece of four-inch galvanized-iron gutter pipe is placed, and the top end of the pipe stuffed with waste to keep the mason from dropping cement into the space between the pipe and the bolt. The concrete is now dumped in and tamped down. After it has set, the wooden joists holding the bolts may be taken away.

The engine is next put over the foundation and supported on iron bars one-half inch square or perhaps larger, these bars being placed near the bolts. By means of wedges, etc., the engine is leveled; the main shaft is placed parallel

shafting which it is to drive. The bolts are next tightened fairly
s it is impossible to core the holes in the engine bed exactly as called
e drawing, the leeway given by the space between the bolts and the
surrounding it takes care of variations of from an inch to an inch and

f putty, sand, or cement about one inch high is built about one inch
ngine bed. A thin, neat Portland cement, mixed to the consistency
cream, is poured under the engine bed and serves to fill the space
e bolts and to give the bottom of the bed a perfect bearing over the
ndation. Before the cement becomes hard, the edge may be trimmed
by means of a trowel; the bolts are then tightened again.
es type metal instead of cement is poured under the engine bed.

ATION. — Full directions for setting the valves of a steam engine
nd in a little book by M. C. Myers, entitled *Types of Modern Engines*
Valve Setting (Boston, 1910). Other useful data on the operation
mance of steam engines will be found in a book published by the
eam Gauge and Valve Co., entitled *Steam Engine Indicator*. See
ore elaborate treatises listed in the bibliography below.

Control. — The speed of an engine can always be controlled by
he opening of the throttle valve, but this method is usually wasteful.
icient method is to change the point of cut-off. This can be done
engine is running by using a suitable link motion (*see above*), or by
he setting of the governor spring if the governor is of the "automatic"
engines driving alternators in parallel this is usually accomplished
an electric motor arranged to act directly on the governor spring so
nsion of the spring may be controlled from the switch-board.

ng Variable Load by Storing Heat in Hot Water. — There is
tory method for equalizing the load on the engines and boilers in
t stations. Storage batteries have been used, but they are expensive
, repairs and attention. Mr. Halpin, of London, proposes to store
g the day in specially constructed reservoirs. As the water in the
ised to 250 pounds pressure, it is conducted to cylindrical reservoirs
English horizontal boilers, and stored there for use when wanted.

STEAM TURBINES. — (*See also Condensers, Steam; Power Stations; Steam; Steam Engines.*) Steam turbines may be classified as impulse, reaction, and composite; single-stage and multi-stage; nozzle expansion and blade expansion; vertical and horizontal. A set of nozzles or stationary guide blades and the rotating vanes through which the steam passes immediately upon leaving the nozzles or stationary blades constitute a single "stage." If there are several sets of stationary nozzles or guide blades and rotating vanes through which the steam passes successively, the turbine is called a "multi-stage" turbine.

APPLICATIONS OF STEAM TURBINES. — The steam turbine, when designed to use steam economically, is characterized by extremely high speed of rotation. The special field of application of the steam turbine is therefore the driving of electric generators, centrifugal blowers and pumps, and other machinery in which a high speed of the motor shaft is desirable. When lower speeds are desired in the motor shaft a reduction gear of some kind is placed between it and the turbine shaft. See also articles on *Generators; Power Stations; Pumps.*

RATING OF STEAM TURBINES. — Turbine ratings are usually based on maximum sustained load. Momentary overload capacity is very large and moderate overloads of considerable duration can be carried but may require the admission of high-pressure steam to low-pressure stages by means of a secondary valve. Small turbines for driving pumps, blowers, etc., are rated in horse-power. Turbines used to drive electric generators are usually rated in connection with the generator, the combined unit or turbo-generator being rated in kilowatts. Turbo-alternators of 20,000 kilowatts capacity each are in use (1913), and still larger units are considered practicable.

DESIGN AND CONSTRUCTION OF STEAM TURBINES. — Below are noted briefly some of the chief features in the design and construction of steam turbines. For further details see the treatises by Stevens and Hobart, Moyer, Stodola, Foster, Thomas, etc.

Impulse Turbines. — An impulse steam turbine of the simplest form is a wheel similar to a water wheel, which is moved by a jet of steam impinging at high velocity on its blades. By expansion of the steam its pressure energy is converted into kinetic energy, and the wheel is propelled by the impact of the steam moving at high velocity.

De Laval Turbine. — The distinguishing features of this turbine are the diverging nozzles, in which the steam expands down to the atmospheric pressure in non-condensing, and to the vacuum pressure in condensing wheels; a single forged-steel disk carrying the blades on its periphery; a slender, flexible shaft on which the wheel is mounted and which rotates about its center of gravity; and a set of reducing gears, usually 10 to 1 reduction, to change the very high speed of the turbine to a moderate speed for driving machinery.

The number and size of nozzles vary with the size of the turbine. The nozzles are provided with valves, so that for light loads some of them may be closed, and a relatively high efficiency is obtained at light loads. The taper of the nozzles differs for condensing and noncondensing turbines. Some turbines are provided with two sets of nozzles, one for condensing and the other for non-condensing operation.

Zolley or Rateau Turbine. — The Zolley or Rateau turbines are developments of the De Laval and consist of a number of De Laval elements in series, each succeeding element utilizing the exhaust steam from the preceding. The steam is partly expanded in the first row of nozzles, strikes the first row of

Digitized by Google

buckets and leaves them with practically zero velocity. expanded through the second row of nozzles, strikes a s buckets and again leaves them with zero velocity. Thi until the steam is completely expanded.

Curtis Turbine, made by the General Electric Co wheel of several stages. Steam is expanded in nozzles three or more blades, at least one of which is stationary non-expanding, and the pressure is practically the same on of blades. In smaller sizes of turbines, only one set of sta blades is used, but in large sizes there are from two to five pressure stage, separated by diaphragms containing addi The smaller sizes and the more recent (1914) larger shafts. Earlier large sizes have vertical shafts support supplied with oil or water under a pressure sufficient weight of the shaft and its attached rotating disks.

Reaction and Composite Turbines.— In a simple re expanding through a set of blades or nozzles capable of axis, produces a reacting force and drives the rotating direction to the motion of the steam. Hero's engine is the tion turbine. The term "reaction" turbine, however, as to a turbine in which the reaction principle is combined ciple, i.e., to turbines in which jets of steam striking blad in the rim of a wheel give it a forward impulse, and escapi direction react upon it.

Parsons Turbine. — This is a reaction turbine large number of rows of blades, mounted on a rotor or tween each pair of rows there is a row of stationary blade ing, which take the place of nozzles. A set of stationary ing set of moving blades constitute what is known as a pands and loses pressure in both sets. The speed of ro speed of the blades and the velocity of the steam throug much lower than in the De Laval turbine. The rotor, o moving blades are carried, is usually made in three secti eters, the smallest at the high-pressure end, where steam largest at the exhaust end. In each section the radial len also their width increase from one end to the other, to increased volume of steam. The Parsons turbine is built by the Westinghouse Machine Co. and by the Allis-Chalm

The Westinghouse Double-flow Turbine. — F law. a turbine is built in which the impulse and reaction It has a set of non-expanding nozzles, an impulse wh stages (that is, two wheels with a set of stationary non- tween), one intermediate section and two low-pressure blading. After steam has passed through the impulse mediate section, it is divided into two parts, one going to th to the left-hand low-pressure section. There is an exhau In this turbine, the end thrust, which has to be balanced of the usual type, is almost entirely avoided. Other adva tion in size and weight, due to higher permissible speed; not exposed to high temperatures; reduction of size of length of shaft; avoidance of large balance pistons.

ence has not made manifest any marked and consistent difference in and reliability between the impulse and reaction types.

al Versus Horizontal Turbines. —There is also no marked difference ny and reliability of the vertical and horizontal types. The former economical of floor space, especially when the base type of condenser yed, but requires more head room, as sufficient overhead space must ed to permit the lifting clear, and removal of, the shaft from the casing.

ction Gear for Steam Turbines. — Double spiral reduction gears, f a ratio of 1 to 10, are used with the De Laval turbine to obtain a of rotation suitable for dynamos, centrifugal pumps, etc. G. W. and J. H. McAlpine have designed a similar gear, with the pinion car- floating frame supported at a single point between the bearings to the strain on the gear teeth, for reducing the speed of large horizontal to suitable speeds for marine propellers. A 6000-horse-power gear uction from 1500 to 300 revolutions per minute has been tested, giving ncy of 98.5 per cent (*Eng'g, Sept. 17; Eng. News, Oct. 21 and Dec. 30,*

INES VERSUS RECIPROCATING ENGINES. — The inherent ges of the turbine are: (1) The perfect continuity and uniformity This permits the working parts to be made light and gives the uni- ular velocity which is desired for the parallel running of alternators. high velocity of rotation and of steam flow. This tends to great com- permits light weights, provides for the full expansion to high vacuum enormous volume of expansive space, cheapens the cost of turbine and r, and is favorable to the efficiency of the latter. The effect of items (2) on weights, sizes and costs may be best appreciated by comparing and gas-engine sets of equal maximum capacity. (3) The reduction nimum of condensation, radiation and leakage. (4) The absence of cation from the steam space. Difficulties of lubrication with high t are thus obviated and the condensed steam is free from oil. (5) The nce of good economy over a wide range of fractional loads. great momentary overload capacity obtained from the high inertia pidly rotating parts. To match this advantage in slow-speed ting engines requires very heavy working parts and the addition pensive flywheel. The reciprocating engine can be built to equal ine in economy over a wide range of loads but the refinements to this end are costly. For equal heat consumption the costs of gine-alternator units are from 35 to 50 per cent greater than those of cts.

nes versus Engines in Units of Small Capacity. — Under this title, Barstow presented the following summary before the A.S.M.E. in er, 1915, for units of less than 500 horse-power capacity.

Digitized by Google

Applicability of Turbines. — 1. Direct-connected units, operating condensing. 60-cycle generators in all sizes, also 25-cycle generators above 1000 kw. capacity. (This paper is, however, not intended to deal with units of this size.) Direct-current generators in sizes up to 1000 kw. capacity, including exciter units of all sizes.

Centrifugal pumping machinery operating under substantially constant head and quantity conditions, and at moderately high head, say from 100 feet up, depending upon the size of the unit.

Fans and blowers for delivering air at pressures from 1½ inch water column to 30 pounds per square inch.

2. Direct-connected units, operating non-condensing for all the above purposes, in those cases wherein steam economy is not the prime factor or where the exhaust steam can be completely utilized, and, in the latter case, particularly where oil-free exhaust steam is desirable or essential.

3. Geared units, operating either condensing or non-condensing for all the above-mentioned applications, and in addition, many others which would otherwise fall in the category of the steam engine, on account of the relatively low speed of the apparatus to be driven.

Applicability of Engines. — 1. Non-condensing units, direct-connected or belted and used for driving: Electric generators of all classes excepting exciter sets of small capacity, unless belted from the main engine.

Centrifugal pumping machinery, operating under variable head and quality conditions and at relatively low heads, say up to 100 feet, depending on the capacity of the unit. Pumps and compressors for delivering water or gases in relatively small quantities and at relatively high pressures in the case of pumps at pressures above 100 pounds per square inch, and in the case of compressors at pressures from 1 pound per square inch and above.

Fans and blowers (including induced draft fans) for handling air in variable quantities and at relatively low pressures, say not over 5 inches water column. Line shaft of mills, where the driven apparatus is closely grouped and the load factor is good.

All apparatus requiring reversal in direction of rotation, as in hoisting engines and engines for traction purposes.

2. Condensing units direct-connected or belted, for all the above purposes particularly where the condensing water supply is limited, and where the water must be recooled and recirculated.

Low-pressure Turbines compounded with high-pressure reciprocating engines are coming into extensive use where it is necessary to increase the capacity or improve the efficiency of existing engine plants. By combining the superior efficiency of the engine in the pressure range above the atmosphere with that of the turbine below the atmospheric range a resultant superior to the efficiency of either single type may be secured. Standard piston engines are able to sustain full-rated load when run non-condensing and often will carry from 25 to 50 per cent above rated load without danger or excessive wear. Under such conditions the water rate per kilowatt-hour is high but all the heat rejected in the exhaust is available to a low-pressure turbine; hence the net economy of the combined engine and turbine may be considerably superior to that of the engine when run condensing. By proportioning the turbine to efficiently utilize the exhaust steam and by connecting to it a high-vacuum condenser, the initial capacity of the unit may be doubled or even trebled, and if the engine is in good condition, the resultant efficiency may be superior to that obtainable from a new complete-expansion turbine of equal capacity.

Structurally, the low-pressure turbine is similar to the full-pressure type with the high-pressure stages omitted. It is, therefore, somewhat shorter but

n spaces are necessarily greater than in a full-pressure type of equal It is highly desirable that an efficient separator be installed between e and the turbine as the presence of moisture in the steam adds greatly ction against the turbine blades. When the exhaust is to be returned oiler it is also necessary to extract the oil from the steam as it leaves e.

CIENCY AND LOSSES. — The maximum theoretical efficiency of a rbine is the efficiency of the Rankine ideal engine between the tem- of admission and exhaust (*see Steam Engines*).

veral losses which tend to reduce the efficiency of turbines below the al maximum are: (1) residual velocity, or the kinetic energy due to ity of the steam escaping from the turbine; (2) friction and imperfect in the nozzles; (3) windage, or friction due to rotation of the wheel ; (4) friction of the steam traveling through the blades; (5) shocks, eddies, etc., due to imperfect shape or roughness of blades; (6) leak- nd the ends of the blades or through clearance spaces; (7) shaft fric- radiation. The sum of all these losses amounts to about 25 per cent ailable energy in the largest and best designs and to 50 per cent or more izes or poor designs.

nsation, leakage and radiation are of small magnitude. Windage and re especially marked in the high-pressure stages and the turbine is cient in its low-pressure stages, in direct contrast to the piston engine. hanical friction is relatively small, due to the small loads on wearing nd the effectiveness with which they may be lubricated. Steam fric- dage and condensation are much increased by moisture in the steam. ted steam is particularly advantageous in turbines because of its low luctivity, dryness and high fluidity.

M ECONOMY OF TURBINES. — Like all heat engines the effi- the turbine depends on the range of expansion and the reduction of Increasing the ex- ange by raising the n pressure affords a small gain in ef- The chief advant- ing from high initial is in the decreased e turbine of a given The relation of essure to the steam consumption per output varies some- th the individual ut the general rela- fixed conditions of and superheat is Fig. 1.

In the utilization of high vacua the tur- Fig. 1 shows the relation of vacuum to This relation depends to a marked degree

on the design of the particular turbine and is therefore not identical in all units of a given general type.

Effect of Vacuum on Economy.— The economical limit of vacuum in turbines is much higher than in engines. The attainment of very high vacua involves a very heavy investment in condensers and auxiliaries and a considerable consumption of heat for their operation. The ultimate effect on plant economy is therefore decidedly less than the percentage gain indicated in Fig. 1. Factors unfavorable to high vacuum are a poor load factor for the unit; costly, warm or corrosive cooling water; the necessity of artificially cooling condensing water when the supply is limited; and very cheap fuel.

The question of the most economical vacuum must be determined by care-

fully weighing against each other the annual charges on the condenser system (interest, depreciation, attendance, repairs, and the net cost of water for its operation included, and, on the other hand, the annual saving in total fuel consumed plus the saving on boiler-plant fixed charges and operation. Such an analysis takes due account of the heat consumed in driving the auxiliaries. Where an abundant supply of cold condensing water is available, experience indicates that the highest vacuum attainable is a good investment in connection with large units operated at load factors of 60 per cent, or above. With ordinary central-station conditions vacua of from 27 to 28 inches are most advantageous.

Effect of Superheat on Economy. — Superheat of almost any practicable degree improves turbine efficiency, though the net saving is much less than that indicated by the water rate, due to the extra heat content of superheated steam of high temperature. On account of the influence of superheat on the first cost and maintenance expense of piping, valves and fittings, also because of the difficulties in providing for expansion of turbine parts at very high temperatures, the tendency of American practice is to exceed a steam temperature of 500° F only in very large units, though the tendency in Europe is toward a higher limit. Fig. 1 shows the effect of superheat on steam consumption and net heat consumption of steam turbines, the relation being practically uniform for all types

ace has not made manifest any marked or consistent differences in nd reliability between the several commercial types. The vertical t well suited to the highest speeds, but is especially economical of in connection with the base type of condenser. It requires greater than the horizontal type. Fig. 4 shows the steam consumption of of small non-condensing turbines (*see paper by G. A. Orrok, Trans. 1909*). All curves are test results.

. 4. Steam Consumption of Small Non-condensing Steam Turbines

OMY OF COMBINED TURBINE AND ENGINE UNIT. — ing is reported by H. G. Stott and R. J. S. Pigott in *Jour. A.S.M.E.*,

Mar., 1910. The steam-engine is one of the 7500-kilowatt Manhattan type engines at the 59th St. Station of the Rapid Transit Co., New York, with two 42-inch horizontal high-pressure and two 86-inch vertical low-pressure cylinders, and the turbine, also 7500 kilowatt, is of the vertical three-stage impulse type. The principal results are summarized as follows: An increase of 100 per cent in the maximum capacity and 146 per cent in the economical capacity of the plant; a saving of about 85 per cent of the condensed steam for return to the boilers [it was previously wasted]; an average improvement in economy of 55 per cent over the best high-pressure turbine results and of 2.5 per cent (between 7500 and 15,000 kilowatts) over the results obtained by the engine alone; an average thermal efficiency between 6500 and 15,500 kilowatts of 20.6 per cent. [This efficiency is not quite equal to that reached by triple-expansion pumping engines.]

TESTING OF STEAM TURBINES. — Turbines are tested in the same way as reciprocating steam engines, measuring the power by a Prony brake or by an electric generator whose efficiency at different loads is known and the steam consumption by weighing the water discharged from the condenser.

SPECIFICATIONS. — See *Specifications* in article on *Steam Engines*.

OPERATION. — Several important features are noted below. For additional information see article on *Power Stations*.

Oil-pressure System for Step Bearing of Vertical Turbine. — When running the end of the shaft is lifted slightly from its seat and supported by a forced circulation of water or oil under a pressure of from 500 to 1200 pounds per square inch. This pressure is produced by a special step bearing pump which may be of the steam-driven, direct-acting type or of the motor-driven, triplex type, and is reinforced by a heavily weighted plunger accumulator. When a double pump equipment is installed the second may serve as a reserve and, if of the motor-driven type, may readily be arranged to automatically take up the load if the accumulator falls to a certain point, due to the failure or inadequacy of the primary pump. The horizontal-shaft type is subject to an end thrust, which must be neutralized by dividing the turbine into two sections through which the steam flows in opposite directions or by the use of pressure rings opposed to the thrust on the turbine.

Speed Control. — Turbines having nozzle expansion are most efficiently governed by varying the number of active nozzles. Reaction turbines are governed by the intermittent throttling of steam at the admission valve. The governor is usually of the shaft or flywheel type (*see Steam Engines*). In both types, when used for driving alternators in parallel, a small motor is attached to the governor spring so that the tension may be controlled at the switchboard. This affords a convenient control of speed for synchronizing and adjusting the loads taken by the several machines.

Speed Control of Combined Turbine and Reciprocating Engine Unit. — In central-station service the two elements are so adjusted that the turbine takes all the steam from the engine, the load on the two is varied simultaneously and the two are electrically coupled by being connected to the same bus bars. This arrangement simplifies the problem of governing and the division of load. It has not been found advantageous to place a governor on the turbine under such conditions. The turbine operates under variable admission pressure, depending on the load. The turbine should be equipped with a speed-limiting relay, which opens the atmospheric exhaust from the engine should the speed of the turbine become unsafe.

STEEL. — (*See also Iron, Pig and Cast; Castings, Iron and Steel; Rails, Tra and Third.*) Carbon steel (the ordinary commercial steel) may be defined a an alloy of iron and carbon produced by any one of the methods described in the following article. It differs from wrought iron in not being slag bearing and from cast iron in being malleable at certain temperatures.

Slag is the substance which collects on the surface of molten iron or ste in the blast furnace, converter or open-hearth furnace. Its constitution vari with the process but it includes oxides of the various impurities found in th iron such as silicon, aluminum, phosphorus, calcium and magnesium. It m also include some oxide of iron. The slag from blast furnaces is often very ri in calcium owing to the amount of limestone added to the charge as a flu The manufacture of Portland cement from blast-furnace slag is an importa industry. The process of puddling used in making wrought iron involves th mixing of some of the slag with the iron, thus making it an integral part of th finished product as explained in the article on *Iron, Wrought.*

METALLURGY. — The various processes by which steel is at present manu factured are described in the following paragraphs:

Bessemer Process. — This process consists of the burning out of most of th impurities and carbon contained in molten iron by the aid of a blast of unheat air, and subsequent recarburization of the mass by the addition of spiegel-eise or ferro-manganese. The molten material is placed in a pear-shaped vess called a converter and the blast is introduced through openings in the bottom After the process has continued long enough to convert the iron into ste the molten material is either poured into iron molds forming ingots which ar later rolled or hammered into commercial shapes, or else cast into *steel castin*

Two processes are in use, the acid and the basic; in the former the converter lining is of refractory acid materials composed principally of silica, so that the phosphorus and sulphur in the charge are unreduced; in the latter, the con verter is lined with burnt dolomite, and lime is added to the charge to reduce the phosphorus and sulphur. The heat necessary for the process is obtained from the combustion of silicon in the acid process and of phosphorus in the ba process. The acid process alone is in use in the United States owing to the prevalence of low phosphorus and sulphur ores. Steel of fair quality is pro duced by this process at low cost and with great rapidity, but Bessemer steel is gradually being replaced for important structures by the more reliable open hearth steel.

Open-hearth Process. — This process consists of the reduction of the carbon and other impurities contained in a mixture of pig iron, scrap iron or scrap steel and iron ore by exposure for seven or eight hours to an intense heat obtained from a mixture of producer gas and air, the process being stopped when the bath is found to have the right proportions as determined by physical and chemical analyses. The steel is then withdrawn from the furnace and either poured into ingots or cast into usable forms. Steel of excellent quality for structural purposes is thus produced in large quantities, a single furnace often having a capacity of 50 tons.

Duplex Process. — This process consists of a combination of the Bessemer and open hearth; pig iron is first blown into the converter to remove the silicon and a portion of the carbon; it is then transferred to the open hearth, where it is dephosphorized and the carbon reduced to the proper percentage. The process permits the use of a poorer grade of material than the Bessemer, and gives a higher grade of finished product, while the speed of production is superior to that of the open hearth.

Digitized by Google

Crucible Process. — This process consists of melting down, in covered clay or graphite crucibles, wrought iron (sometimes diluted with steel scraps) with charcoal, ferro-manganese and various so-called physics, such as salt, oxide of manganese, etc. The crucibles hold from 50 to 100 lb. each. Crucible steel is high in carbon and low in sulphur and phosphorus. It is superior to Bessemer and open-hearth steel and is used for tool making.

Cementation Process. — This process consists of converting wrought iron into steel by piling iron bars and charcoal together, bringing to a yellow heat and keeping in this condition for a period extending from ten days to two weeks. The steel thus obtained is known as blister steel. If the blister steel is cut, piled, heated and forged, *shear* steel is produced; if the operation is repeated on shear steel, *double shear* steel is obtained. Blister steel is frequently melted in the crucible to free from slag; the resulting product is of the highest quality and is used in making the finest grades of cutting tools, such as razors. Case hardening is a special form of cementation by which the outer surfaces of articles forged from wrought iron or steel are hardened. Harveyizing of armor plate is also a cementation process.

MECHANICAL TREATMENT. — (*See also Steel Mills, Electric Drive of.*) Steel made by any of the preceding processes may be put into usable form either by casting, or by forging while hot under the hammer, or usually by rolling while hot between heavy grooved rollers, the latter process being used for rods, plates, rails, and structural shapes such as angles, channels and I-beams. The rolling process is usually divided into two parts: (*a*) the reduction of the ingot into *blooms* or *billets* by the *blooming mill;* and (*b*) the reduction of the blooms or billets into commercial shapes by the *shaping mill.*

The blooming mill consists of a pair of horizontal grooved rollers, one above the other, between which the ingot is passed back and forth, the rolls being gradually forced closer together. These rolls are actuated by a reversing engine. This process reduces the ingot from a block of steel perhaps 16 inches square by 6 feet in length to a bar of small cross-section, usually rectangular and of considerable length. This is then cut into sections several feet in length which are called blooms if the cross-section contains more than 36 square inches and billets if less. In England this mill is called a cogging mill.

The shaping mill is similar to the blooming mill, but there are usually three non-reversing rolls in a vertical plane, the bloom passing forward between the lower and middle rolls, and returning between the middle and upper roll.

HEAT TREATMENT; CRITICAL TEMPERATURE. — When iron or steel cools from a high temperature, say 1000° C., the rate of cooling is not uniform, but is marked by certain periods of retardation accompanied by spontaneous evolution of heat, the opposite phenomena occurring when the temperature is increased. There are in general three of these critical points which are designated by metallurgists by the letters A_1, A_2 and A_3, A_1 being at the lowest temperature. Owing to *lag* the changes occur at slightly lower temperatures on cooling than on heating, and to distinguish between them, the cooling points are designated Ar_1, Ar_2 and Ar_3, and the heating points Ac_1, Ac_2 and Ac_3. These points vary with the percentage of carbon, and for certain grades of steel the three cooling points may be merged into one and also the three heating points. With favorable conditions when the temperature Ar_1 is reached an increase in temperature of the metal may be detected by its change of color. This point is called the point of recalescence. At this temperature also a softening of the metal occurs. An interesting feature of the point A_2 is that at a higher temperature steel is *non-magnetic*, but in passing through Ar_2 it becomes suddenly *magnetic*. *See Magnetic Properties of Iron and Other Metals.*

CARBON STEEL. — The alloy of carbon and iron of which ordinary carbon steel is composed is divided into the five following groups by Sauveur:

Grade of steel	Hardness	Carbon content, per cent
Very low carbon	Very soft	Not over 0.10
Low carbon	Soft	Not over 0.25
Medium-high carbon	Half hard	0.26 to 0.60
High carbon	Hard	Over 0.60
Very high carbon	Hard, extra hard	Over 1.25

The properties of these different groups when made under normal conditions depend upon the relative amounts of the following constituents:

Ferrite, or iron free from carbon, this being the same as the ferrite in wrought iron (q.v.).

Pearlite, consisting of a mixture of iron carbide and ferrite.

Cementite, or iron carbide, with the formula Fe_3C, combined with a varying amount of carbide of manganese.

Austenite and Martensite. — Steel that is suddenly cooled from a high temperature contains also certain other compounds of iron and carbon, the two of most importance being known as *austenite* and *martensite*. The former is generally considered as a solid solution of carbon, or of the carbide Fe_3C, in iron in the allotropic condition in which the latter exists at a high temperature (above 875° C.). It is not a constituent of constant composition, and is seldom found in ordinary steels since it is rapidly transformed in cooling into an aggregate of ferrite and cementite. To obtain it highly carburized steel may be suddenly cooled from a temperature of 1000° C. or more by a bath such as ice cold water. It may also be obtained by slow cooling if the steel contains a considerable portion of manganese or nickel. Martensite is generally believed to be an early stage in the transformation of austenite.

Phosphorus and Sulphur. — The common injurious impurities in carbon steel are phosphorus and sulphur, both of which cause brittleness and should be allowed only in small quantities. Specifications (*see section below on this topic*) frequently forbid more than 0.05 per cent of sulphur and 0.04 per cent of phosphorus. Other impurities commonly occuring in small quantities in steel are silicon and manganese, which in small quantities help to reduce blow holes by their deoxidizing action. These elements while often present in higher percentages than the carbon have comparatively little influence upon the strength of ordinary carbon steel.

Composition of Low-carbon Steel. — Low-carbon steel consists chiefly of a mass of ferrite with pearlite occuring at the junction of the grains of ferrite, the percentage of the former decreasing in medium and hard steels until in steel having 0.8 per cent to 0.9 per cent carbon, it disappears entirely, the steel then consisting exclusively of pearlite. In still higher carbon steels some of the pearlite is replaced by free cementite, the substance which gives steel its hardening property.

Strength and Weight of Carbon Steel. — The tensile strength of steel varies with its composition. For ordinary carbon structural steel the working values given in the following table may be adopted with safety:

Digitized by Google

Nature of stress	Working strength, pounds per square inch
Tension on net section, and extreme fiber stress in bending	16,000
Compression in columns*	$16{,}000 - \frac{70\,l}{r}$, with a maximum of 14,000
Shear on net section of plate-girder webs and on machine-driven shop rivets	12,000
Bending on extreme fiber of pins	24,000
Bearing on pins and shop-driven rivets	24,000
Bearing on hand-driven rivets	18,000
Shear on hand-driven rivets	9,000
Modulus of elasticity	28,000,000 lb. per sq. in.

* In the expression for compression in columns, $\frac{l}{r}$ = maximum value of ratio of the unsupported length of column to radius of gyration, both values being expressed in inches. This ratio should be restricted by the form of the column so that it will not exceed 100 for main members and 120 for lateral and other secondary members.

Steel weighs approximately 490 lb. per cu. ft., or 2 per cent more than wrought iron.

ifications for Structural Steel and Steel Castings. — The American for Testing Materials has adopted standard specifications for steel to in various classes of structures. (*See A.S.T.M. Standards.*) Among s covered are the chemical and physical properties of the material, the ns and methods of tensile and bend tests and the permissible variation t and gauge. The preceding tables give the requirements as to chemical ion and tensile properties as given in the Society's specifications for al steel for bridges and ordinary steel castings (*A.S.T.M. Standards,*

CIAL OR ALLOY STEELS. — The more usual forms of special d their uses, composition and general characteristics are as follows:

el Steel. — Steel containing a considerable percentage of nickel, but not more than 3½ per cent, is called nickel steel. This steel has a strength and a higher elastic limit than carbon steel, and practically the odulus of elasticity; it is more ductile in proportion to its strength and at harder than carbon steel of like properties, it is more expensive be- the cost of the nickel, and the additional cost of working. Nickel steel used considerably in recent years for bridges of large size, for steamer utomobile parts, etc.

Steel. — This is a nickel steel containing about 36 per cent of nickel. icient of expansion is practically zero. It is used in making steel tapes line measurements in geodetic surveying.

ganese Steel. — The steel commonly known as manganese steel con- m 12 per cent to 13 per cent of manganese and generally from 1.25 per 2.00 per cent of carbon for castings; for forgings or rolled steel, less s used. It is austenitic in composition and is very hard without brittle- king it well fitted for railroad frogs, railroad rails or curves and burglar- fes. It is adapted principally to parts that can be cast, since working ools is practically impossible and forging is difficult. It is not used for al work as its elastic limit is so low as to offset the advantage of its rength. Like nickel, the manganese interferes with the transformation nite to pearlite during cooling. It is often called "Hadfield" steel from e of its inventor.

ne Steels. — Steels containing from 1 per cent to 2 per cent of chromium hard and have a high elastic limit. They are well adapted for armor- projectiles, steel balls, files and automobile gears. Krupp armor plate contain 3.25 per cent nickel, 1.5 per cent chromium and 0.25 per cent

dium Steels. — The addition to steel of a small amount of vanadium, less than 0.3 per cent, adds greatly to the elastic limit, ductility and e. Vanadium is especially advantageous in increasing strength, tough- l temper of nickel and chromium steels. This steel is particularly use- springs, axles and automobile parts.

on Steels. — The only silicon steels in use contain less than 5 per cent n. The alloy recommended by Hadfield, its patentor, contains 2.75 per con with the smallest possible amounts of carbon, manganese and other es. Such steel has a greater magnetic permeability than the purest d also a high electrical resistance. Its magnetic hysteresis is low. It uable material for use in electromagnetic and in electrical generating ry. See *Magnetic Properties of Iron.*

sten Steels. — These steels have the property of becoming martensitic eating to a high temperature and air cooling and are said to be "self-

Digitized by Google

hardening." Such steels are used for springs, magnets and with manganese added for self-hardening tools. See also *High-speed Steels and Magnetic Steels, below.*

Self-hardening Steels. — Steel which is hard without tempering and cannot be annealed by known processes is called self-hardening steel. All such steels are non-magnetic. Any steel which is in an austenitic condition at atmospheric temperature is self-hardening. (*See Mushet Steel, below.*)

Ternary and Quartenary Steels. — These are steels consisting of three or four essential components, viz., iron, carbon and one or two alloys. Some of the more important ternary steels are nickel steel, manganese steel, chrome steel, tungsten steel and silicon steel. Among quartenary steels are nickel-chromium, nickel-manganese, nickel-vanadium, tungsten-chromium, etc. The effect of these various alloys upon carbon steels is very striking and the possibilities are very great.

Chrome-nickel Steel. — The chrome-nickel steels in use are pearlitic and contain moderate amounts of carbon, nickel and chromium. Such steel has a high elastic limit combined with high ductility and has greater hardness, resilience and wearing power than carbon steels. It is used in automobile construction and for the manufacture of armor plate.

Chrome-tungsten Steel. — Tungsten and chromium have the property of producing a finely martensitic structure in steel when heated to a high temperature and cooled in air. The martensite in this case is so stable that the steel may be heated to a red heat without losing hardness. Such steels are known as "high speed steels" (q.v.).

High-speed Steels. — These steels have a finely martensitic structure which is stable up to red heat. They may contain from 0.25 per cent to 1.00 per cent of carbon, from 5 per cent to 25 per cent tungsten, 2 per cent to 10 per cent of chromium and seldom over 0.40 per cent of manganese. Tungsten may be replaced wholly or in part by molybdenum. Steels of this character are of great importance in machine work as tools made from them can be driven without injury until the cutting edge is red hot.

Mushet Steel. — This steel contains both tungsten and manganese. It is a self-hardening steel and has been used for many years for tools which make very heavy or deep cuts such as is required for armor plates. The speed allowable is a little greater than for carbon steel, but it lasts a long time without grinding.

Magnetic Steels. — Steels containing 4 per cent to 5 per cent of tungsten and from 0.5 per cent to 0.7 per cent of carbon if heated to red heat and quenched in water will retain their magnetism better than carbon steel. The addition of chromium increases the permanency but decreases the magnetic force.

STEEL MILLS, ELECTRIC DRIVE OF.—(*See also Flywheels for Load Equalization; Motors, Industrial Applications of.*) The application of electric motors to steel mill service may be divided in two general classes; 1. that dealing with the application of motor drive to the main rolls, that is to those rolls in which the ingot or billet is reduced in section, and 2. that dealing with the problems of electrifying the numerous other auxiliary machines and devices, such as tables, screw-downs, charging machines, etc.

MAIN-ROLL APPLICATION.—The term "mill" is sometimes used to designate a single stand or group of stands, and sometimes to include the main rolls and all auxiliaries involved in the production of a given class of materials. The stands are generally classified according to the arrangement of rolls and method of operation, that is two-high or three-high, the two-high being either reversing or non-reversing, see Fig. 1.

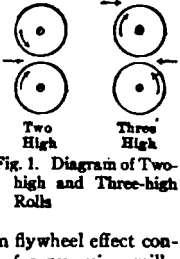

Fig. 1. Diagram of Two-high and Three-high Rolls

Reversing and Non-reversing Mills.—The great majority of rolling mills in this country are of the non-reversing type where the rolls run continuously in one direction. Flywheels are used to equalize the input to the motor. The ideal combination would be to use a motor of sufficient capacity to carry the average load and a flywheel which would take care of all the peaks. Such a wheel would be too large and a compromise between the motor and flywheel must generally be made. As opposed to the heavy flywheel effect required by the two-high or three-high non-reversing mill, the minimum flywheel effect consistent with the necessary speed and torque is desirable for reversing mills. In order to avoid the reflection of peak loads of these motors back upon the system, it is customary to interpose a flywheel motor-generator set with one or more generators between the power station and the mill. In order to minimize the flywheel effect of the reversing motor, two or more direct-current motors are often mounted on the same shaft and their armatures connected in series. This arrangement renders possible the use of smaller armature diameters with consequent reduction of acceleration losses and also permits the use of a high-voltage generator on the flywheel set. The mill motor is separately excited and perfect speed control is obtained by varying the excitation of the generator on the flywheel set. Direct-current generators can be designed for 2400 volts to give excellent results when operating two 1200-volt motors in series.

Power Required.—Rolling mill loads are irregular in the extreme due to the intermittent character of the process. For any particular ingot the motor load consists of periods of heavy duty increasing in length with the length of the metal in the pass, interspersed with periods of friction load only. With a given mill the load varies widely with the difference in the section rolled, differences in temperatures of metal, personal equation of the operator, etc. The practical determination of the power required to roll steel is a matter of elaborate and extensive tests under widely varying conditions. For methods and results see papers in *Bibliography*. The information for predetermining the sizes of motor and flywheel for an installation must cover the following points:

Type of mill; rail, plate, etc.	Time between passes.
Diameter and speed of rolls.	Elongation in each pass and total.
Weight of ingot.	Initial length.
Initial and final section.	Average and maximum rate of rolling.
Number of passes.	Temperature of metal.

Google

Load Curves. — From these data and a thorough understanding of the many variable factors encountered in steel-mill practice, it is possible to lay out load curves similar to the ones shown in Figs. 2, 3 and 4. From such curves it is then possible to determine the proper size of the motor and the flywheel.

The typical curve shown in Fig. 2 represents a load curve calculated for a two-high single-stand reversing blooming mill in which a 3000-pound ingot is reduced from initial to final section in eleven consecutive passes occurring at 5-second intervals. This curve is characteristic of blooming mills, roughing mills, etc., which in general give the lowest load factor. The work done in horse-power seconds is indicated by the area under the curve. Fig. 3 is representative of a large and mixed class with medium load factor, such as small merchant mills, bar mills, sheet mills, etc. Fig. 4 shows a load factor so high as to be scarcely approximated except in merchant mills with a large number of stands working at full capacity.

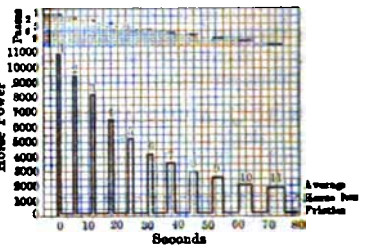

Fig. 2.

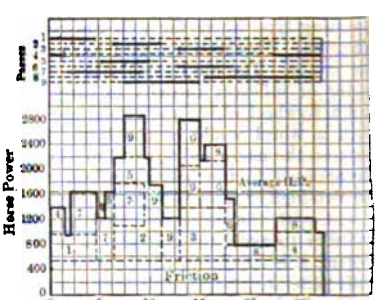

Fig. 3.

Fig. 4.

In determining the most suitable size of motor for the work indicated by the load curve full consideration must be given to the fact that excessive loads may be encountered at times due to the low temperatures of the metal in the pass, too heavy draft or other causes, and ample margin allowed. Assuming for the moment that by properly combining simultaneous passes on the several stands and the application of a suitable flywheel the load curve has been flattened out as much as appears possible, the question of continuity of service and duration of peaks must be considered to determine whether the limiting feature will be maximum torque or heating. With rolling-mill motors the limiting feature of design is usually torque rather than heating. The motor rating is determined by a consideration of the root-mean-square value of the current for a single cycle, and the frequency and duration of successive cycles.

Induction Motors. — The choice of alternating- or direct-current
main rolls must be determined by a careful consideration of several
ief of which are the capacity of individual units, constant, variable or
speeds, reversing or non-reversing, transmission distance, existing
ion equipment, etc.

eneral conceded that for large units and constant speed, constant-load
luction motors with phase-wound rotors possess many advantages over
ent motors. This is due to the ruggedness of construction and
of operation of the induction motor, and to the facility with which
current may be stepped up to any desired voltage, thus rendering the
f economic power distribution relatively simple.

se main-roll drives where it is essential that close regulation be main-
a large number of speeds, each constant under varying loads, a direct-
otor with shunt characteristics has until recently been practically
It is now possible to obtain these characteristics by using standard
motors with phase-wound rotors and speed regulating sets.

thod of obtaining speed control consists in replacing the non-inductive
esistance by a compensated commutator machine which may be
either on the shaft of the main motor, or more commonly as one
f a two-unit motor-generator set, in which latter case, the second
s a squirrel-cage induction motor. The speed of the motor driving
ay be varied both above and below synchronism. When operating
chronism, the commutator machine acts as a motor and drives the
machine slightly above synchronism, thus returning to the line energy
al to the slip of the main motor minus the losses in the regulating set
hen the main motor is operated above synchronism, the induction
cts as a motor and drives the commutator machine as a generator
vers power to the slip-ring circuit of the mill motor.

Equipment for Induction Motors. — The control for large steel
s is important because of the size of the apparatus involved and the
mportance of continuous operation. Most motors for main-roll drive
l up at the beginning of a shift, immediately brought up to full speed,
nning until the end of the shift. Provision must be made for running
ne at reduced speed when desired, for making adjustments to the mill,
versing, in order to back out ingots which have stuck in the mill. If
is used, there should also be provision for quick stopping, so that if a
broken, the motor can be brought to rest quickly and a new spindle
d without delay. Current-limiting relays are desirable in order to
re fluctuations in input during starting and to maintain an approxi-
en torque without depending upon the intelligence of the operator,
service magnetically-operated contactors are necessary. It is always
to have some device by which the motor can be shut down from a
int in case of accident.

sistors for Starting Rheostats. — The resistance should be liberal,
he control may often be held on the first point for some time when
nts are being made and the starting torque may sometimes be heavy,
ly when an ingot has stuck in the rolls. Also, where a flywheel is
acceleration is necessarily slow, and some mills, particularly cold rolls,
very heavy torque during starting and until they have warmed up.
es should always be furnished having at least enough capacity to pro-
ll-load torque for two minutes. In special cases more will be required.

ntactors and Oil Switches. — Where 440- or 550-volt alternating
used, contactors can be employed for both primary and secondary,
te control is an easy matter. 2200- or 6600-volt motors require oil

switches in the primary, which cannot be operated read
ing current. They can be operated with direct curre
the system and makes the operation of the alternating-
upon the direct-current supply. As remote control is
majority of cases, hand-operated oil switches can be us

Control Systems. — Figs. 5 and 6 show two
grams of double-range speed-regulating equipments. T
show the main mill motor when used with a speed regulating set. This set consists of an induction machine and a polyphase, commutator regulating machine with shunt-field excitation. The slip rings of the main induction motor are connected to the shunt winding of this regulating machine so that its counter electromotive force opposes the voltage of the main motor. The slip-ring voltage of the induction motor follows the variation in counter electromotive force of the regulating machine produced by changes in its shunt excitation. The shunt characteristics of the regulating machine are reflected in the speed-torque characteristics of the induction motor which is similar to that of the well-known shunt direct-current motor. The slip energy o conserved by converting it through the induction g power and returning it to the power lines. Another arr the diagram) consists of mounting the polyphase reg main-roll shaft and thus convert this slip energy into m

-current Motors are used only on low-voltage circuits, usually 250 d can be handled by contactors. Quick stops can be accomplished . motors by dynamic braking, by which the armature is disconnected line and connected across a resistance so that the motor becomes a . Where flywheels are used, compound motors are necessary in order tomatic reduction in speed as the load increases.

cteristics of Gary Equipment. — The characteristics of the main- r equipment for the rail, billet, and sheet-bar mills of the Indiana npany, Gary, Indiana, are given in the table on page 1508.

IARY MOTOR APPLICATIONS.—The application of electric or auxiliary steel-mill machinery has been used for a long time. re of this service is unusually severe and has led to the development l-type motor for both d-c. and a-c. service. These motors are de- withstand heavy overloads and abnormally rapid acceleration, and truction is such that various parts are interchangeable, which greatly repairs and minimizes the delays incident to the same.

C. versus Mixed System. — Whether a-c. or d-c. motors should be driving the auxiliary machinery in a steel mill is a problem which has seriously discussed, and has led to the use of two recognized systems. known as the all a-c. system, where no direct current is used, and the tem, where both a-c. and d-c. motors are used.

many factors must be considered in comparing the two systems. In lace, it is to be assumed that power will primarily be alternating cur- e transmission distances ordinarily preclude the use of direct-current

ERS, MECHANICAL. — (*See also Boilers.*) Mechanical stokers wofold purpose: they make possible a more uniform and a more combustion of the fuel and thereby prevent the formation of smoke, and reduce the amount of labor required in handling and firing the fuel. e the prevention of smoke a fire-brick arch should also be used over part of the furnace.

S OF STOKERS. — There are three general types of mechanical lthough there are several which cannot be conveniently placed in any ese classes.

-grate Stoker. — The first is the chain-grate stoker consisting of an hain placed in the furnace of the boiler with its top side revolving om the front of the furnace toward the back. The coal is fed onto this rate in front and is burned as it passes toward the bridge wall, where, grate is moving at its proper speed, the coal will have been completely ash which will drop down into the ashpit below.

e great advantage of the chain-grate stoker over most of the others is suitable for burning with natural draft bituminous coals of very high ontent. In plants where the load is reasonably steady and where eaks are not thrown upon the boilers this stoker makes a first-class on.

d Overfeed Type. — The second type of stoker is the inclined type. These stokers consist of movable bars forming an inclined a mechanism for moving these bars in such a manner as to cause the h is fed in at the top to be pushed gradually down the grates until it e dumping grate at the bottom, at which point it should be completely

feed Type. — The third type is the underfeed. In these stokers the onto the grate or up under the grate in such a manner that the fresh ways close to the grate while the coal which is being burned is at the air is also introduced at the bottom and while passing up through f coal is heated and thoroughly mixed with the volatile gases distilled coal and when passing through the incandescent layer at the top s temperature of combustion, so that generally no arches are neces-

Types. — There are several other stokers which are used to a greater extent and work on somewhat different principles, perhaps the most ing the so-called "finger" stoker, which has several oscillating paddles k up the coal and throw it into the furnace. There is another stoker of this order in which the coal is mechanically shovelled into the These stokers, however, have not reached any extensive application in general are only applicable to particular conditions.

G BY USE OF MECHANICAL STOKERS. — The difference ood and bad firing may easily amount to from 5 to 20 per cent of the fuel fired; hence, there is no investment around a steam plant which etter than the extra amount paid to secure good boiler practice.

tic stokers are now developed to a remarkable degree of perfection, suited to the fuel, have an advantage over hand-firing in that under ons they are reliable, can be adjusted to the minimum of the air and ium of load, and can be depended upon to operate continuously with ium amount of skilled labor. The economic saving will depend on f comparison and the method of operation. Compared with an ordi- or fireman, they should show a large saving. Whether a stoker will

save labor in the fire room depends upon the size of

STRENGTH AND ELASTICITY. — (*See also Buildings, Allowable Unit Stresses in; Mechanics, Principles of; Structures, Simple.*) When opposing external forces are applied to a body the latter is in general deformed more or less, and, in the case of solids, when the applied forces are increased sufficiently the body ruptures.

STRESSES. — A stress is the internal resisting force set up within a body opposing the external forces which tend to deform it. When the external forces cause a stretching of the body the stress is called a tension; when the external forces compress the body the stress is called a compression; when the external forces cause a relative slipping of the particles in two contiguous parallel planes in the body the stress is called a shear.

Unit Stress. — By unit stress is meant the stress per unit area; in the case of tension or compression the area is taken perpendicular to the line of action of the forces producing the stress; in the case of shear the area is taken parallel to the forces producing the stress. Unless otherwise stated the stress is assumed uniformly distributed over the area upon which it acts.

Ultimate Stress or Ultimate Strength. — The ultimate stress which a body will stand, or the ultimate strength of the body, is the greatest stress which can be produced in the body without rupturing it. Ultimate strength for tension and compression are usually quite different; the former is usually called tensile strength and the latter compressional strength. The ultimate strength of materials is usually specified in terms of the stress per unit area; see *Units and Conversion Factors*.

DEFORMATIONS OR STRAINS. — The deformation accompanying any stress is usually called a strain. The strain corresponding to a tension is called an elongation, the strain corresponding to a compression is a shortening, the strain corresponding to a shear is called a detrusion. An elongation is usually specified as the ratio (or percentage) of the increase in length to the original length of the specimen. For example, if a rod 10 feet long is stretched by an applied force to a length of 10.2 feet, the elongation is $(10.2-10)/10 = 0.02$ or 2 per cent. The term elongation is frequently used to designate specifically the *maximum* elongation just before rupture.

Hooke's Law. — Experiment shows that when the unit stress in a body does not exceed a certain value it bears a constant ratio to the resulting unit strain (ratio of change in size to original size). This fact is known as Hooke's Law. In the case of a tension the change in size is usually taken as the change in length, no attention being paid to the decrease in cross-section, which is usually negligible, except just before rupture.

ELASTICITY. — A body deformed under stress will return to its original shape when the stress is removed, provided it has not been strained beyond the point at which the proportionality between stress and strain ceases. This ability to return to its original form after deformation is called elasticity.

Elastic Limit. — The stress per unit area corresponding to the point at which the proportionality between stress and strain ceases is called the elastic limit of the material.

Permanent Set. — When a body is stressed beyond its elastic limit, the deformation per unit increase in stress becomes greater than it was before this point was reached, and the material takes a permanent "set," i.e., when the stress is removed the body does not return to exactly its original form. As a measure of the "set" is taken the ratio of the permanent change in size (after the stress is removed) to the original size.

Digitized by Google

Modulus of Elasticity. — Let ΔF denote the change in the total tension producing a change Δl in a rod of length l and cross section A; then the quotient of the increase in the unit stress by the increase in the elongation per unit length, is called the modulus of elasticity (Young's modulus) of the material, and may be designated by the symbol M, i.e.,

$$M = \frac{\Delta F}{\Delta l} \cdot \frac{l}{A}.$$

This modulus has the dimensions of pounds per square inch.

VALUES OF TENSILE STRENGTH AND MODULUS OF ELASTICITY. — Values of these properties given by different authorities are extremely variable, since the measured values depend largely upon the chemical composition, heat treatment, age, size and shape of the test specimen.

Alloys, Miscellaneous. — See articles on *Alloys* and *Wires, Resistance.*

Aluminum. — See article on *Aluminum.*

Belting. — Tensile strength, in pounds per square inch: Cotton, 4500 to 8900; Single leather, 3200 to 5900; Double leather, 2200 to 5400. See also article on *Belts and Belting.*

Brass Wire. — Tensile strength ranges from about 50,000 to 150,000 pounds per square inch; modulus of elasticity is about 14×10^6 pounds per square inch.

Brick. — See article on *Bricks and Brick Masonry.*

Bronze Wire. — The tensile strength of phosphor-bronze wire ranges from about 44,000 to 140,000 pounds per square inch; of silicon-bronze wire, from 95,000 to 115,000 pounds per square inch.

Cement. — See article on *Cement.*

Concrete. — See article on *Concrete.*

Copper. — See articles on *Copper* and *Wires and Cables, Bare.*

Earth. — See *Soils*, below.

Glass. — Tensile strength of common green or of flint glass ranges from about 2500 to 5000 pounds per square inch. Modulus of elasticity ranges from about 8.5×10^6 to 11.5×10^6.

The crushing or compressive strength of glass ranges from about 13,000 to 40,000 pounds per square inch.

Granite. — Crushing or compressive strength ranges from about 9700 to 34,000 pounds per square inch.

Iron. — See articles on *Iron, Pig and Cast*, and *Iron, Wrought.*

Lead. — Tensile strength ranges from about 2600 to 3300 pounds per square inch.

Limestone. — Crushing or compressive strength ranges from about 6000 to 25,000 pounds per square inch.

Marble. — Crushing or compressive strength ranges from about 7500 to 21,000 pounds per square inch.

Nickel. — Tensile strength of cast nickel ranges from about 40,000 to 85,000 pounds per square inch, and tensile strength of annealed nickel ranges from about 70,000 to 95,000 pounds per square inch. Modulus of elasticity ranges from about 24×10^6 to 27×10^6 pounds per square inch.

Rope. — See *Ropes and Rope Drive.*

Soils. — See articles on *Power Stations, Hydroelectric*, and *Buildings, Allowable Unit Stresses in.*

Digitized by Google

Steel. — Tensile strength in pounds per square inch:

Bessemer: 56,000 to 74,000, Open-hearth: 50,00
Cast: 67,000 to 106,000, Wire: 50,00

Modulus of elasticity of various kinds of steels usually
and 35×10^6 pounds per square inch. See also articles
Cables, Bare.

Timber. — See articles on *Timber* and *Poles for Overh*

Tin. — Tensile strength ranges from about 4000 to
inch; modulus of elasticity from about 2.5×10^6 to $6 \times$
inch.

Zinc. — Tensile strength ranges from about 7000
square inch; modulus of elasticity is about 12×10^6 pou

Wood. — See *Timber*, above.

ITIONS AND FUNDAMENTAL RELATIONS. — The more erms used in the treatment of structures are defined below.

of Gravity; Moment of Inertia; Radius of Gyration; Stress and See *Mechanics, Principles of.*

Axis. — The neutral axis of the cross-section of a stressed bar is of those points in the plane of the cross-section at which the direct equals zero. If the bar is of homogeneous material and subjected (*see Bending Moment, below*) only, the neutral axis passes through of gravity of the cross-section, and if the loads causing flexure are the plane of one of the principal axes, the neutral axis coincides with principal axis. This is the condition commonly occurring in wooden eams. Table I which follows gives the location of the neutral axis for only. If the cross-section is subjected to combined flexure and direct neutral axis will not pass through its center of gravity, but will deviate an amount depending upon the ratio of bending moment to direct hing infinity when the stress is direct tension or compression only, se of a tie rod or column centrally loaded.
eam is of unhomogeneous material the position of the neutral axis termined by calculation. The reinforced concrete beam is the only xample of such a case. For formulas for this case, see *Concrete,*

Modulus. — If c is the normal distance from the neutral axis of a surface to the most remote portion of its perimeter, and I the mo- rtia of the surface about its neutral axis the expression I/c is called the dulus. For symmetrical beams exposed to pure flexure only, c = one- th of the beam. Tabular values of this quantity for plane surfaces of apes are given in Table I and for the ordinary structural steel beams II to VI, which follow.

of Resistance. — If s is the allowable unit stress per square inch treme fiber of a beam or girder, the expression $\frac{sI}{c}$ is called the moment since its value equals the maximum bending moment which the mem- rry without causing a stress greater than the allowable unit stress.

Moment. — The statical moment of a plane surface about a given the plane is the summation of the products of each elementary area,

Google

dA, of which the surface is composed, times the distanc from the given axis, distances above the axis being c below negative. It may be expressed mathematically follows: (See Fig. 1.)

Let Q = statical moment of a given area about an a Y-Y lying in the plane of the area,
dA = an elementary area,
y = distance of center of gravity of the area from the axis,

then $Q = \int y dA$.

The statical moment of an area about an axis of syn zero since the positive lever arm of any elementary are corresponding negative lever arm.

Equations of Equilibrium. — (*See also Mechanic* following laws apply to a structure lying in a plane an lying in the same plane:

1st. The algebraic sum of the components of all th to any axis in the plane of the forces must equ
2nd. The algebraic sum of the moments of all the f right angles to the plane of the forces must equ

If we resolve the applied forces into components par axes, OX and OY, and let ΣX and ΣY equal the alge parallel respectively to OX and OY, and ΣM the algebr about any axis, normal to the plane of the forces, thes comprehended by the three equations:

$$\Sigma X = 0,\ \Sigma Y = 0,\ \Sigma M = 0.$$

If OX and OY are respectively horizontal and vertical generally used form:

$$\Sigma H = 0,\ \Sigma V = 0,\ \Sigma M = 0.$$

Unless a structure satisfies all these conditions it can

Reactions. — The forces which the abutments or pie such as beams, girders or trusses, are called the reactio in general, have three unknown factors, viz., directio of application. In order to simplify computations it is trusses to eliminate three of these unknowns by the meth in end-supported trusses and long girders, the ends are u of comparatively small diameter thereby fixing the poin reactions. Moreover, the pin at one end is in turn sup thereby making that reaction normal, or nearly so, to its fixing the direction of one of the reactions. These refin applied to short girders the ends of which are supporte ings. Even in such cases, however, the point of ap comparatively small limits, and the base plate at on thus making the reaction at that end approximately n surface. For ordinary beams no special provision is reaction conditions but each reaction is assumed to be n surface and to act at its center.

When the unknown reaction factors are thus reduc may be determined by the three equations of equilibriu being the usual procedure in the case of beams on tw later. For beams supported at more than two points, tion (*see below*) may be applied.

Digitized by Google

Moment Equation. — This is an equation connecting the moments adjoining points of support of a continuous structure. It is strictly le only to structures having a constant moment of inertia and on level but is applied approximately to structures the moment of inertia of not constant.

ormula for concentrated loads is as follows:

M_c = moment at any support,
M_a = moment at adjoining support on left,
M_b = moment at adjoining support on right,
L_1 = length of span to left of support at which M_c acts,
L_2 = length of span to right of support at which M_c acts,
P_1 = any load in span L_1 and k_1L_1 its distance from left support,
P_2 = any load in span L_2 and k_2L_2 its distance from support at left of that span.

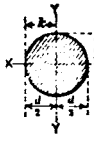
$$M_a L_1 + 2 M_c(L_1 + L_2) + M_b L_2 = \Sigma P_1 L_1^2(k_1^3 - k_1) + \Sigma P_2 L_2^2 (3 k_2^2 - k_2^3 - 2 k_2).$$

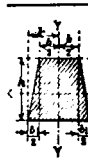
iform load of w_1 lb. per ft. over span L_1 and w_2 lb. per ft. over span L_2 ding formula becomes

$$M_a L_1 + 2 M_c(L_1 + L_2) + M_b L_2 = -\frac{1}{4} w_1 L_1^3 - \frac{1}{4} w_2 L_2^3.$$

pplication of these formulas to successive series of spans enables the at all supports to be computed and from these the reactions and shears be determined, and the structure completely solved; see section below *s, Design of.*

. — The shearing force or shear at any section of a body is the force nds to produce slipping along the given section. Shearing failure ue either to transverse fracture or to slipping of the fibers on each other. rdinary structural materials wood is the only one of fibrous character ring failure in this material frequently occurs on planes parallel to the





ng Moment; Flexure. — The bending moment at any section of a e to a set of coplanar forces is the resultant moment about an axis hrough the center of gravity of the section of all the forces on either e section, it being understood that the section and the axis are perpen- o the plane of the forces. Fractures due to excessive bending moment rough longitudinal failure of the fibers either by tension or crushing. ling which results from the application of a bending moment is termed

and Live Loads. — The loads acting upon a given structure may be nto two distinct types: viz., quiescent loads which are known as *dead* l moving or intermittent loads which are known as *live loads*. The includes all loads which are fixed in magnitude and position such as nt of the structure itself and such superimposed loads as the floor of g or bridge; the second class includes such loads as crowds of people, dise, snow, wind and vehicles of all sorts. The live load through its and irregularity of application is more injurious in its effect than the d, hence in a structure subjected to live loads, either the value of the should be increased as explained below under *Allowances for Impact*, lowable unit stress in the material should be reduced. The former eems to be more logical and is commonly adopted at the present time g structural engineers.

Impact is the name given to the dynamic force which is added to the forces due to live and dead loads to obtain the true forces acting upon structures; see section below on *Allowances for Impact*.

Beam or Girder. — A beam is a bar of wood, metal, concrete or other stress-resisting substance supported at certain definite points along its length and loaded transversely to its longitudinal axis, which is usually but not always placed in a horizontal position. The name girder is commonly applied to large beams built up of structural members; for example, a plate girder is a steel or iron structure made up of plates and angles, or other structural shapes, riveted together.

Floor Beam; Panel.—Frequently girders and trusses receive all their live load and much of their dead load through other members called floor beams. Fig. 1 illustrates such construction. The distance between adjacent floor beams is the panel length.

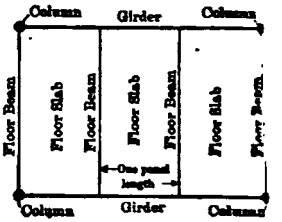

Fig. 2.

Column. — A column is a member intended primarily to resist direct compression, although it may also be subjected to bending stresses due either to transverse loads or to eccentric application of the direct loads.

Truss. — A truss is a structure consisting of separate bars constructed to carry either direct tension or direct compression. These bars are connected at their ends and occasionally at intermediate points, the points of connection being called joints. The connections are sometimes made by riveting the bars directly together and sometimes by riveting them to a common steel plate, the truss in either case being called a *riveted truss*. The connections may also be made by fastening together with a large steel pin all the members meeting at a joint; such a truss is called a *pin truss*. The outer forces should be applied at the joints only, since the members are not intended to carry bending. This is accomplished by the use of floor beams in a bridge and purlins in a roof.

PROPERTIES OF PLANE SECTIONS. — In Table I are given the location of the center of gravity, and values of the moment of inertia, section modulus and radii of gyration of the more common plane sections.

From *Cambria Steel*, George E. Thackray, Engineer, 1919.

* Divide by span in feet to determine total allowable dead load in pounds, including weight of beam, uniformly distributed over length of beam. Table is based upon a fiber stress of 16,000 lb. per sq. in. For allowable live and dead load reduce load as determined from table by amount of impact. Compression flange should be supported laterally at intervals not greater than 20 times its width. If this cannot be done reduce coefficients to one-half of above value where unsupported length divided by width = 70, and proportionally for intermediate values between 20 and 70.

(a) Weights revised Sept. 1, 1920.

(a) Weights revised Sept. 1, 1920.

rmined since it depends upon such uncertain factors as rapidity of ap- irregularity of track, improper counterbalancing of locomotive driving raying action of crowds of people and similar causes. The allowance t (so-called) ranges from 0 to 100 per cent of the live load and is d by empirical rules as indicated in the formulas below. An excep- is rule is made in the case of timber structures where the effect of commonly allowed for by using a low unit stress. (*See Timber.*)

on Buildings. — No allowance is generally made for impact on except with special loadings such as moving machinery, swinging ., for which the designer should use his judgment. The building laws er cities fix arbitrary loads and unit stresses by which the designer overned; see article on *Buildings, Allowable Unit Stresses in.*

on Highway Bridges Carrying Electric Railways. — The fol- ract from the *Specifications for Bridges Carrying Electric Railways* the Massachusetts Public Service Commission (revised March, 1915), fely used for such cases:

tal maximum stress in any piece shall be computed by adding together nd live stresses, the live loads being placed in the most unfavorable ogether with a percentage of the live stress to allow for impact and This added percentage shall be as follows:

truck.

ringers, floor beams hangers and truss members receiv- their whole load from one panel point only ..... 50 per cent

ther live loads:

ood flooring and wood stringers..... no impact
or beams and stringers..... 25 per cent
or beam hangers..... 40 per cent
l counters..... 40 per cent

members in trusses, and for main girders, the percentage shall be one-twelfth the loaded length in feet with a maximum of 25 and a f 10 per cent."

on Steam Railroad Bridges. — The following rule of the American ngineering and Maintenance of Way Association is commonly used ed States:

namic increment of the live load shall be added to the maximum com- oad strains* and shall be determined by the formula $I = S\frac{300}{L+300}$,

ere I = impact or dynamic increment to be added to live-load strains,
S = computed maximum live-load strain,
L = loaded length of track in feet producing the maximum strain in the member.

es carrying more than one track, the *aggregate length of all tracks* he strain shall be used. Impact shall not be added to strains pro- ngitudinal, centrifugal and lateral or wind forces."

ATION OF REACTIONS. — The reactions upon a truss, girder ng in a plane and acted upon by forces lying in the same plane may ed by the application of the equations of equilibrium (*see preceding* vided there are but two reactions which together have three unknown ; such a structure is said to be statically determined. If more than wn reaction components exist the reactions cannot be computed by the structure, although stable, is statically undetermined; if less than

* as here used means stresses in the more modern meaning of the words.

Digitized by Google

three exist the structure is unstable. If the structure is supported at more than two points it cannot be made statically determined except by the insertion in the structure of special devices, such as hinged joints. The tower shown in Fig. 3 is statically determined with respect to the outer forces since the points of application of the reactions at *a* and *b* are fixed in position, and the reaction at *b* is also fixed in direction. If neither of the reactions were fixed in direction the structure would be indeterminate; if both of the reactions were fixed in direction the tower would be unstable, e.g., if both ends were on rollers and neither end bolted to the masonry.

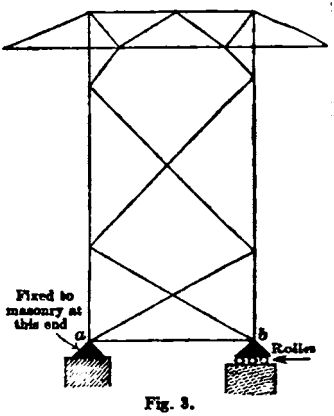

Fig. 3.

Such towers when used for transmission lines are seldom built with rollers or even planed plates, and frequently the bottoms of the columns are imbedded in a concrete base, the latter condition making it impossible to accurately compute the reactions. Similar towers for railroad and highway bridges are usually made determinate.

Method of Computation. — The following example illustrates the analytical method of computing reactions on statically determinate structures. The method may be applied equally well to uniformly distributed loads provided the resultants of such loads are used in place of concentrated loads.

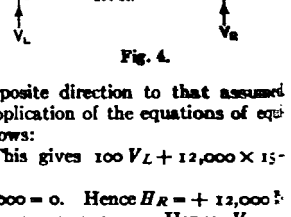

Fig. 4.

To Compute the Reactions on Truss Shown in Fig. 4. — Let V_L = left reaction, and V_R and H_R = the components of the right reaction, the direction of which is unknown. V_L will be vertical since it is supported on rollers bearing on a horizontal surface. V_R and V_H may be assumed to act in either direction. A negative sign in the final result indicates that the force acts in the opposite direction to that assumed. The determination of the reactions by the application of the equations of equilibrium (*see above*) may be carried out as follows:

1st. Apply $\Sigma M = 0$ about right end. This gives $100\,V_L + 12{,}000 \times 15 - 20{,}000 \times 75 = 0$. Hence $V_L = 13{,}200$ lb.

2nd. Apply $\Sigma H = 0$. This gives $H_R - 12{,}000 = 0$. Hence $H_R = +12{,}000$ lb.

3rd. Apply $\Sigma V = 0$. This gives $V_R + 13{,}200 - 20{,}000 = 0$. Hence $V_R = -6800$ lb.

In these results a positive sign shows that the reaction acts as indicated in Fig. 4.

Reactions on Continuous Girders. — See sections which follow on *Continuous Girders, Beams, Slabs* and *Trusses*.

CALCULATION OF SHEAR. — The nomenclature used in the discussion of shear is as follows:

V = the total external shear on any section in pounds,

P = magnitude of a single concentrated load in pounds,

Digitized by Google

= a uniform load in pounds per foot,
= span of beam in feet (distance center to center of supports),
= length of a panel in feet,
= distance in feet from a given section to one of the points of support,
= total number of equal panels into which a girder is divided,
= number of panels between a given panel and the more remote abutment.

of Computation. — The magnitude of the shear at any section of to a set of coplanar forces may be readily computed in the following Resolve each force into nents, parallel and per- respectively to the on; the algebraic sum ponents parallel to the all the forces on either he section equals the he shear is generally positive when the re- ce is *upward* on the *left* on.

of Shear. — A curve a line the ordinate to any point equals the the given body at the here the ordinate is Fig. 5 shows typical his sort.

m Shear with Single Uniform Load. — In a supported beam, girder oncentrated load causes shear at a given section d an infinitesimal dis- the section on the side more distant point of he magnitude of this ls that of the nearer A concentrated load aximum shear on the placed an infinitesimal one side of either point this shear equals the of the load itself. A distributed live load imum shear at a given n placed over the entire om the section to the t point of support; its s that of the nearer re- s given by the equation . Its maximum value equals $wL/2$ at either end of the beam when fully loaded.

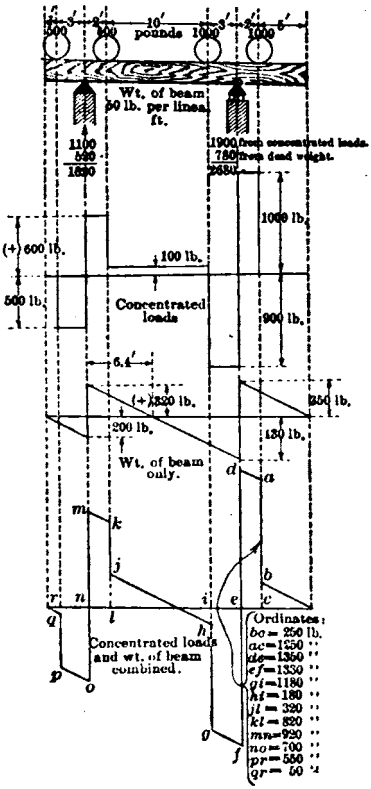

Fig. 5. Curves of Shear. Positive results are shown above the axis. Curve shown by full line

-supported Girders or Trusses with Loads Applied by Floor- A concentrated load causes maximum shear in any panel when

Digitized by Google

placed at the end of the panel nearer the more remote reaction. The value is equal panels is given by the equation $V = Ps/n$. The maximum shear occurs in the end panel and its value for equal panels is $V = P\ (n-1)/n$.

Maximum positive shear in any panel due to uniform load occurs when all panel points to the right are assumed to be loaded with full panel loads, and all panel points to the left are unloaded; its value equals the left reaction. This method is approximate but is on the safe side and is commonly used.

The maximum positive shear occurs in the left panel and for girders with equal panels is given by the formula:

$$V = \frac{wp}{2}(n-1).$$

The same rules are applicable for the maximum negative shear by interchanging left and right in the discussion.

Computation of Maximum Shear for System of Concentrated Loads. — The shear at any section of a beam, girder or truss, due to a system of concentrated loads such as wheel loads of a moving crane, electric car or electric locomotive, equals the algebraic sum of either reaction and the loads lying between that reaction and the given section. In case the girder is divided into panels and the shear in a given panel is to be computed, only that portion of the load acting in the panel under consideration which is carried by the floor-beam at the end of the panel nearer the selected reaction should be deducted from the reaction. To determine the position in which a system of concentrated loads should lie to give maximum shear it is often necessary to proceed by trial. The use of the following simple rules may be helpful.

(*a*) The maximum shear at a given section of a simple beam always occurs with one of the loads at an infinitesimal distance to one side of the section. This load should usually, but not always, be one of the heavier loads of the system; e.g. one of the driving wheels of a locomotive. The proper load may be determined by starting with the first load just to the left of the section and moving the loads to the left until $\sum \frac{Pa}{L} \leq P'$. In this expression P = any load which may be on the span during the process of moving the loads, and a is the distance which it is moved. P' = the load which passes to the left of the section as the loads are moved from one position to another.

(*b*) The maximum shear in a given panel of a girder always occurs with one of the loads directly over one of the adjoining floor-beams. This load should usually, but not always, be one of the heavier loads.

(*c*) The position of the loads for maximum positive shear in an intermediate panel may be determined as follows. Place the first load of the system at the right end of the panel and move the system to the left until $\sum \frac{Pa}{L} \leq \sum \frac{P_1 a_1}{p}$. Apply the same criterion to the second load and following loads until the position giving maximum shear is reached. In the above expression, P and a are as before, P_1 = any load which may be at any time in the panel under consideration during the process of moving the loads, and a_1 = the distance which P_1 may move in the panel.

If no load comes on or goes off the span and if no load passes out of the panel, $a = a_1$ and we may write

$$\sum \frac{P}{L} \leq \sum \frac{P_1}{p}.$$

It follows that for this case the first load should lie at the panel point unless the average load per foot on the entire span is greater than the first load divided by a panel length, in which case the second load should be tried at the panel point and so on until the position for maximum shear is determined.

e maximum shear in the end panel of a girder equals the maximum
at the first panel point divided by the length of the panel. (*See section
g Moment, below.*)

JLATION OF BENDING MOMENT. — The nomenclature used
scussion of bending moment is as follows:

= external bending moment at any section in foot pounds,
= magnitude of a single concentrated load in pounds,
= a uniform load in pounds per foot,
= span of beam in feet (distance center to center of support),
= length of a panel in feet,
= distance in feet from a given section to one of the supports,
= total number of equal panels into which a given girder is divided.

es its value:

$$\frac{P\,(L-x)}{L}\,x.$$

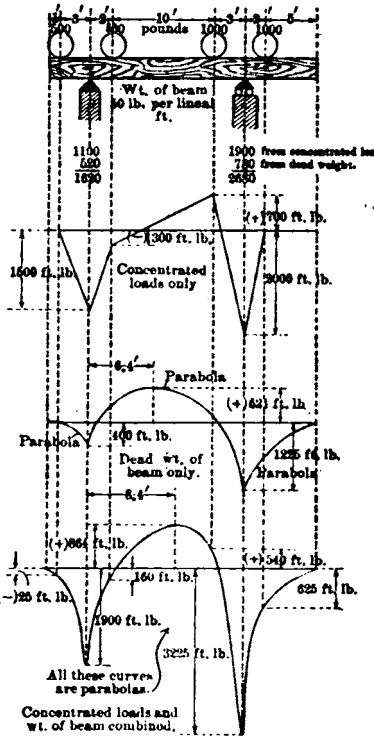

Fig. 6. Curves of Moments

um possible moment occurs when $x = L/2$ and has the value

e end-supported structures a uniform load causes maximum moment
on when it covers the entire beam. Its value at any section is

$$M = \frac{wx}{2}\,(L-x).$$

Digitized by Google

The maximum possible moment occurs at the center of the span and equa $wL^2/8$.

End-supported Girders or Trusses with Loads Applied by Floor-Beams. — Moments at panel points are exactly the same as moments at co responding points on simple girders. It is seldom necessary to consider moment between panel points for concentrated loads. For a uniform load the mom between floor-beams varies uniformly; i.e., the moment due to that portion the load applied through the floor-beams.

The maximum moment due to a concentrated load occurs at the panel poi nearest the center with the load at that point. Its value is given by the follo ing equations:

For even number of equal panels, $M = \frac{Pp_n}{4}$.

For odd number of equal panels, $M = \frac{Pp}{4n}(n^2-1)$.

The maximum moment due to a uniform load occurs at the panel point near the center with load over entire span. Its value is:

For even number of equal panels, $M = wL^2/8$.

For odd number of equal panels, $M = \frac{1}{8}\left[wL^2\left(1-\frac{1}{n^2}\right)\right]$.

Computation of Moment for System of Concentrated Loads. — Th moment at any section due to a system of concentrated loads, such as whe loads of a moving crane, electric car or electric locomotive equals the algebra sum of the moments of either reaction and the loads lying between it and th given section, the lever arm for each load being its distance from the sectio In case the girder is divided into panels and the section under consideratio is at some intermediate point in a panel only that portion of the load applied in this panel which is transmitted to the girder by the floor-beams between it and the reaction used should be considered.

Determination of Maximum Moment at a Given Section. — Th maximum moment at any section of a simple beam or at any panel point of a girder loaded through floor-beams always occurs with some load at the sectio (usually one of the heavier loads). This load should be one which when locate just to the right of the section makes the average load per foot of all the loa on the span to the right of the section greater than the corresponding averag load per foot on the left of the section, and which reverses this condition whe placed just to the left of the section. Such loads may be selected by trial; i more than one satisfies this criterion the largest moment must be determine by actual computation.

Determination of Position of Maximum Moment on a Beam. — Previous articles deal with maximum moment at a given section. The maxi mum moment on a beam caused by a system of concentrated loads usua occurs near the center but not at it. The following method may be used t determine the location of the section at which the maximum moment occu

(*a*) Select, by inspection, one of the heavier loads which would probably b located at the center to give the maximum moment at the center.

(*b*) Determine by inspection the loads which would be on the span when th load is near the center and compute the position of their resultant.

(*c*) Place the loads on the beam in a position such that the center of the spa lies half way between this resultant and the assumed load. If the loads on the span in this position correspond to those assumed under *b*, the moment at the load should be computed; otherwise, another trial may be made. If more

Digitized by Google

an one set of loads corresponds to this condition the moment at the load ould be computed for both sets of loads.

(*d*) Apply the same method to any other load which would possibly give aximum moment at the center.

Since the maximum moment at any section always occurs with some load at e section this method if applied to enough loads will give the absolute maximum oment. It is often unnecessary to try more than one load, and seldom more an two. It should be noted that with two equal loads such a distance apart at with one at the center the other will not be on the span, but that with the nter of the span midway between the resultant and one of the loads both will on the span, the maximum moment may possibly occur with either condition, th of which should be investigated.

BEAMS; FORMULAS AND COSTS. — The effect of the external forces on any cross-section of a simple beam is to cause bending moment and ear, the former usually being the predominant factor in determining the size the beam. If the beam is subjected to axial forces as well as transverse rces, it becomes a combination of beam and column, or beam and tie, and n no longer be considered as a simple beam. If a beam has an end which

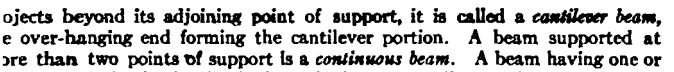

Fig. 7.

ojects beyond its adjoining point of support, it is called a *cantilever beam*, e over-hanging end forming the cantilever portion. A beam supported at ore than two points of support is a *continuous beam*. A beam having one or th ends rigidly fixed either by being built into a wall, or by being fastened to other member is called a *fixed ended beam*. Fig. 7 represents all of these types.

Beam Formulas for Ordinary Cases. — As a preliminary step in the design beams, it is necessary to determine the maximum value of the external bend- g moments, shears and reactions on the beam by the methods given in the ctions above which deal with these subjects inclusive. With these items de- rmined, the following formulas of mechanics (*see Mechanics of Materials, erriman, 10th Edition, Arts. 41 and 108*) may be employed for the design of ams of *symmetrical section* and *homogeneous material* loaded with *transverse loads* plied in the *plane* of one of the *principal axes*. For the treatment of beams unhomogeneous material (reinforced concrete) see article on *Concrete*.

Let M = maximum external bending moment on beam in inch-pounds,
I = moment of inertia in (inches)^4 about the neutral axis lying perpendicular to the plane of the external loads. (This axis in a symmetrical beam lies at mid-height.)
c = distance in inches from neutral axis to extreme fiber, equals one-half the depth for symmetrical beams,
s = allowable value of fiber stress (working value),
Q = statical moment about the neutral axis of that portion of the cross-section lying above the neutral axis,
v = allowable intensity of longitudinal shear in lb. per sq. inch,
V = maximum external shear on beam in pounds,
b = thickness of beam at neutral axis.

Then, $$M = \frac{sI}{c} \qquad \frac{I}{c} = \frac{M}{s},$$

nd $$v = \frac{VQ}{bI} \qquad \frac{Q}{bI} = \frac{v}{V},$$

Steel Beams. — Such beams are made in the shape of the letter I in order to obtain maximum strength for a given amount of material. They are rolled to desired shape and size while hot. For dimensions, allowable loads and properties of the standard sizes made in the United States see Table V above. In addition to the I-beams listed in the table of standard I-beams which are manufactured by all the leading structural steel makers, the Bethlehem Steel Co. manufacture certain special beams of the same general shape but either of greater depth or with wider flange, and the Carnegie Steel Co. also manufacture certain special types of beams. These beams may often be used to great advantage.

Cost of Steel Beams (Pre-war prices). — The cost of steel beams in place depends upon the cost of transportation, punching, riveting and other necessary shop work and the cost of erection and painting. The base price at the mills is quoted each week in the *Iron Age;* the figures which follow are from the issue of June 19, 1913, and are representative of average prices prior to the European war.

I-beams under 15 in., 1.45¢ to 1.50¢ per lb.
I-beams over 15 in., 1.55¢ to 1.60¢ per lb.
H-beams over 18 in., 1.55¢ to 1.60¢ per lb.
For cutting to length, under 3 ft. to 2 ft. inclusive, 0.25¢ per lb.
For cutting to length, under 2 ft. to 1 ft. inclusive, 0.50¢ per lb.
For cutting to length, under 1 ft., 1.55¢ per lb.
No charge for cutting to lengths 3 ft. and over.

For total cost in place an estimate of 3 cents per pound is ordinarily safe.

PLATE GIRDERS; FORMULAS AND COSTS. — A typical plate girder with the various parts is shown in Fig. 8. Plate girders are used for openings

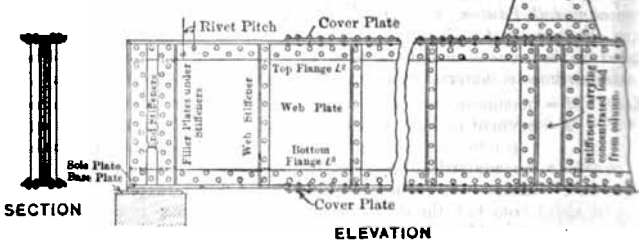

Fig. 8. Typical Plate Girder

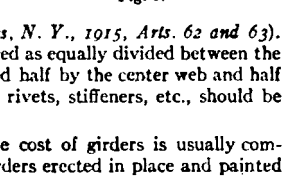

where either the load to be carried is too heavy or the clear span too great to be spanned with safety by rolled beams. The maximum length and depth are limited by the possibility of transportation. Probably the largest girder yet made was designed for the Boston & Albany Railroad for use at Worcester, Mass. It is 122 feet 6 inches long, 10 feet 11½ inches deep, and weighs 172 tons. The ordinary and economical depth of plate girders is from ⅛ to 1/12 the span; ⅛ the span is a common value. The maximum depth is usually restricted to 10 feet 6 inches or less.

al Points in Plate-Girder Design are as follows:
letermination of area of web required to carry the maximum external

etermination of area of flange required to resist the maximum external oment.
letermination of the flange rivet spacing necessary to transmit the ss from web to flange.
letermination of spacing and size of stiffeners required to prevent the from buckling sidewise, and of size of stiffeners at all points of appli- oncentrated loads together with number of rivets required therein.
etermination of length of flange cover plates.
esign of splices for web, angles and cover plates.
esign of bearing plates to transmit end reactions into masonry.

possible to give in the limited space available here the necessary nd data for the design of plate girders. For further information see *Theory of Structures*, N. Y., 1915.

of Box Girders. — Box girders resemble plate girders, but have two ebs as indicated in Fig. 9. They are used where conditions require irder of great strength. The rules to plate girders appiy in general ders, but owing to their shallow is usually advisable to determine gth against bending by the general ula $M = \frac{sI}{c}$, the moment of inertia nputed with due allowance for (*see Spofford's Theory of Structures, N. Y., 1915, Arts. 62 and 63*). in a two-web girder may be considered as equally divided between the and in a three-web girder as carried half by the center web and half o side webs combined. The flange rivets, stiffeners, etc., should be on the same basis.

Fig. 9.

Girders (Pre-war prices). — The cost of girders is usually com- cent-per-pound basis. Price of girders erected in place and painted nges in the Eastern states from 2½ to 4 cents per pound, depending state of the market, location, amount and complexity of the work, specifications and inspection, cost of maintaining traffic (in railroad The price of 3½ cents per pound may be considered a fair average or approximate estimates. In the West this figure should be mate- ased to cover the additional freight rate from Pittsburgh or Chicago. c prices of material see below under *Price of Structural Material*. rates to various points from Pittsburgh, see below under *Freight*

INS; FORMULAS AND COSTS. — Steel columns may be made lled sections such as I-beams or channels, or of compound sec- sting of single sections riveted together. A typical steel column n Fig. 10. Single sections of steel columns should be limited in convenience in erection and economy in shipment to 60 feet over all . Lengths up to 120 feet may, however, be shipped in one piece if

columns are made by pouring liquid iron into molds. They may be shapes, but are always of comparatively short lengths seldom ex- or 20 feet. Common shapes are shown in Fig. 11. To obtain free- itial stresses due to unequal rates of cooling and from stresses due to

eccentricity with centrally applied loads, the shells of hollow cast-iron columns should be of uniform thickness throughout. This result may best be secured by pouring the column in an upright position; if cast in a horizontal position the core must be carefully restrained against flotation.

Timber columns should consist of single sticks and may be either circular or rectangular in cross-section. Two lengths are sometimes connected by means of cast-iron caps which also furnish seats for beams.

Concrete columns are made by pouring concrete into wooden or metal molds; they may be made of any desired shape or length. Such columns are generally reinforced by longitudinal steel rods extending from end to end of the column and held in place at intervals by transverse steel rings. The transverse reinforcement may be made to add materially to the strength of the column by placing the rings at frequent intervals or by making it in the form of a spiral extending from end to end of the column, the column then being called a hooped column. The strengthening effect of the transverse reinforcement is due to its influence in preventing the bursting tendency of the concrete when subjected to compression.

Splices. — Steel columns are commonly spliced by bringing the abutting ends into close contact after first planing them at right angles to the axis. Splice plates are used on webs and flanges to hold the sections in line. If the column carries no bending moment the size of splice plates and number of rivets may be determined by the designer's judgment; if the column carries flexure as well as direct stress the splice must be sufficient to transmit the flexure.

Fig. 10

Changes of cross-sections in steel columns may be accomplished by changing the thickness of the material or by adding additional material. An advantageous location of a splice is at a section where the cross-section area is to be changed. If the column carries only direct compression and is loaded at intervals throughout its length such a section should be near the point of application of one of the loads and on that side of it in which the smaller stress occurs, e.g., in a high building column the section should be changed just *above* one of the floors. For columns carrying flexure as well as direct stress the splices should be located where the bending moment is small, as for example at a point of contraflexure. Cast-iron columns should

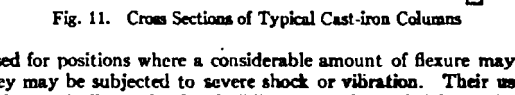

Fig. 11. Cross Sections of Typical Cast-iron Columns

not be used for positions where a considerable amount of flexure may occur or where they may be subjected to severe shock or vibration. Their use in construction is practically confined to buildings of moderate height. They may be spliced by bolting the flanges. In interior building columns the load is sometimes transferred from one section to another by means of a pintle extending between the beams which are supported on the cap of the lower column. Such a joint depends for its lateral rigidity upon the friction between the beams and column cap and can evidently transmit no bending moment.

Ratio of Unsupported Length of Column to Radius of Gyration. — The controlling factor in column formulas is the value of the ratio between the unsupported length of the column and the radius of gyration of its cross-section. If the column is of constant cross-section and restrained against lateral deflection at

nly, then l equals the total length of the column and r its least radius
n. If the column is held against lateral deflection in every direction
several intermediate points, the value of $\frac{l}{r}$ equals the largest value
tween any two adjoining lateral supports. If the column is held at
diate point in one direction only, the value of $\frac{l}{r}$ equals the maximum
by using for l the length of either section, or the total length of the
d for r in each case the corresponding least radius of gyration re-
ny axis about which the column is free to bend. If the column is of
oss-section the designer must use his judgment in determining the
to be used, but generally the value should be that at the middle of
orted length of the particular portion of the column that is under
on.

n of Ends.—It was formerly assumed that the strength of columns
actice depended very largely upon the condition of the ends. At
time, however, no difference is made between round-ended, pin-
square-ended columns as used in ordinary practice. For columns of
that Euler's formula should be applied, a distinction should be made
und-ended and square-ended columns (*see following section*). Col-
one free end should receive special consideration.

ended Formulas for Steel Columns.—

Columns of Ordinary Length:

$$\frac{P}{A} = 16{,}000 - 70\frac{l}{r}, \qquad (1)$$

l/r not to exceed 120 for principal members,
l/r not to exceed 150 for secondary members,
P/A not to exceed 14,000 lbs.

of symbols, see list following equation (4).

Long Columns having values of l/r greater than allowed in formula
mn may fail by collapsing rather than crushing; in this case the fol-
ulas should be used:

Fixed Ends $$\frac{P}{A} = \frac{4\pi^2 E}{c}\left(\frac{r}{l}\right)^2, \qquad (2)$$

Round Ends $$\frac{P}{A} = \frac{\pi^2 E}{c}\left(\frac{r}{l}\right)^2, \qquad (3)$$

One Free End $$\frac{P}{A} = \frac{\pi^2 E}{4c}\left(\frac{r}{l}\right)^2, \qquad (4)$$

total allowable centrally applied load on column in pounds includ-
ing proper allowance for impact,
minimum area of cross-section in square inches,

maximum ratio of length to radius of gyration for any laterally
unsupported section of column,
suitable factor of safety, usually 5 to 6,
modulus of elasticity in pounds per square inch.

ally Loaded Columns. — If the resultant force acting at any cross-
column is not applied at its center of gravity the column is said to
ially loaded. The effect of an eccentric load is to subject the column
ation of direct stress and flexure, and thereby to increase the maxi-
ress over what it would otherwise be. A similar condition arises if
t force on the cross-section is the resultant of an axial force acting
of gravity of the section and a couple causing flexure at the section.
m fiber stress at such a section may be determined by the following
oximate formula for the usual case where the resultant force acts
of one of the principal axes and the neutral axis for flexure coin-
e other principal axis.

$$s = \frac{P}{A} + \frac{My}{I - \frac{Pl^2}{10E}}, \qquad (7)$$

maximum fiber stress at any section in pounds per square inch,
resultant axial force on section in pounds,
unsupported length of column in inches,
area of cross-section in square inches,
bending moment on section in inch-pounds,
moment of inertia of cross-section about neutral axis in (inches)^4,
modulus of elasticity in pounds = 29,000,000 for steel,
distance in inches from neutral axis to most remote fiber. (Neu-
tral axis as used in this formula is the neutral axis for flexure.)

e in a Building Column Carrying an Eccentric Load. — The
ding column supporting a track for a traveling crane is a common
rve of moments for such a case is shown by

nect, rivets shall be used on each side of the joint in exc
cally required to the extent of one-third of the number

Column Caps, Bases and Brackets. — The proj
plied loads to the column, and the distribution of the
ing, is a matter of great importance. The three follow
in designing column caps:

a. Provide sufficient bearing area so that the crushi
or of the loading beam, girder or column will not be

b. Arrange connections to eliminate eccentric app
this is impossible to reduce the eccentricity to the

c. Arrange connections so that the stress-bearing
shall be directly under the stress-transmitting portio
e.g., if a column receives load from a girder, the ou
stiffeners on the girder should be located directly ove

Typical column bases are shown in Fig. 13. The
be observed in the design of column bases as in the de
advantage of a separate base is that it can be set up on the foundation and leveled to receive the column with less difficulty than would be the case with the finished column. Such bases should always be planed on top and the base of the column should also be planed. Steel columns to which cap and base plates are shop riveted should be planed at each end before these plates are riveted on, and the cap and base plates are also generally planed on top and bottom respectively.

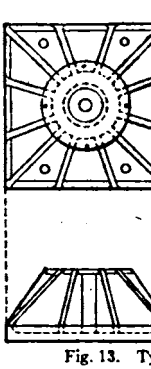

Fig. 13. T

It is important that brackets for connections of girders to columns should always be designed so as to throw the resultant beam reaction as near th
possible in order to reduce the eccentricity of loadi
occur. This is particularly important for cast-iro
the brackets should be slightly beveled downward
or girder cannot be supported at or near the edge of t

TRUSSES, DESIGN OF. — All trusses may be c
classes based upon the methods necessary to determine
stresses can be determined by the application of the th
rium (*see paragraph on Equations of Equilibrium, above*
termined; otherwise they are statically undetermined.
a truss may be statically undetermined with respect to
reactions cannot be determined by statics; or it may be
with respect to the inner forces, i.e., the bar stresses c
statics.

Trusses that are statically indeterminate through ha
reactions are frequently constructed because of their
economy, but it is doubtful if such trusses are desirable

Statically determined trusses may be distinguished
mined trusses by comparing the number of unknown re

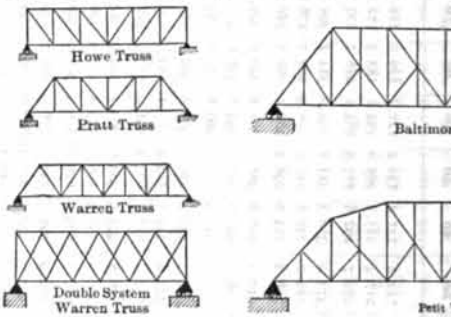

Fig. 14. Bridge Trusses

the number of bars with the number of joints. In ge
that any planar truss supported at two points will b
provided the number of bars equals $(2n-3)$,
where n is the number of joints. If the number
of unknown bars and reaction components com-
bined exceed twice the number of joints the
truss is statically indeterminate but may usually
be computed by methods based upon its elastic-
ity. If the number of unknowns is less than
twice the number of joints the truss is unstable
and may collapse; such structures should never
be constructed.

The preceding test should not be used alone
to determine whether a truss is or is not stable.
The framework should also be so put together as
to make it consist of a series of triangles.

Common Types. — All the trusses shown
in Figs. 14 and 15, except the double-system
Warren truss and the roof truss with monitor,
are statically determined; the former may
be made statically determined by omitting one
of the bars, say a diagonal; the latter by omitting o

Theory of Trusses. — The common theory of trusse
lowing assumption:

Digitized by Google

he members are connected at the intersections of their center of nes by frictionless pins, and that in consequence the stresses in the embers are all direct stresses. The assumption of frictionless pins is ate particularly in the case of riveted trusses; however, the results by this method are sufficiently accurate for trusses of ordinary ns and are in common use. Great care should be used in design that center of gravity lines meet at the joints, otherwise the connec- be eccentric and the truss exposed to bending as well as direct

ethods of computing stresses in ordinary trusses involve only the pplication of the three equations of statics (*see section on Equations of m, above*). Three methods are in common use: viz., method of joints, f moments, and method of shear. All of these are methods of sections pplied by passing a section through the bar under consideration, cutting apart and applying the equations of equilibrium to the outer forces on ese sections and the stress in the bar under consideration. The first ese methods are described below.

d of Joints. — The method of joints is the most general of the three f computing the stresses in trusses; it may be applied either analyt- graphically.

alytical Method. — The mode of procedure for this method is as (1) Computation of reactions. (2) Selection of a joint at which only meet. (3) Application of the two equations of equilibrium, $\Sigma H = O$ O, to the outer forces and unknown bar stresses acting at this point. tresses should be assumed as tension, that is, as acting away from the negative result in any case would indicate compression. (4) Con- of any other joint at which only two unknown bars meet and deter- of the stresses in these bars in the same manner, treating known bar s outer forces.

raphical Method. — This method consists of drawing polygons for each joint in succession. e employed readily by drafts- others who are not familiar ss theories. It is also self- and reasonably rapid. It is ate than the analytical method, e diagrams are carefully con- t is accurate enough for ordinary s.

ode of procedure is: (1) A the structure is drawn to any scale and on it are shown all forces including reactions. (2) forces and bars are designated s so located that each force and will lie between two letters and , as illustrated by Fig. 16. (3) n of outer forces is drawn. This e drawn to a scale of sufficient ve the desired accuracy. The forces should be plotted in the order in ey are reached by going around the figure in a clockwise direction, and lettered at the ends by the letters in the order obtained by this clock- tion. This polygon should close if the reactions have been determined

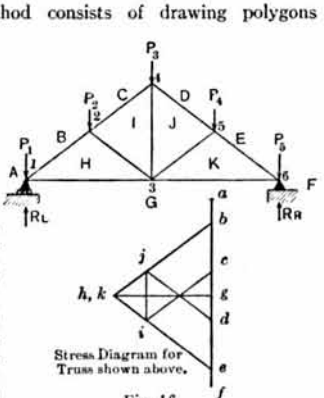

Fig. 16.

correctly. (4) A triangle of forces for each joint is drawn, beginning at a joint where an outer force and two bars only meet, and proceeding thence joint by joint, selecting the joints in such an order that at no joint will there be more than two undetermined forces to consider. The sides of these triangles representing the outer forces are the sides of the force polygon. The sides representing bar stresses should be lettered at the ends by the letters obtained by going around the joints in a clockwise direction. The diagram thus drawn should form a closed figure. (5) The magnitude and character of the bar stresses are determined from the diagram. The magnitude of the stress in any member equals the length of the line of the diagram parallel to the bar in question measured to the scale of the force polygon; its character is determined by the order in which the letters are reached in going about any joint in a clockwise direction. For example, to determine the character of the stress in bar *CI* of Fig. 16, note that *ci* in the stress diagram acts downward to the left, as determined by the order in which the letters are reached in going around joint 2; hence the stress in *CI* also acts downward to the left, or toward the joint, since the bar is above the joint, and is therefore compression. A similar result is obtained by considering joint 4. For this joint clockwise reading gives the designation of the bar as *IC*, and *ic* in the stress diagram acts upward to the right, that is toward joint 4, since the bar is below this joint.

Solutions by Graphical Method. — Fig. 16 shows a small truss drawn to scale and with all the outer forces represented in direction and point of application. The force polygon is *abcdefga;* this is a straight line, since all the forces are vertical. In it $ab = P_1$, $bc = P_2$, etc. The reactions R_L and R_R are represented by *ga* and *fg*. The triangle of forces for joint 1 is *gabkg* (*gb* is the resultant of R_L and P_1). Reading around joint 1 in a clockwise direction shows that the magnitude and direction of the stress in bar *BH* is determined by the length and direction of *bk* in the force polygon; as this acts downward to the left, it acts toward joint 1 and hence is compression. In the same manner the stress in *HG* is found to be tension. The stresses in the other bars may be determined similarly.

Fig. 17 shows a simple tower with wind forces acting on one side only. Ordinarily the wind forces on a tower would be equally divided between the two sides but they are all taken on one side here in order to more clearly illustrate the method. The only difference in the result would occur in the stresses in the horizontal members. In this case the diagonals in all panels are assumed to be tension members, only one of which in any one panel is in action under the forces shown. Inspection shows that in each case the bar shown dotted should be considered as out of action. The stress diagram and the scaled values of stresses in the bars are also shown in the figure.

Method of Moments. — This method of finding truss stresses is based upon the application of the equation $\Sigma M = 0$. It is very useful for determining stresses in individual bars of many trusses, but is not so general as the method of joints and is frequently inapplicable to some bars even in the simplest trusses. Like the method of joints, it is also a method of sections, the truss being considered as divided into two portions and the equilibrium of one of these portions under the influence of the outer forces and the stress in the cut bar being considered. The method can be used to determine the stress in a given bar when all the other bars cut by the section, or their prolongations, meet at a point not on the line of action of the given bar. This point should be selected as the origin of moments.

Design of Tension Members. — The design of tension members involves little more than the selection of bars with sufficient net area to carry the total stress without exceeding the allowable unit stress. Steel or iron tension

bers may be divided into two general types: viz., solid bars rectangular or lar in cross-section, and built-up members composed of structural shapes ed together. Solid bars are used generally in pin trusses for diagonals bottom chord members, and in Howe trusses for verticals. Built-up mem- are generally employed for tension members in riveted trusses and for the hangers in pin-trusses.

Solid Tension Pieces. — The eye bar shown in Fig. 18 is commonly l for the solid bar type of tension members. Such bars are made by most he large steel manufacturers and are fully described in their handbooks. heads of these bars are designed so that the bar if tested to destruction fail in the body rather than in the head, and the engineer should specify : full-sized tests should give this result and not attempt to proportion the ils. A good rule to observe in selecting bars is to keep the thickness between

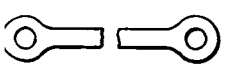

Fig. 18.

Fig. 19.

-sixth and one-third the width. Eye-bars are generally used in pairs, since odd number of bars would give a poor arrangement on the pin. For counters justable eye-bars, such as those shown in Fig. 19, may be used, the two parts ing connected by a turnbuckle or sleeve nut; iron rods with loops formed by lding may be used if the stresses are small. In proportioning adjustable embers allowance must be made for the decrease in section due to the screw reads. It is usually advisable to upset the screw end, so as to give sufficient ea at the root of the thread to make the bar as strong there as elsewhere. or short rods, however, the labor cost involved in this process may be greater an the saving of material would warrant.

CONTINUOUS GIRDERS, BEAMS, SLABS AND TRUSSI

iese are structures which are continuous over several points of su
iey are statically indeterminate (*see section on Trusses, above*) with r
the outer forces and hence the moments and shears should be deter
the "three-moment equation" (*see above*). Continuous girders are
only used in reinforced-concrete construction, in which case the cont
allowed for by the following simple rules recommended by the Joint
ttee on Concrete and Reinforced Concrete. (*See article on Concrete.*)

(*a*) For floor-slabs, the bending moments at center and at support
taken at $\frac{wl^2}{12}$ for both dead and live loads, where w represents the lo
ear unit and l the span length.

(*b*) For beams, the bending moment at center and at support for i
ans should be taken at $\frac{wl^2}{12}$ and for end spans it should be taken at
iter and interior support, for both dead and live loads.

(*c*) In the case of beams and slabs continuous for two spans only, with
ds restrained, the bending moment both at the central support and ne
ddle of the span should be taken as $\frac{wl^2}{10}$.

(*d*) At the ends of continuous beams, the amount of negative moment
ll be developed in the beam will depend on the condition of restraint o
ss, and this will depend on the form of construction used. In the or
ses a moment of $\frac{wl^2}{16}$ may be taken; for small beams running into
umns this should be increased, but not to exceed $\frac{wl^2}{12}$.

For spans of unusual length, or for spans of materially unequal length
uct calculations should be made. Special consideration is also requi
e case of concentrated loads.

ATIONS, RAILWAY. — (*See also Converters, Synchronous; Rail-ergy Requirements for; Switchboards; Switchgear Equipment; Trans-*

Substations are used for electric railways when the length of the road t that the whole road cannot be supplied with one power station at ge required by the motors without either an excessive drop in voltage ibitive amount of copper or both. Practically all electric railways eloped to such an extent that substations are required for successful

OMIC CONSIDERATIONS. — The location, capacity and num-bstations is a matter for careful study and calculation, involving not cost of the copper required for distribution and the cost of the sub-but also the distribution of traffic and special local conditions. The tal economics of the subject are expressed by the general theorem cost of operating the substations plus the cost of interest and fixed n investment in substations and line copper shall be a minimum. plained by the fact that if to any given arrangement an additional be added with the proper rearrangement of the spacing, the amount used in the distributing system may be considerably decreased on f the lesser distance between substations. If the saving in interest lue of the copper is greater than the cost of operation of this new plus the interest and fixed charges on the first cost of the substation, e is warranted.

ble Voltage Drop. — The distance between substations depends on the allowable loss in voltage, the amount of copper in the trolley ely as the load. The allowable loss of voltage is a matter of the nditions of each road. Roads may be logically divided into two sses: City and Interurban. In City roads a drop in voltage of 8 per average load and 15 per cent with maximum load is frequently In Interurban roads a drop of 12 per cent with average load and t with maximum load is customary.

o conditions which determine the allowable drop in voltage are the he lights and the effect on the control circuit of the car, each of which quires a lesser drop in voltage than the actual operating character-ne motors.

ce between Substations. — For the service usually found in prac-llowing tabulation shows the average or customary distance between s.

he length of track receives its power from only one direction the distance for a given drop in voltage is one-quarter the distance allow-en substations.

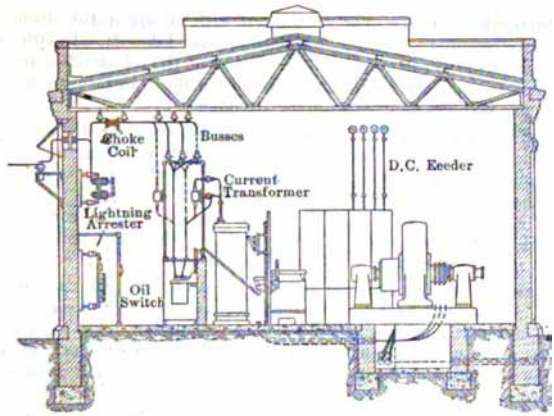
y Required. — The capacity of the substation depends upon the the size of the cars, since if there are many cars operating it is prob-only a few will be starting simultaneously and it is during starting ars demand the maximum amount of power. It is, therefore, neces-termine the number of cars which will be located on the section of plied by one substation and the frequency of starting. In inter-rice the number of cars on a given section is given by the formula:

$$X = \frac{2 \times (\text{length of section}) \times (\text{number of cars per hour})}{\text{schedule speed in miles per hour}}$$

ge load on the substation is equal to the average power demand of imes the number of cars on the section divided by the efficiency of bution system. In a complex system the local conditions must be

Volts	Type	Miles between substations	
		Single-track road	Double-track road
600	Direct-current, Trolley	10	15
600	Direct-current, 3d Rail	13	19
3,300	Single-phase, Trolley	17	23
1,200	Direct-current, Trolley	19	25
1,200	Direct-current, 3d Rail	38	43
6,600	Single-phase, Trolley	45	50
11,000	Single-phase, Trolley	..	70

studied to determine how many of these cars are liable to be starting at one. In other than city roads a load factor of from 0.3 to 0.5 may be used to determine the maximum load on a substation, and in single-track interurban roads it is customary to assume one car starting and one car running. See article on *Railways, Energy Requirements for*.



TYPES OF SUBSTATIONS. — In practice there are two types of substations: 1. for transforming from alternating to direct current, and 2. for transforming from high-voltage alternating current to low-voltage alternating current.

In standard direct-current railways it is customary to generate power in the power stations at about 2200-volt three-phase alternating current, step up by means of transformers to 33,000 volts 3-phase, transmit over any distance to the substations at this voltage, transform from 33,000 volts to approximately 400 volts 3 phase and then to convert to direct current at 600 volts in which form the power is used by the motors of the cars. This is the standard a-c.-d-c. substation. In certain single-phase a-c. railways it is found necessary to transmit the power over long distances at a higher voltage than can be collected from the trolley, in which case the a-c.-a-c. transformer substations are installed to convert the alternating current at the high transmission voltage to alternating current at a voltage convenient for the trolley and collector devices.

SUBSTATIONS FOR TRANSFORMING FROM ALTERNATING TO DIRECT CURRENT. — In these stations it is almost universally the custom to employ synchronous converters to convert from a-c. to d-c., rather than motor-generator sets, as the converters have a higher efficiency and may be compounded to give the desired regulation. Thus the converter makes possible a saving in first cost, space and energy as compared to the motor-generator set. A standard a-c.-d-c. railway substation usually contains the following pieces of apparatus: converters, transformers, reactances, blowers, cables, switching apparatus.

Arrangement of Apparatus. — (*See also article on Switchgear Equipment.*) It is customary to arrange the apparatus in a substation so that the current travels in as nearly as possible a straight line across the station. Thus, with the incoming line on one side there are in the order mentioned: the lightning arresters, oil switches, transformers, a-c. switchboard, reactance coils, con-

Digitized by Google

verters, d-c. line panel. A typical arangement for a small station is shown in Fig. 1; see also Fig. 16 in article on *Switchgear Equipment*.

Floor Space Required. — For substations with all apparatus on one level the floor space required is about 0.20 square foot per kilowatt. In cities where real estate is expensive, it may be desirable to put the oil switches and lightning arresters in a gallery on the upper level and the transformers on a floor above, but this involves more expense for attendance.

Standard Voltages and Frequencies. — The following three-phase voltages have been standardized for railway work: 11,000 volts with transformers delta connected on the high-tension side; 33,000 volts with transformers *Y* connected; 66,000 volts with transformers *Y* connected. A frequency of 25 cycles per second is employed in almost all railway installations, as converters are more reliable at this frequency. Certain stations which are obliged to take power from previously existing power stations use a frequency of 60 cycles.

Converters. — (*See article on Converters, Synchronous, for data regarding converters.*) Compound-wound converters are used where the load is variable to provide automatically any desired voltage regulation. The converter by means of its series winding is made to take a leading current which, in passing through the reactance of the line, the transformers or through an additional reactance introduced for the purpose, tends to neutralize the line drop. (*See Transmission Lines.*) In city service where a large number of cars are operating on one section, the load is fairly constant and shunt-wound converters are generally used.

Both 3-phase and 6-phase converters are universally used, the 3-phase for the smaller capacities and the 6-phase converters for the larger capacities. In a 3-phase converter for a direct e.m.f. voltage of 600 at no load, the transformers should supply the converter with 370 volts between rings or between lines. In the 6-phase converter it is customary to use the diametrical connection, in which each transformer secondary supplies 430 volts to the converter, giving 600 volts at the commutator. Each converter for railway work is customarily supplied with a "speed-limiting" device on one end of the shaft and an "end-play" device on the other end. (*See Converters, Synchronous.*)

Methods of Starting Converters. — (*See also below under Operation.*) There are several methods of starting rotary converters, as is explained under *Converters, Synchronous*. Starting from the alternating-current end as an induction motor is most desirable for railway work, as it avoids the necessity of synchronizing and requires less time. The ability to start a machine quickly and get it on the line in the shortest possible time is very important in railway work, and is an advantage inherent in this method of starting. Three-phase converters are started, by means of suitable starting switches, from one-half voltage taps on the transformer secondaries and take approximately full-load current from the line. Six-phase converters are started from ½ voltage taps and take ¾ full-load line current. Since 60-cycle converters usually take a greater starting current than 25-cycle converters and are usually operated on a system supplying power for other purposes, where voltage disturbances are objectionable, special means of starting 60-cycle converters are frequently employed.

Transformers. — (*See article on Transformers.*) The transformers used in railway substations may be either of the oil-cooled, air-blast or water-cooled type. The oil-cooled type is used where the units are small in capacity, i.e., less than 400 kilowatts, and where the expense of the complications for air blast or water cooling are not warranted. Air-blast transformers are used in all except the smallest sizes, and for voltages up to and including 33,000; the objections to their use are the necessity of providing a pit, air ducts and blower

Digitized by Google

to supply the ventilation. Water-cooled transformers (which are oil-insulated transformers with water circulating in a special coil submerged in the oil) are built in sizes from 500 kilowatts upwards and for all voltages. Their use depends upon the availability of water for cooling purposes. The usual aggregate capacity of transformers for the various sizes of synchronous converters is about the same as the converter capacity.

Transformer Connections. — The transformers may be either of the single-phase or three-phase type. For small or moderate installations the single-phase type is preferable on account of the economy of maintaining only one single-phase transformer as a spare for a whole station. In railway work it is customary to connect the secondary of the transformers in delta for three-phase, because of the possibility of operating at reduced output on open delta in case of failure of one transformer. The primary windings of the transformer are usually connected *Y* with grounded neutral. It is common practice to provide transformers for railway work with four 2½ per cent taps on the high-potential winding, in order to use similar transformers in all substations and yet make allowances for the difference in the line drop between the power station and the various substations. Either ⅛- or ½-voltage taps are provided on the low-potential side for starting the converters.

Blowers for Air-blast Transformers (*see Blowers and Compressors*) are usually driven by 25-cycle 3-phase induction motors receiving power from the low-tension side of the transformers. The amount of air required per minute per kilowatt rating of each transformer ranges from 3 cubic feet in the large sizes to 5 cubic feet in the small sizes. This air is supplied at a pressure of from ⅜ to 1 ounce per square inch. The blowers must be capable of supplying this amount of air with an allowance of about 10 per cent for leakage in the air-blast chamber. It is customary to provide two blower sets each capable of supplying air for all the transformers in the station and maintaining one as a reserve unit. In a very large station 3 blower sets are sometimes provided, two of which are together capable of supplying the service and the third is a reserve. A rough idea of the size of the motor necessary to drive a blower for a given purpose may be obtained from the following formula:

$$\text{Horse-power} = \frac{(\text{cu. ft. air per minute}) \times (\text{pressure in ounces})}{1200}.$$

Air Duct for Air-blast Transformers. — The pit or trench over which air-blast transformers are placed must be made water-tight and well drained, as any moisture accumulating is liable to be carried into the transformers where it will injure the insulation.

Voltage Regulation. — Use of Reactances. — The voltage at the d-c. bus-bars is regulated automatically by means of line compounding which consists in adjusting the shunt-field excitation of each converter so that the converter takes lagging current at no load, operates at unity power factor at about ¾ load and takes leading current at all loads greater than ¾ load. To accomplish this compounding, it is necessary that there should be a certain amount of reactance between the power-station bus-bars and the converters. (*See Converters, Synchronous.*) There is seldom enough reactance in the transmission line for this purpose, so that additional reactance is inserted either by the use of special transformers having considerable leakage reactance, or by means of reactance coils. The usual reactance coil has a capacity in kv-a. equal to 15 per cent of the kilowatt rating of the converter, i.e. with full-load current passing through the reactance the voltage measured across its terminals would be 15 per cent of the voltage to neutral on the a-c. side of the converter.

Digitized by Google

Reactance coils are either oil cooled or air blast depending upon the transformers used and are usually built with the three circuits in one unit, with the starting switches for the converters mounted upon the frame. For 6-phase converters a 3-phase reactance coil is used, but since the current per wire is one-half that of the current of a 3-phase converter of the same rating, the reactance per line must be twice as great for the 6-phase converter.

Switchboards. — (*See also article on Switchboards.*) The following sections of switchboards are standard for converter substations.

1. Incoming a-c. line panel.
2. Outgoing a-c. line panel.
3. High-tension a-c. converter panel.
4. D-c. converter panel.
5. D-c. feeder panel.
6. Equalizer and negative panel (on the converter).

Where a substation is tapped off a transmission line at an intermediate point it is good practice to bring the transmission line into the substation, interpose control switches, and then carry the circuit out of the substation on to the next substation. For this reason, in all but terminal substations, it is customary to provide both an incoming and an outgoing a-c. line panel. In connection with the a-c. panel of the switchboard there are a line switch, lightning arrester, choke coil, current transformers and main oil switch, by means of which potential may be removed from all transformers. Between the transformers and the converter are the starting switches, reactance coil and possibly measuring devices.

Direct-current Panels. — Single-pole switchboard panels are used, the positive main bus-bar being the only one on the board. The negative terminals of the converters are connected with switches to the negative or ground return bus-bar, which is frequently located beneath the converter. The series field is connected on the negative side, and the equalizer, series-field-shunt and field break-up switches are frequently placed on the machine itself. The equipment of a standard d-c. converter panel comprises one of each of the following:

Carbon break circuit breaker with overload and low-voltage release, the latter interconnected to the speed-limit device.
Illuminated dial ammeter with shunt.
Field rheostat.
Two-point receptacle.
Single-pole main switch.
Single-pole double-throw station lighting switch.
Watt-hour meter.

Storage Battery. — In certain installations, where reliability of service is of utmost importance, a storage battery is installed, operating in parallel with the converters, and preferably regulated by a series booster. Such a storage battery will not only take care of the load for a considerable period of time in case either the transmission line or converters are out of action, but it will also improve the load factor of the system and thereby the line regulation. In other cases, where the service does not warrant the outlay for such a storage-battery system, a small storage battery is sometimes installed to take care of the lighting of the substation in case the converters should shut down accidentally. See articles on *Batteries, Storage.*

Ventilation. — As the transformers, reactance coils and converters all dissipate a considerable amount of energy in the form of heat, a substation must be well ventilated in order that the temperature of the air surrounding the apparatus

not so great as to cause an injurious temperature in the apparatus itself. This is particularly important where oil-cooled transformers are used.

Crane. — Where ground space is limited it is good economy to provide a crane in order that the various pieces of apparatus may be lifted over each other when they are taken apart for repairs, as otherwise considerable space must be left to move them about to and from the entrance. See article on *Cranes*.

Operation of Converter Substations. — The only apparatus in a converter substation that requires any great amount of attention are the synchronous converters. As noted above these are usually started from the a-c. supply.

Instructions for Starting a Synchronous Converter from A-C. Supply. —

1. Open all switches except main negative (on machine).
2. Close a-c. line switch feeding busses.
3. Close H.T. transformer switch.
4. Close starting switch on low-voltage taps.
5. When converter reaches synchronism as shown by low frequency of swings of d-c. voltmeter, close equalizer switch.
6. Close switch between series field and the shunt to series field.
7. Correct polarity if necessary by throwing shunt-field break-up switch to reverse position, leaving it closed only momentarily, then throw to running position.
8. Connect a-c. terminals of converter to full voltage of transformers by throwing starting switch to running position.
9. Close d-c. circuit breaker.
10. Adjust field rheostat.
11. Close main d-c. switch.
12. Adjust for correct division of load, power factor and voltage.

Load Factor and Efficiency. — The load factor (q.v.) of a converter substation is usually low, from 30 per cent to 50 per cent, i.e., the load on the station is relatively light except during the morning and afternoon rush-hours, 7 to 9 A.M., and 5 to 7 P.M respectively (*see Train Dynamics*). The all-day efficiency of the station itself, or the ratio of the kilowatt-hours output to the kilowatt-hours input, is less than the efficiency at maximum or rated load; but the over-all efficiency between the a-c. generators in the power house and the cars is about constant throughout the day, since the efficiency of a transmission line increases with decrease of load, thus offsetting the low light-load efficiencies of the transformers and converters. In general practice in inter-urban 600-volt railways the maximum and all-day efficiencies of the various apparatus are approximately as given in the following table:

Apparatus	Full-load eff., per cent	All-day, eff., per cent
Step-up transformers	98	97
High-tension line	95	98
Step-down transformers	97	94
Converters	90	88
Low-tension distribution	85	88
Over-all, a-c. generator to motors	69	69

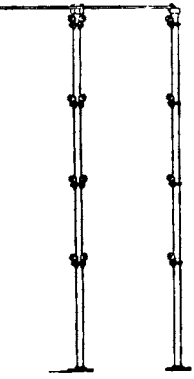
SWITCHBOARDS. — (*See also Bus-Bars; C Switches; Switchgear Equipment for Power Stations*
formerly comprised all apparatus in that portion of collecting, measuring and distributing the electric en of the switchgear is mounted on a single structure whic board. In large modern plants the control and mea are frequently mounted on one structure, and the another. In such cases the term switchboard is whether panel, pedestal, or desk type, which suppo handles and similar devices. The following article of apparatus on representative switchboards selecte trend of switchboard design. For a description of arrangements required by direct control and distant *Switchgear Equipment in Power Stations.*

CONSTRUCTION OF PANEL SWITCHBOA
called "panel" boards were made of wooden pane instruments, etc., each on its own base, were attac with the wiring on either the front or the rear. The the elimination of the wooden panel and framework. was mounted on a marble slab, which was arranged f framework, and switchboards were made by combini voltmeter, switch and rheostat slabs to make the pa rators, feeders, etc. This form of construction was en disadvantages ultimately lead to its being supersede panel switchboards with the apparatus grouped on p comparatively large pieces of marble, or slate.

The design of modern panel switchboards has un process that has been applied to all electrical appara requirements the vast majority of plants of moderate control switchboards that are made up by assembling

Framework of Panel Boards. — In general the f switchboard may be divided into two types. The c are mounted on a framework of gas pipe, and usua 4 feet high with a space between them and the flo expensive boards have a total height of about 7 feet the floor, and are provided with an angle iron or pipe



Gas-pipe Frames. — Although the gas-pipe ably lighter than the angle-iron construction it has be these smaller switchboards and in fact some manuf struction for most of their larger switchboard installa of panels does not exceed four or five the complete shipped with the panels attached to the framework an etc., undisturbed, but if the boards are large ones shipped separately.

Fig. 1 shows the pipe framework for switchboard pa is made of 1¼" wrought-iron pipe with one wrough with cast-iron foot nuts and panel supports. The v attached to the vertical pipes by "J" bolts or "U" b fitting is required.

Angle-iron Frames.—Fig. 2 shows a typical switchboard panels 90 inches high. Each panel of a is provided with 2 by 3 by ¼ inch or some similar se narrow web bolted to the panel. These angle irons

Digitized by Google

to within ½ inch of the top. The vertical angles on adjacent olted together through the 3-inch web. They are provided with

—Pipe Framework

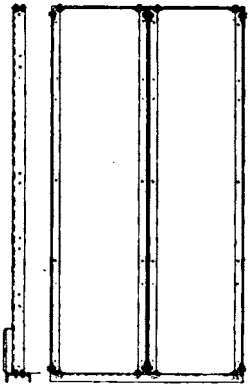


Fig. 2.—Angle Framework

for bolting at the bottom to a 6 by 2-inch channel iron forming he frame and at the top to two ½ by 1⅜-in. iron strips. The and the top irons are made continuous the entire length of the is not over 16 feet. Each panel is shipped bolted to the two angle m its individual frame, which obviates any necessity of disconnect- between the various slabs making up the panel. This practice of framework with the panels reduces to a large extent the breakage handling and facilitates the erection of the board at its destination.

rd Panels. — After trying various materials practically all switch- s have adopted either slate or marble, although in a few instances ick or steel has been used. The marble used in switchboards is grade known as "Blue Vermont," although occasionally "White Pink Tennessee" is used.

arison of Slate and Marble. — Where switchboard panels are black finish the choice of slate or marble is largely a question of ation. Slate is considerably cheaper and somewhat stronger than here the voltage of live metal parts mounted on the panels does not lts it answers just as well.

Used on Panels. — The marble is sometimes polished on the d bevels, and occasionally on the edges and back. The present h for marble is a dull black marine finish applied to honed panels. e, owing to its irregular color and marking, is usually given an rine finish and natural black slate is given an oil finish.

sions of Two-piece Panels. — The total height of standard anels is 90 inches from the channel iron. The division resulting wer slab as furnished by one company is due to the fact that these ensions were best adapted to the line of switches, circuit-breakers which were in use at the time the standard railway switchboard rst brought out. The lower 25-inch slab was used for rheostat face

Digitized by Google

plates having the contacts and contact mechanism In order to correspond with the old d-c. panels the a having a lower slab 25 inches high and a main slab 6 design of another company provides panels with sla high which dimensions were suited to their apparat ization.

Dimensions of Three-piece Panels. — W brush-type, carbon-break circuit-breaker was desig to mount this breaker at the top of the panel in ord tendency of an arc to rise. As all these standard b capacity required a vertical space of less than 20 divide the main upper 65-inch panel into two slabs, high to contain the circuit-breaker and the other contain the meters, switches, etc. For this reason of one maker, both for railway and for light and into three slabs, the upper 20 inches high, the middl 25 inches.

As the size of rotary converters has increased to breakers larger than 3000 amperes are often required 25 inches high to accommodate breakers up to 10, middle slabs 45 inches high and lower slabs 20 inches of 90 inches. Another manufacturer uses sections 3 inches having the same total height of 90 inches. slab usually contains the instruments as well as th all switchboard builders have adopted the three-sect heavy capacity carbon circuit-breakers.

TYPICAL DIRECT-CURRENT SWITCHBO equipments described in the subsequent paragraphs lustrate standard practice.

Small Isolated Plant Switchboards. — Whe generator of small capacity with one or two feeders of any additional equipment being needed, a board like Fig. 3 can be used with a main slab 36 inches high, 16 inches wide, provided with a polarized ammeter and voltmeter, single-pole carbon breaker, 2-pole main switch, field rheostat in the generator circuit, and switches with fuses in the feeder circuits. This type of board uses subpanels for the feeder switches and is usually limited to 10 kw. at 125 volts or 20 kw. at 220 volts.

2-Wire Switchboards. — For the control of small capacity, d-c. generators operating in parallel on a 2-wire, d-c. circuit the connections are made as indicated in Fig. 4. Each generator is provided with a 3-pole, single-throw switch, a single-pole circuit-breaker, an ammeter, and rheostat and a 4-point voltmeter receptacle used for connecting the voltmeter to any machine. Each feeder is provided with a 2-pole switch with ground detector is connected across the bus-bars.

3-Wire Switchboards. — Fig. 5 shows the diagra cal d-c., 3-wire installation and indicates the meth

onnection from the middle point of auto-transformers; the use of series fields the positive and negative circuits; the placing of the ammeter shunts on the

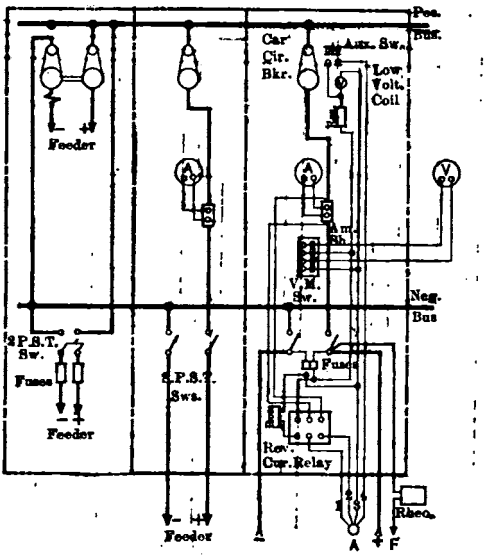

Fig. 4.

terminal boards of the machines so as to be connected inside the series fields; and the 4-pole circuit-breakers or the equivalent two single-pole breakers with equalizer contacts to open the positive, positive equalizer, negative and negative equalizer circuits.

Double-bus Railway Switchboards. — For direct-current railway or tramway work at about 600 volts it was for a long time the standard practice to bring both the positive and the negative leads from the generator to the switchboard and to locate both the positive and negative bus-bars on the switchboards, such boards being called "double-bus" boards. With these boards it was customary to use compound-wound d-c. generators with the series fields in the armature circuit which connected to the overhead trolley. The equalizer connection was usually made through a switch at the machine and the equalizer connection ran from one machine to the other without going to the panel board.

The double-bus scheme is still usually adopted for 250-volt, 2-wire industrial switchboards or any d-c. installation that does not use the ground return.

Single-bus Railway Switchboards. — Modifications in this class of switchboards came from placing the series fields in the grounded circuits instead of in the trolley circuits, and running only one polarity, usually the positive, to the switchboard. The equalizer switch and the negative switch, if the latter is used, are mounted at the machine. Fig. 6 is a typical diagram of a d-c. generator installation arranged for single-bus operation with only one polarity, namely the positive, on the board. The advantages

Digitized by Google

of this single-bus d-c. system are greater security against short circ narrowing of the d-c. generator or synchronous converter panel, consequer

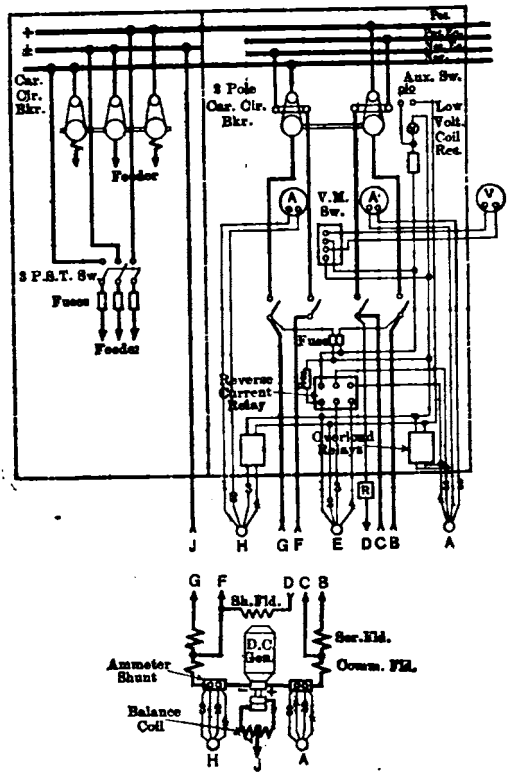

Fig. 5.

reduction in length of switchboard, reduction in amount of cable required and the use of bare copper strap or cables between machines for the negative and equalizer buses.

For converters or motor-generator sets, the panel switchboard if such is used, takes care of both the d-c. and a-c. circuits, which are usually controlled by separate panels. The d-c. panels are practically the same as those used for d-c. generators. The a-c. panels usually correspond with a-c. feeder panels and control the high-tension side of the step-down transformers used with the converter where the latter is made self-starting from the a-c. end. With such machines, in addition to the panels on the high-tension side of the transformers, it is customary to furnish a small slab mounted near the step-down transformers for connecting the converter, first to low-voltage taps for starting, then to full voltage taps for running.

Digitized by Google

It is customary to locate the 3-pole, double-throw switch used for starting the synchronous converter, on a panel with the 2-pole double-throw field reversing switch, so that if the converter should build up with its polarity reversed, it is a very simple matter to make the machine slip a pole and build up with the correct polarity. For railway service, the equalizer and negative switches are frequently mounted on the same panel as the starting switch and field-reversing switch.

It is customary practice to provide automatic protection on the alternating-current side of synchronous converters by making the breaker on the high-tension side of the step-down transformer automatic with inverse time element relays, or with inverse time element attachments on the trip coils of the breaker. A low voltage and instantaneous over-load carbon circuit-breaker is provided for the direct-current side. The low-voltage trip of the direct breaker is actuated by a speed-limit switch furnished with and mounted on the converter, the operation of which opens the breaker. It is also actuated by an auxiliary switch that is provided on the oil circuit-breaker so that when this breaker opens the direct-current breaker also opens in this manner providing against the motoring from direct-current and eliminating the liability of reversal in polarity on compound wound machines. For 600-volt railway service where there is an independent source of direct-current power such as an adjacent substation, d-c. reverse current relays are provided, these relays being arranged to trip the alternating-current breaker upon reversal of direct-current power and this in turn opens the direct-current breaker.

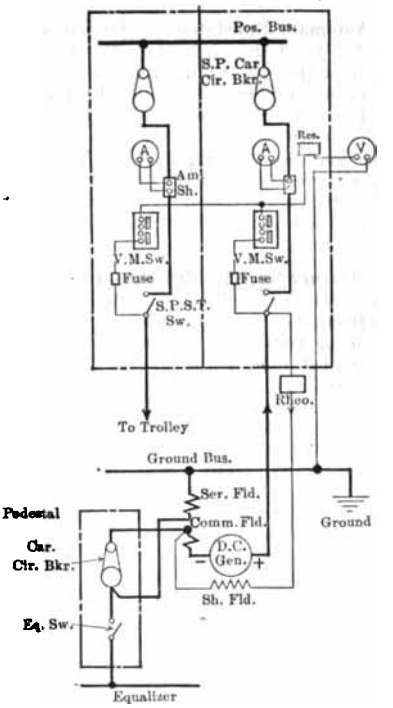

Fig. 6

High Voltage Direct-current Railway Switchboard. — For 1200-volt d-c. railway service the switchboard panels differ from those used for 600 volts, in the increased height of panel and in the fact that the circuit-breaker and knife switch are mounted out of reach and are mechanically operated by an insulated mechanism.

For 2400–3000 volt d-c. service special precautions have to be taken to carefully insulate the circuit-breakers and switches. Owing to the greater likelihood of flash-over occurring on the high-voltage d-c. converters or motor-generators, high-speed circuit breakers have been designed to trip on overload before the current in the machine rises to a dangerous amount. The same

Digitized by Google

result is obtained by a high-speed device that places an a-c. short circuit on the converter or generator before the direct-current has an opportunity to rise to a dangerous amount.

Automatic Substations. — On interurban railways operating cars or trains on hourly schedules it has been found advisable in certain cases to install automatic devices for starting a synchronous converter on the approach of a train or car and to shut it down after the train or car has passed.

This is usually accomplished by a series of contactor switches that start the converter and connect it to the lines whenever the voltage on the trolley line drops below a certain percentage of normal, this drop usually being caused by the approach of a car drawing a relatively heavy current from the line. After the car has passed and the current from the substation has dropped to a certain point, the converter will be shut down after the expiration of a definite time interval.

Mercury Rectifier Switchboards. — Another combination of a-c. and d-c. equipment met with in switchboard practice is that furnished for mercury rectifiers used in conjunction with constant-current d-c. arc lights fed from a constant-potential a-c. system. The apparatus supplied usually comprises a two-pole oil switch with fuses for the primary circuit of the regulator, plug switches in the secondary circuit, a mechanism for tilting the bulb of the mercury rectifier, and a high-voltage d-c. ammeter placed under a glass cover. The switchboards furnished with low-tension rectifiers are of similar arrangement, except that they are fitted with low-tension meters and switches, and have a single-pole starting switch which automatically applies a rheostat load for starting.

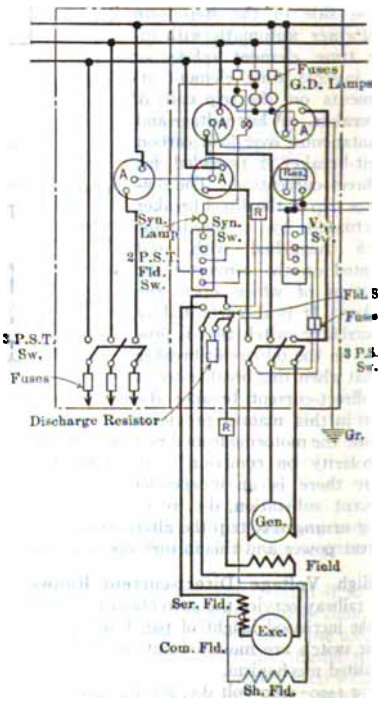

Fig. 7.

Other Arc-light Switchboards. — For use with d-c. series arc generators, switchboards are frequently supplied with a multiplicity of plug switches to permit any generator or feeder circuit to be connected in series with any other circuit to circuits. (*See Switches.*)

Exciter Panels, although d-c., are almost invariably combined with and form part of a-c. switchboards. The d-c. sections of the board are naturally considered with the a-c. sections and made to correspond with them in general design

Digitized by Google

els are either single or double, depending on whether they control machines. Usually no fuse equipment or other automatic provided with exciter panels, as the sudden opening of the field to the blowing of an exciter fuse or the tripping of an exciter pt to injure the insulation of the generator and cause far greater the plant than the overloading or short circuiting of an exciter. e are several large exciters operating in parallel with each other or age battery, it is occasionally considered good practice to furnish ent circuit-breakers in the exciter circuits.

L ALTERNATING-CURRENT SWITCHBOARDS. — Some uipments are described and illustrated in the following paragraphs.

ow-voltage A-C. Boards (Fig. 7), made for circuits of not over s capacity at 500-volts, are usually built of panels 48 inches high on . Each a-c. generator may have its own exciter as shown in Fig. 7, ers may be operated in parallel and controlled from exciter panels. n this diagram the d-c. circuits are taken care of by an exciter rheostat, rheostat and a 2-pole field switch with discharge resistance. Each or is provided with a 3-pole single-throw knife switch, three ammeters, ltmeter switch, and a synchrononizing switch. Each feeder has a ch and an ammeter. A lamp ground detector and a voltmeter are n such a manner that the voltage can be read across any phase of e. In this diagram lamps are used for synchronizing.

igh-voltage A-C. Boards. — A similar arrangement of panels may small-capacity high-voltage switchboards, using oil switches in place itches in the generator and feeder circuits, and operating the volt- amp ground detector from potential transformers.

ow-voltage A-C. Boards. — For low-voltage a-c. circuits of greater an can be readily handled by the 48-inch panels, larger panels made hree sections with a total height of 90 inches are usually employed. vice where the voltage does not exceed 550 volts, knife switches are used but the practice is rapidly growing, of utilizing oil circuit-break- moderate voltages, owing to the greater safety, greater convenience, dvantages. Where the voltage does not exceed 2400, or the amount es not exceed 3000 kv-a., it is customary to use oil circuit-breakers rectly on the switchboard panels. Fig. 8 shows a typical switch- panel-mounted oil breakers arranged for the control of two exciters, ators, and two feeders.

ket devices comprise two voltmeters, one connected through trans- the bus, and the other arranged to plug on any phase of any of the ators through suitable transformers, one synchronoscope with two ng lamps, and one voltage regulator. The first panel on the left o exciters and is provided with two d-c. ammeters, one d-c. volt- rheostats, two 2-pole switches, and one equalizing switch. three panels are generator panels, each being provided with an a-c. . polyphase indicating wattmeter, field ammeter, field rheostat, , voltmeter and synchronizing receptacle, ammeter switch and a tic breaker.

wo panels on the right are feeder panels and are each provided with eters, a watthour meter, two overload relays, and an automatic

in excess of about 3000 kv-a., it is preferable to locate the oil breakers apart from the board and to control them either electrically or mechanically from the panel.

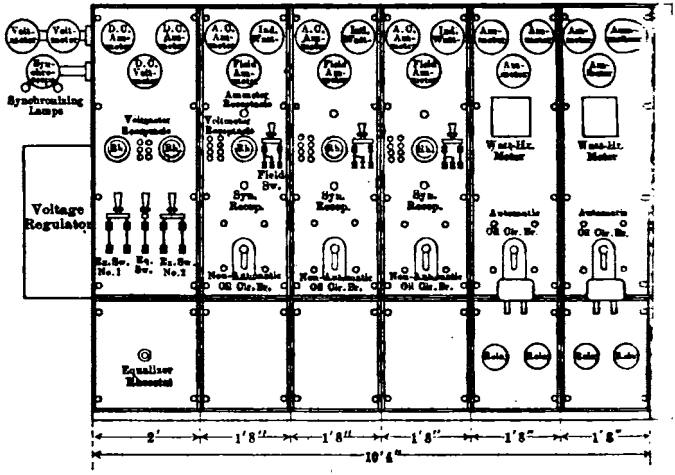

Fig. 8.

Large Distant-control A-C. Switchboards. — Where the amount of power to be controlled is large or the voltage is above 3300 it is customary to mount the oil circuit-breakers apart from the board and to operate them either mechanically or electrically. On these boards the usual equipment of instruments is mounted at the top of the panel, the switch-control handles are in the middle and the time-limit relays at the bottom. Targets and signal lamps to indicate the condition of the feeder are furnished with electrically operated boards.

Fig. 9 shows diagrammatically the various standard arrangements for electrically controlled equipment. *a* illustrates a typical vertical panel board with the instruments, control switches, relays, and similar devices mounted on the face of the panel.

b shows an arrangement of a control desk with the control switches placed on the desk and the instruments mounted on a wall in front of the operator. *c* shows an arrangement of control desk where there are comparatively few meters, these being set flush in the face of the desk. *d* shows a modification of the desk arrangement with the meters on a small slab or bracket extending up from the horizontal slab of the desk. *e* shows the control desk arrangement with vertical panels forming the back of the desk, the vertical panels containing the indicating meters. *f* is a further modification of the control desk arrangement with vertical panels containing the indicating meters and a complete switchboard at the rear to contain the recording meters, relays, and similar devices. polyphase indicating wattmeter to show the amount of power going over the transfer bus, a synchronoscope, power factor indicator, field ammeter, ammete in the circuit of the synchronizing bus, a frequency meter, and an indicati temperature meter. In addition to the indicating temperature meter a pote tiometer is sometimes provided with a dial switch for other temperat readings.

Control Desk with Separate Instrument Frame. — Fig. 11 shows the plan view, elevation and side view of a control desk provided with 7-inch diameter round pattern meters located on an instrument frame back of and above the desk. The height of the instrument frame is 7 feet 8 inches, which corresponds to the height of standard 90-inch switchboard panels mounted on the usual 2-inch channel iron base. This control desk with a total length of 11 feet, when fully equipped, is to take care of six 10,000-kv-a., 3-phase, 6600-volt generators, six banks each of three 3333 kv-a. step-up transformers, and four 110,000-volt transmission lines.

As shown by the miniature bus system placed on the top of the contro desk, each of the six sections intended for a generator and its bank of transformers is provided with a generator ammeter, transformer ammeter, generator indicating wattmeter, power-factor meter, voltmeter, and field ammeter, as well as four circuit-breaker controllers. Each generator, with the low tension side of its bank of step-up transformers, is provided with three breakers, one in the main generator circuit connecting the generator to generator bus, one for connecting this generator bus to a main bus, and th

Knife Switches for A-C. Service. — Up to 800 able difference in the heating of knife switches on di For larger capacities it is found that for the same sary to rate lower for alternating-current. The co designs and different capacities, a typical case being of 3000 amperes (d-c.), 30 degrees; 2500 amperes, amperes, 60 cycles, 30 degrees; 2400 amperes (d-c.) 25 cycles, 20 degrees; 1800 amperes, 60 cycles, 20 The 30-degree rise is that covered both by the N and A.I.E.E. Rules.

Field Switches (Fig. 1). — A modification of the knife switch (q. v.) as shown in Fig. 2 is furnished connection with field circuits. These field switches single-pole or double-pole, single-throw or double-t provided with an auxiliary contact and extra jaw used for connecting a resistor across the field termin the field is disconnected from the source of supp field discharges through this resistor without any kick such as will occur on the sudden opening of a ductive circuit without such a device.

Auxiliary Breaks and Quick-break Attachm furnished with knife switches in many cases so as t impossible to draw a dangerous arc by opening t slowly. Fig. 2 shows a typical quick-break knife blade here carries auxiliary blades, which are atta a hinge and spring. When the switch is opened, the auxiliary blades are held in the jaws by friction until they are suddenly jerked out by the spring tension. A similar attachment is used on the field switch shown in Fig. 1.

Starting Switches. — A modification of the standard knife switch is the multi-point starting switch used occasionally for starting d-c. motors, or synchronous converters or motor-generator sets from the d-c. end. These multi-point starting switches consist usually of single-pole, single-throw switches with several break jaws connected to various steps of the starting resistor.

Disconnecting Switches. — In all high-tension circuits it is customary to install knife-type disconnecting switches for isolating feeders, oil circuit-breakers, etc., or for making various connections that do not have to be opened under the knife switches for 2500 volts or less are usually of soapstone, marble or similar material; for higher vo kinds are used to support the switch jaws. Up to necting switches are made for either front connectio but for higher voltages they are almost invariably only.

Fig. 3 shows a disconnecting switch built in ca amperes at 7500 and 15,000 volts, and up to 600 a up to and including 66,000. In this switch a corr insulator is used with the switch part attached to t the bottom of the insulator attached to a metal bas

or proves defective, it can readily be replaced without the necessity g the balance of the switch. Owing to the severe mechanical stresses the instant of short circuit on f large capacity, latches are on these disconnecting switches them being blown open.

ecting Switches on Post sulators. — For voltages of d above, it is customary to sconnecting switches mounted in posts of the built-up type a sufficient number of sections secure the voltage test desired, indoor or for outdoor service. ype of switch if an insulator amaged or defective, the units dily unbolted from the built- nd replaced by a new section.

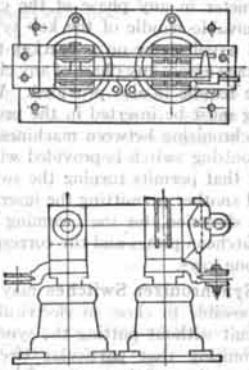

Fig. 3

SWITCHES are often used fically-operated devices such as field switches and circuit- In the type shown in Fig. 4 ing handle and direction dial ed on the front of the switchboard, while the contacts are back of and are made part of a drum-type controller. This construction en the d-c. operating voltage from the front of the board and readily

f for use on 550-volt control circuits. The handle is so designed urning to the trip position it can be pulled out in such a manner as t the control switch and extinguish the indicator lamps. For use ntrol switch lamp indicators with colored prisms are furnished.

WITCHES are commonly used for interrupting small currents at . They are particularly applicable for such uses as reading the oss various phases or circuits. By placing suitable receptacles on d feeder panels and using only one voltmeter plug switch, one n a suitable location can be used for reading the voltage across any circuit without the possibility of trouble from an attempt to con- more circuits to the voltmeter at the same time. Other types of nd plugs are used in connection with current transformers for con- uments into any phase of any circuit. By using suitable current l receptacles it is feasible to connect in testing meters for calibrat- hboard instruments without removing them from the board.

Google

The latest designs of instrument switches are bui attached or removable handles, depending on thei switch usually has an attached handle and the swit ammeter in any phase of the circuit. The voltme removable handle of the key type so that by havi and a voltmeter on a bracket the instrument can voltage across any phase of any circuit With the sy able handle is also provided. When synchronizing plug must be inserted in the proper receptacle and synchronizing between machines the escutcheon pla chronizing switch is provided with two slots, one pe key that permits turning the switch in one directio and another permitting the insertion of a key for tur site direction, for the incoming machine. Proper escutcheon plates and the corresponding pins on the wrong keys.

Synchronizer Switches may be fitted with auxi impossible to close an electrically-operated breaker circuit without putting the synchronizing plug in t chronizing that particular circuit. The tripping independent of the synchronizing receptacle so that out independently of the position of the plug.

Plug Switches for Arc Service are built in capac suitable for use on circuits up to 10,000 volts. Eac of fiber or similar material, with socket contacts at sisting of a metallic rod or tube with an insulating h usually mounted on the rear of the switchboard. through the hole in the panel connects the contacts

Pull- or Push-Button Switches of twin type are of oil circuit-breakers. The switch operated by one and the switch operated by the other button opens wiring are mounted on the back of the panel, so that a live circuit. By using pull buttons in place of p likelihood of the attendant operating the device uni or working about the switchboard. Red and gre prismatic lenses are used for signals. A little red between the button shows the last movement that the target shows one color and the indicating lamp the breaker has been tripped automatically.

Push-Button Switches with Signal Devices a former-type ground detectors, engine-room signal These are frequently arranged as the equivalent of mally maintained in one position by a spring to m and making other connections when pushed in by ha

Button and Snap Switches of various designs circuit (*see Wiring of Buildings*).

OIL SWITCH. — (*See Circuit Breakers.*) The drawn between the terms "oil switch" and "oil ci some cases the term "oil switch" is applied to a contacts that tend to remain closed, and the term "oi to a device with butt, brush, cone wedge or similar open and must be held closed by a toggle, latch c circuit-breaker" is the term usually employed.

END-CELL SWITCHES. — (*See Batteries, Storage.*)

COSTS. — Switches vary so much in design that it is impossible to give a comprehensive table of costs in a limited space. The following table gives the approximate range of (1922) prices of a few typical switches:

S. P. S. T.,	100–3000 amps., 600 volts.....	$3.50 to $130.00
S. P. D. T.,	100–3000 amps., 600 volts.....	5.00 to 200.00
D. P. S. T.,	100–3000 amps., 600 volts.....	6.50 to 235.00
D. P. D. T.,	100–3000 amps., 600 volts.....	9.00 to 360.00
S. P. D. T. Q. B.,	100–3000 amps., 600 volts.....	9.50 to 375.00
Disconnecting Switch,	15,000 V., 400 A.....	30.00
Disconnecting Switch,	37,500 V., 400 A.....	40.00
Disconnecting Switch,	73,000 V., 600 A.....	75.00
Disconnecting Switch,	115,000 V., 400 A.....	150.00
Simple Plug Switch.....		3.00
Simple Snap Switch.....		.50

The switching requirements of the several classes following.

DIRECT-CONTROL SWITCHGEAR IN GEN

— Direct-control panel switchboards are usually inst ing, power and railway service of low voltage and m boards for such plants are of the panel type and may floor, on a platform or in a gallery. All the switchin directly on the panels of the switchboard. With s simple to locate the switchboard in such a manner a the amounts of connecting cables and similar materia tive position of the switchboards and generators.

The amount of space required and the amount of c needed in a direct-current railway generating station imum by arranging to have only one polarity, usually board, and to place the negative and equalizer busse conduit near the machine, locating equalizer and machine.

DISTANT-CONTROL SWITCHGEAR IN A-C TIONS DISTRIBUTING AT GENERATOR V

that distribute current at the generator voltage there for the bus-bars, oil circuit breakers and control app pally on the amount of space needed for this portion locations are: 1. at the end of the building; 2. at th 3. in a separate switch-house.

Digitized by Google

of Switchgear. — The end of the building is a favorite location for ear when the number of feeders is such that this location provides ace for the breakers and the bus-bars, making due allowance for ture additions. With this arrangement it is customary in large ovide a number of galleries for the switching equipment. The is usually placed on one of the upper galleries so that the station an readily watch the operation of the machines which he is con-

e end of the building does not provide sufficient space the switch- ent is frequently located along one of the side walls, usually the from the boiler room in a steam station, or from the incoming pen- ydraulic station. The switching equipment when arranged in one eries along the side of the building can easily be extended, as the of the building provides for the switchgear proportionately with ailable for the generating equipment. With this arrangement it is mary to locate the generator breakers directly opposite the individ- s and to run the bus-bars the length of the station; the length of r leads will then be reduced to a minimum and it is sometimes possible conductors for these leads. The switchboard itself, if electrical provided, may be located either on one of the side galleries or at he building in such a position that the switchboard attendant can h the operation of the machines which he is controlling.

on of this scheme of utilizing the side walls is to provide a separate and to control all of the apparatus electrically from a switchboard building or from a switchboard in the switch-house as preferred.

s for Bus-bars and Circuit Breakers. — The arrangement of ng structures for bus-bars and circuit breakers is influenced chiefly ge and capacity of the circuits. For circuits of moderate capacity ts or less, mechanical control is usually employed, though electrical metimes used; for circuits of large capacity or of higher voltage ctrical control is practically universal.

tures for Mechanical Control. — Fig. 1 shows a typical arrange- nt mechanical control applied to circuit-breakers mounted on the metal framework. The view shows a section through a 2300-volt, rator circuit. Each circuit is provided with a 3-pole oil circuit- h can be connected to the three-phase bus-bars supported on the . Sprocket-operated face plates with suitable resistors are located ent to allow for the regulation of the voltage on the generators. and voltage transformers for the instruments are located back of a suitable framework or on the wall.

tures for Electrical Control of Moderate Capacity. — Fig. 2 on and the front and rear elevations of a part of the structure for breakers and bus-bars for the control of four 500-kw., 2300-volt, rators, nine 3-phase feeders and six single-phase feeders. Though and voltage of these machines would have permitted the use of l oil circuit-breakers, other considerations caused the adoption of ration for the breakers and of inclosed bus-bars. The relative be circuit-breakers, disconnecting switches, series transformers, rmers, bus-bars, etc., are indicated in the cut. The bus-bars of pper strap are supported on petticoat insulators, and porcelain e used for insulating the leads where they pass through the back ructure. The breakers here used are self-contained and all three he same compartment. The disconnecting switches are mounted apstone bases.

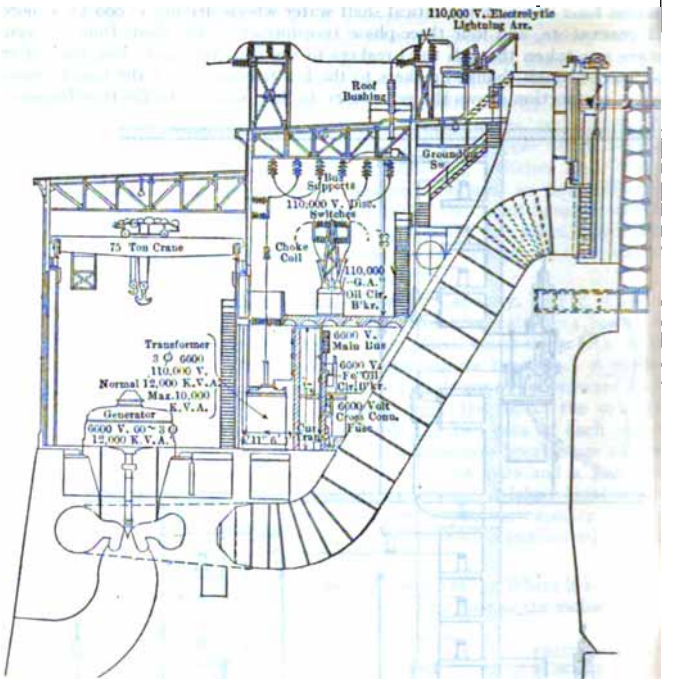

Fig. 7

SWITCHGEAR IN SEPARATE BUILDING. — In many cases it proves desirable to utilize a separate building for the transformers and switchgear. Fig. 8 shows a sectional view through a typical station of this kind with two 500-kw. 250-volt exciters, six 12,000-kv-a. 6600-volt three phase generators, six banks of transformers, and four 110,000-volt transmission lines. Advantage is taken of the natural slope of the ground as the plant is built on the side of a hill. The diagram for this station is shown in Fig. 9.

Bus Connections. — Each generator as shown in Fig. 9 is normally used with its own bank of step-up transformers. Three circuit-breakers, however, are provided with each transformer and generator group so that, if desired, any generator or any bank of transformers may be connected to the 6600-volt bus-bars. The low-tension neutral bus is provided with a grounding resistor and each generator is furnished with a single-pole, single-throw knife switch for connecting it to this grounding bus. In a similar manner the high-tension neutral bus is provided with a grounding resistor, and each bank of transformers is furnished with a single-pole, single-throw knife switch for connecting its neutral point to this ground bus.

Ventilation of Generators and Field Rheostats. — It should be noted that it is intended to locate directly opposite each machine a field-regulating panel containing electrically operated field rheostats and field switches, the

icators (q.v.), but are connected between the two circuits which
t into synchronism. They are designed to indicate by a movable
the machine to be synchronized is running too fast or too slow,
n synchronism with the circuit to which it is to be connected.

Type. — A fixed coil is connected through a resistor across the
se circuits across one phase. The movable coil is connected
nser to the terminals of the machine to be synchronized, and
in a position at right angles to the fixed coil by means of a
ill be no torque acting on the movable coil when the machine
are either exactly in phase or 180° out of phase with respect
cause in either case the currents in the fixed and movable coils
e. When the two circuits are not in synchronism, the pointer
novable element will swing back and forth over the scale. In
ish the point of synchronism from that of 180° phase dis-
nslucent glass scale is placed in front of the pointer, the scale
by a lamp connected to the low-tension side of a "synchroniz-
which causes the lamp to be lighted when coincidence of phase
and bus occurs. Hence the pointer is visible only during
g, i.e., it will appear to rotate in one direction; the direction
tes whether the machine is fast or slow.
t is applicable to single-phase as well as polyphase circuits,
nnecessary to indicate synchronism of more than one phase
The moving-coil synchroscope is ordinarily used with trans-
the line voltage down to 110 volts.

vane Type. — This instrument is similar to the moving-vane
tor meter (q.v.). The movable iron vane is magnetized by
connected across the machine to be synchronized. A rotat-
ced by passing current from the bus-bars through a split-
two fixed coils placed nearly 90° apart. The pointer indicates

Digitized by Google

at any instant the phase displacement between the voltages of bus-bars and machine. The speed and direction of its rotation depends on the difference in frequency of the two circuits. When exact synchronism is reached the pointer will remain at rest in a vertical position. The instrument is usually connected through potential transformers; on polyphase circuits only one phase is used.

Lincoln Synchroscope. — This instrument has a rotating iron core carrying two coils placed nearly 90° apart; one coil is connected through a resistance across the other through an inductance, both being supplied from the machine to be synchronized. A bipolar, laminated iron field is magnetized by means of a coil connected to the bus-bars. The operation of this instrument is similar to that of the moving-coil type of single-phase power-factor meter. A pointer attached to the moving system indicates at every instant the difference of phase angle, as well as the approximate difference of frequency, between the voltages of the bus-bars and that of the machine to be synchronized. The current is led into the armature coils through slip rings as the armature is free to revolve. These instruments are furnished for direct connection to circuits of 110 or 220 volts; other circuits require transformers.

Weston Synchroscope. — This consists of an electrodynamometer instrument having the fixed coils connected to the buses through a non-inductive resistance and the moving coil to the incoming machine through a condenser. When the voltage of the machine is either in phase with or in opposition with the bus voltage no torque is exerted on the moving coil, and the pointer is vertical. For any other phase relation the pointer will be deflected to right or to left when the incoming machine is ahead or behind. The pointer is back of a translucent screen, and only its shadow, cast by a synchronizing lamp, can be seen. Thus when the shadow is seen to be vertical, the incoming machine is in step and when the machine is too fast or too slow the shadow appears to rotate in the clockwise or counter-clockwise direction respectively.

Use of Reactance in Synchronizing. — Synchronous machines may be connected to the bus through suitable current-limiting reactors, and brought up to speed by an auxiliary motor. They will synchronize after a few oscillations. With large machines, considerable current rushes will occur when the reactors are short-circuited. Osnos has described (Elektrotechnik und Maschinenbau, Vol. 19, p. 29, 1917), the use of reactors having an auxiliary d-c. winding which may be connected in the field circuit. The field current is very small at starting, and as it increases the d-c. flux in the reactors reduces their reactance gradually to a value permitting the machine to synchronize as it approaches normal voltage. The reactors may then cut out of circuit without disturbance.

COSTS. — A moving-coil synchroscope costs approximately $80, a polyphase moving-vane synchroscope costs approximately $70; a Lincoln synchroscope for voltages of from 110 to 220 costs from $55 to $65; transformers and accessories are extra in all cases. Only one synchroscope or synchronizer is required in a station, although a spare instrument is usually installed. (1922 prices.)

PH INSTRUMENTS AND APPARATUS. — (*See also nication; Telegraph Lines; Telegraph Systems.*) The more impor- nts and apparatus used in the various systems of telegraphy are *n.*

A telegraph key is essentially a switch for opening and closing a us types of keys are in use.

Morse Key (Fig. 1). — The knob end of the lever is normally s to open the key by an adjustable coiled spring. The auxiliary nstitutes the "circuit closer" by it of the line is kept closed, through the key is not in use.

Fig. 1. Standard Morse Key

ng Key. — While the key of the ustrated in Fig. 1 is still standard, ms, having a sidewise rather than n motion of the lever, have come e. One type of these, known as the double-acting key, has its arranged to swing in a horizontal arc between two stationary The key lever normally stands clear of both points, leaving the movement either to the right or left will close the circuit.

Another type of key is represented by such instruments as which are more properly semi-automatic transmitters. The ey lever in this is similar to that of the double-acting key just ver normally standing in the middle or open position. When d to the left, it closes the circuit in the ordinary way to make ushed to the right, a vibratory reed is set in motion, which opens ircuit rapidly to form a succession of dots, the number of dots by the length of time the key is held in this position. By this tor is relieved of the muscular effort of rapidly vibrating the .

Paralysis. — The objects of the double-acting key and of the ther similar transmitters are, in the main, twofold: To relieve malady known as "operator's paralysis" or "loss of grip," s follows long continued use of the ordinary key; and to d of transmission.

C TRANSMITTERS. — (*See also Telegraph Systems.*) The utomatic systems usually employ a paper tape, perforated in the code to be sent. This tape, so prepared, is caused, by ng rollers, to pass rapidly through the transmitter, the perfo- s they pass to permit electrical contacts to be made which mpulses to the line.

(Fig. 2). — A standard form of in Fig. 2. The winding of the connected directly between the own on the base of the instru- nature is attached to a lever nions in a fixed support. The provided for the lever permit a n movement of its free end, the ent being caused by the pull of , and the upward one by the force of an adjustable retractile ged construction of the armature lever and its co-operating to produce the necessary loudness and quality of sound.

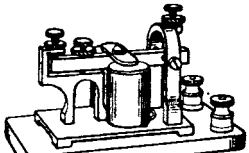

Fig. 2. Morse Sounder

Digitized by Google

This, with the heavy retractile spring necessary for the prompt return m ment of the lever, makes the instrument require more energy for its oper than can usually be delivered to it directly over the line wire. On this acc the sounder magnet is usually placed in a local circuit, which is in turn contr by the more sensitive relay, the magnet of which is placed directly in the lin

When used in local circuits sounders usually have a magnet resistanc about 4 ohms, and require about ¼ ampere for their proper operation. Wh the sounder magnet is placed directly in the line, it is termed a main line sou and differs in no respect from the local sounder except that its magnet is wo to about 20 ohms.

RELAYS. — Two kinds of telegraph relays are employed; the ordinar Morse relay, and the polarized relay. The armature of a Morse relay al moves in the same direction irrespective of the direction of the current impu while the armature of a polarized relay moves in one direction for a posi impulse, and in the opposite direction for a negative impulse.

Morse Relay (Fig. 3). — The Morse relay has the same essential p as the sounder, with the addition of a pair of contacts closed by the arma lever when in its attracted position. The armature lever is usually mounted vertically, and is made light in construction so as to be capable of the necessary rapid to and fro movements with a minimum expenditure of energy. The retractile spring is light and delicately adjustable. An extra pair of binding posts is added to form the terminals of the local circuit, these binding posts being wired to the armature and the magnet frame, respectively, so that the circuit between them will be closed upon attraction of the armature. The back contact of the relay is non-conduct so as to avoid closing the circuit when the armature is released. A typ form of relay, known as the "pony relay," is shown in Fig. 3.

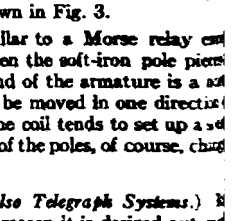

Fig. 3. Morse Relay

Polarized Relay. — A polarized relay is similar to a Morse relay ex that the end of the armature which plays between the soft-iron pole piece permanently magnetized. For example, if this end of the armature is a n magnetic pole, then, obviously, the armature will be moved in one direction the other, according as the magnetizing force of the coil tends to set up a n pole in one or the other of the poles. The polarity of the poles, of course, chan with the direction of the current in the coil.

RECORDERS OR REGISTERS. — (*See also Telegraph Systems.*) R corders or registers are used only where for some reason it is desired autom cally to record a message. Simple forms of comparatively slow speed regis are used in connection with district telegraph messenger and fire alarm telegr service. More elaborate high speed recorders are used in connection with au matic and printing systems. A special form of recorder, known as a si recorder, is used on submarine lines.

Slow Speed Registers. — The paper upon which the message is to recorded is a narrow strip of tape, carried on a reel. A clock-work mo is provided for moving the tape at uniform rate under the recording pe stylus. The receiving magnet of the register is placed in a local circuit co trolled by a relay in the line, and this magnet, when attracted, serves eit to move the pen or stylus against the tape or the tape against the pe stylus, in either case resulting in a mark upon the tape. Some registers re by merely embossing the tape; others by marking thereon with a pen or pe and still others by actually punching holes in the tape.

Digitized by Google

peed Recorders. — In very high speed automatic and printing eiving devices have been developed giving a record in ink on ordi-, or a record on a sensitized paper, or in ordinary print. For a of the more important printing recorders see below under *Telegraph*

nical Recorders. — For very high speed work with non-printing he chemical recorder has been generally found the most satisfactory. ape is impregnated with a solution of some unstable chemical com- will easily be decomposed upon the passage through it of an electric which, either by changes within itself or by combination with the he pen through which the current passes, will cause a definite dis- the tape upon the passage of the current.

n sensitizing solution is formed of 5 parts of prussiate of potash, ammonic nitrate, and 100 parts of water. Under electric decom- solution sets free an acid which attacks the iron of the pen, leaving on the paper.

Recorder. — The high electrostatic capacity of long submarine necessary some modification of the methods ordinarily employed work. This high capacity results in the variations in the signaling less sharply defined than on land lines. The receiving apparatus es must, therefore, be responsive to minute variations in current xtent as to preclude the use of the responsive devices employed

recorder is merely a special form of recording galvanometer. The proper is of the D'Arsonval or swinging coil type. The motion imparted to a very light glass tube bent to form a siphon and sus- its long end opposite the receiving tape and its short end dipping ank of ink. The siphon moves across the width of the tape, the the tape being agitated so as to be nearly frictionless. Displace- record line to the left of an imaginary zero line represent dots, ight, dasbes. The Continental code is universally employed when rder is used.

APH REPEATERS. — When, for any reason, it is desired to ages from one line to another line without manual retransmission, repeater is used. By its use lines of excessive length may be a consequent increase of speed may be attained. Also, the en useful in automatically transmitting messages from a through le circuit.

natic or "Button" Repeater (Figs. 4 and 5). — A fundamen- of the repeater may be gained from Fig. 4, where a relay magnet

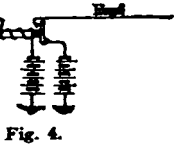

Fig. 4.

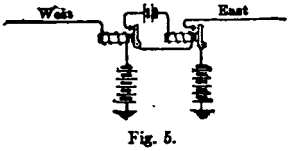

Fig. 5.

line causes an armature to act as a key to make and break the his conception may be carried a step farther by considering Fig. 5, magnet in the West line receives impulses from the distant West ontrols a local circuit containing a battery and a second relay latter causes its armature to act as a key in transmitting signals

Google

to the East line. From these two figures it is obvious that such a repeating scheme would transmit in one direction only, providing no facilities for transmitting from East to West.

The "button repeater" of early telegraph history consisted practically of two such sets of relays as are shown in Fig. 5, these sets being arranged for transmission in opposite directions. Only one set of relays could be kept connected to the line, for when both are connected in, the impulses sent out from the repeating station on, say, the West line react on the line relay of that line at the repeating station in such way as to act through its local circuit to send impulses back on the East line. This difficulty was overcome in the button repeater by providing a button switch, operated by an attendant at the repeater station, this switch being thrown manually in one direction or the other, according to the direction of transmission desired.

Automatic Repeaters. — The necessity of an attendant for the purpose of working the switch of a repeater has long since been overcome by the production of the so-called automatic repeaters, of which there are many forms. In these the arrangement is such as to automatically prevent the transmitter of the line that is being repeated into from reacting to make and break the line over which the signals are initially sent.

The Milliken Repeater (Fig. 6). — This is one of the most common of the automatic repeaters for the simple Morse system. Its action may be

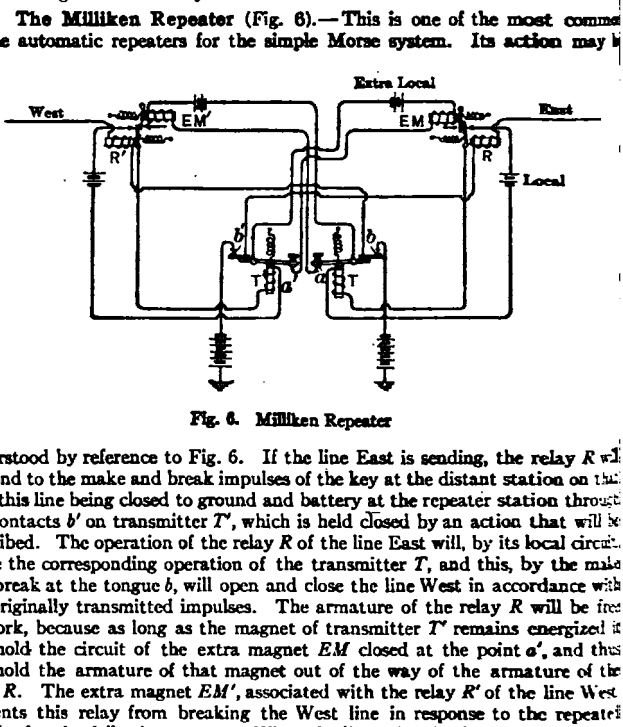

Fig. 6. Milliken Repeater

understood by reference to Fig. 6. If the line East is sending, the relay R will respond to the make and break impulses of the key at the distant station on this line, this line being closed to ground and battery at the repeater station through the contacts b' on transmitter T', which is held closed by an action that will be described. The operation of the relay R of the line East will, by its local circuit, cause the corresponding operation of the transmitter T, and this, by the make and break at the tongue b, will open and close the line West in accordance with the originally transmitted impulses. The armature of the relay R will be free to work, because as long as the magnet of transmitter T' remains energized it will hold the circuit of the extra magnet EM closed at the point a', and thus will hold the armature of that magnet out of the way of the armature of the relay R. The extra magnet EM', associated with the relay R' of the line West, prevents this relay from breaking the West line in response to the repeated signals, for the following reason. When the line West is closed by the transmitter T, the current through the relay R' holds its armature attracted. When

st is opened, however, by the transmitter T, the circuit of the extra
' is also opened by this transmitter, and the retractile spring of the
et prevents the armature of the relay R' from falling back. In this
relay of the West line cannot react on its own transmitter to cause
breaks in the transmitting line. When the operator at the distant
he West line breaks, the relay R' is then permitted to open and thus
ansmitter T' to open the line East.

lex and Quadruplex Repeaters. — Automatic repeaters are
for duplex and quadruplex systems than those already described
wire working. The reason for this is that in the duplex or quadru-
smission from a given sending operator is always to a corresponding
rator, and — as between these operators — it is never in the reverse
Hence, a one-way repeater only is required for any one of the several
transmissions. It therefore suffices to place the transmitter at
station under the control of the neutral or polar relays of the duplex
x, the repeating operation for each set being in one direction

T SUPPLY. — Either a battery or a dynamo may be used to
rrent required for telegraph transmission.

attery. — The gravity battery was once almost universally used
current in telegraph systems. It is still largely used on unim-
and in small offices where it is not economical to employ machine
secondary batteries.

attery. — The storage battery, on account of its extremely low
ance, is capable of handling any desired number of lines in parallel,
the use of the so-called "universal battery system," in which a

it may be made to generate either positive or negative according to which of t regular sets it is to replace. The dynamo arrangement employed by the Pos Telegraph-Cable Company is shown in Fig. 9.

TELEGRAPH SWITCHBOARDS (Fig. 10). — Telegraph switchboa were the precursors of the vastly more complicated telephone switchboar The telegraph switchboards which have been most commonly used in America are of two types — the "strap and disc" and the "cross-bar."

A simple "strap and disc switchboard" with its connections is shown in Fig. 10. The lines terminate in the vertical straps and the instrument circuits, each including key and relay, terminate in the horizontal rows of discs, the discs in each row being connected together, as indicated by the dotted line. This figure also shows a typical method of line and instrument protection.

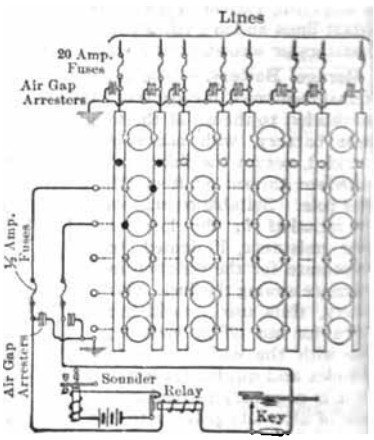

Fig. 10. Strap and Disc Switchboard

COSTS (Pre-war figures). — The following prices were current prior to the World War, standard Morse key, $2.20; double-acting key, $10.00; Vibroplex, $12.00; standard Morse sounder, $3.00; standard Morse relay, $7.0 polarized relay, $20.00; ink recorder, $35.00; punching recorder, $75.00. APH LINES. — (*See also Poles and Cross-Arms; Telephone nsmission Lines; Wires and Cables.*) The conductor over which n is effected is commonly referred to as the line. These conductors s open wires, or they may be disposed in aerial, underground and cables.

WIRE LINES. — Most of the open-wire telegraph lines are of hard- per or of galvanized iron. Recently a wire known as copper-clad sting of a core of steel wire with an outer shell of copper welded appeared as a competitor. For the properties of these wires *nd Cables, Bare.*

wn copper wire is vastly superior to iron in point of conductivity ability to withstand the action of the elements. Galvanized-iron ntageous in point of first cost, it has a somewhat greater strength, fe ranging from 4 to 20 years, according to atmospheric conditions. steel has a conductivity superior to that of iron, but inferior to that It is stronger and somewhat cheaper than hard-drawn copper, and ss the same ability as copper to indefinitely withstand the action of .

ohm values (i.e., the weight in pounds of a wire one mile long sistance of one ohm) of the various grades of wire used for tele- poses are as follows: E.B.B. iron, 4700 pounds; B.B. iron, 5500 l, 6500 pounds; hard-drawn copper, 895 pounds; copper-clad steel uctivity 40 per cent of solid copper), 2010 pounds.

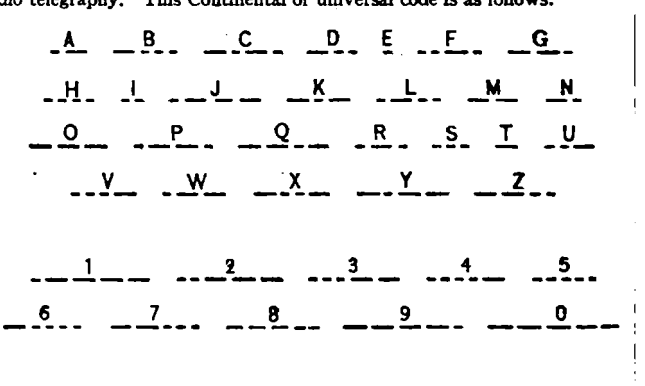
ht modification the original system of electric telegraphy devised still largely used, the great bulk of telegraph work still being done its simplest form it consists of a circuit, connecting the points ich intelligence is to be transmitted, a battery or other generator it for supplying the current, a key at each station for facilitating and closing of the circuit by hand, and a sounder for giving response ng and closing of the circuit by audible clicking.



APH CODES. — Two different codes are used in telegraphy, ode and the Continental code.

ode. — The Morse code is an arbitrary system of interpreting the rs, numeral digits and punctuation marks employed in writing, this n being intelligible either audibly or visually. This code is formed es and spaces. The dot is made by a quick depression of the key its immediate release; the dash by a depression of the key with a se; and the space by permitting a short interval to elapse between on of two dots. Thus, the letter *a* is represented by a dot and a is formed by depressing the key, immediately releasing it, depress- again and holding it a slight interval before release. Similarly, is represented by two dots, and it is formed by depressing and key twice in rapid succession. The letter *o* is an example of a so- letter, and is represented by dot-space-dot. It differs from the in that an interval of time is allowed to elapse between the two Morse code, as it has been employed practically without modifi- the time of Morse, is as follows:

Digitized by Google

Continental Code. — The so-called Continental Code differs from the Morse code in that it is composed entirely of dots and dashes, employing no spaces. It is almost universally used for submarine lines, for land lines in nearly all countries except the United States, and is the world's standard for radio telegraphy. This Continental or universal code is as follows:

SIMPLEX OR MORSE SYSTEM. — There are two types of circuit used, the so-called "open-circuit" system and the "closed-circuit" system. In both cases but one line wire is employed, the earth forming the return circuit.

Closed-circuit System (Fig. 1 and 2). — This system is mainly used in the United States. In its simplest form the keys and the sounder magnets are placed in series in the line with a source of current, as shown in Fig. 1.

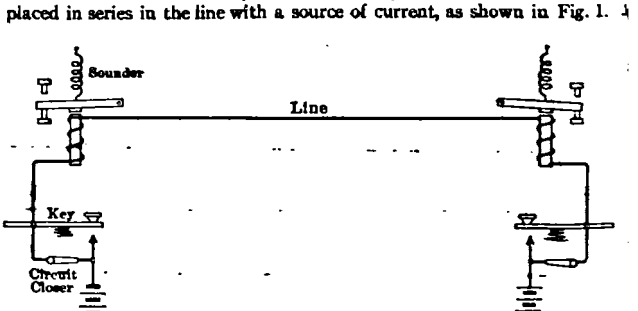


Fig. 1. Simple Telegraph Circuit

switch or "circuit closer" is provided with each key, the function of which is to keep the line circuit closed around the key contacts when the key is not in use. When an operator begins to send he opens this circuit-closer, thus making his key effective in controlling the line circuit. When the line is idle, the circuit is closed at all stations, and all sounder levers are held down by the magnetizing effects of the current flowing in the line.

Digitized by Google

but two stations are shown, one at each end of the line. Obviously
e or way stations could be added by merely placing the necessary
unders in the line circuit at the desired points.
ommon practice is to employ a line relay at each station as the device
ponsive to the line currents, using this line relay to control a local
aining a local battery and a sounder. The reason for the choice of
more complicated system for commercial practice is that the sounder,
make the necessary amount of noise, is required to be of a rather
re and is not as readily responsive to the comparatively small line
s the relay, which, having no other function than to be responsive,

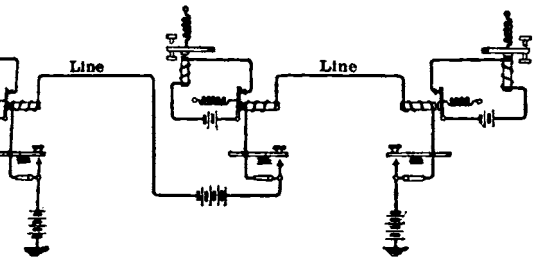

Fig. 2. Closed Circuit System with Way Stations

le of the required sensitiveness. A line equipped for three such

the possible speed far below the limitations pres
operators. While speeds of over fifty words a mi
experts during short periods of time, and while ope
ceive thirty-five and forty words a minute in a
average under working conditions is far below t
twenty words a minute.

DUPLEX SYSTEMS. — Duplex telegraph
ous sending of two messages in opposite directio
different methods are employed for making the re
sive to the home key. These two methods are te
"bridge" methods, respectively. There are also
sending impulses over the line, one of which depe
strength and the other on changes in current direct

Differential Method (Fig. 4). — The differen
stood from a consideration of Fig. 4, which sho
windings in opposite directions. Current
from the battery is supplied through one
of these windings to the line, and through
the other of these windings to the artificial
line represented by a resistance at the left.
The resistance and other characteristics of
the artificial line are made approximately
equal to those of the real line, so that im-
pulses of current sent by means of the key
from the battery to the line will produce
no effect on the relay, because an equal
current passes also through the artificial
line. Obviously, however, there is no such diffe
currents, and, therefore, the relay is re-
sponsive to currents from the distant
station.

Fig.

The differential method is ordinarily
employed in land telegraphy.

Bridge Method (Fig. 5). — The
bridge method of rendering the home
relay unresponsive to the home key and
responsive to the distant key is illus-
trated in principle in Fig. 5. In this

arm of the balancing rheostat, delicate adjustmen
and artificial cables are secured.

Jacobs' Duplex for Submarine Cables — Submarine cables frequently have two conductors, making

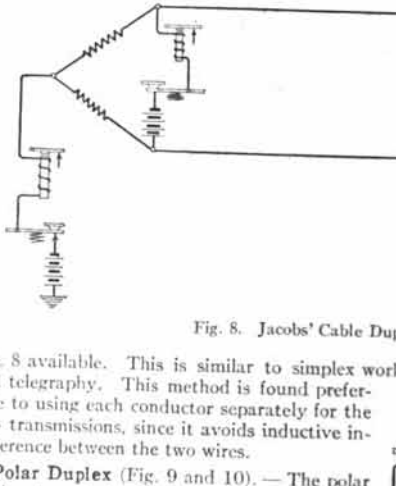

Fig. 8. Jacobs' Cable Du

Fig. 8 available. This is similar to simplex worl
and telegraphy. This method is found prefer-
able to using each conductor separately for the
two transmissions, since it avoids inductive in-
terference between the two wires.

Polar Duplex (Fig. 9 and 10). — The polar duplex depends for the principal feature of its operation on the fact that a polarized relay will move its armature oppositely for opposite directions of current. The key used in sending operates to close and open a local circuit which controls a pole-changing transmitter. The action of this is made clear in Fig. 9. With the key closed, as shown in that figure, the negative side of battery will be connected to line and

Digitized by Google

th the key open, the reverse will be true. The circuit of the polar duplex hown in Fig. 10.

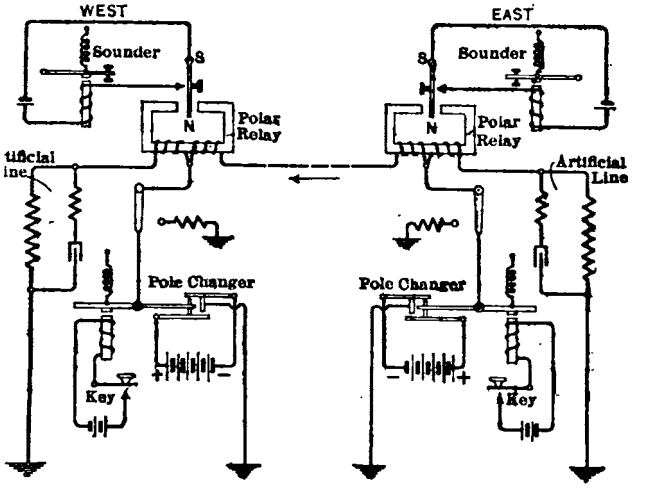

Fig. 10. Polar Duplex

QUADRUPLEX SYSTEMS. — In quadruplex systems four messages, in each direction, may be transmitted simultaneously over a single line

Edison Quadruplex (Fig. 11 and 12). — The Edison quadruplex depends its principle of operation on a combination of the two duplex systems, Stearns and the polar just described. At each station two relays are pro-d, one, the neutral relay, responsive to currents in either direction, and other, the polar relay, responsive only to currents in one direction. At each

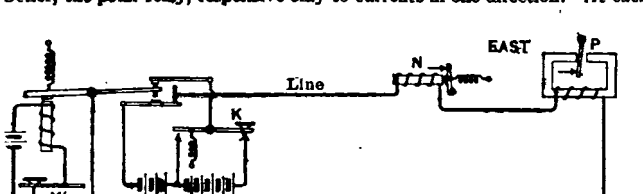

Fig. 11. Principle of Edison Quadruplex

on also two key-controlled transmitters are provided, one of which operates, the polar duplex, to change the direction of current in the line and the r, as in the Stearns duplex, to increase and diminish the strength of cur-flow.

ie principle of transmitting in one direction by means of the Edison quad-x is indicated in Fig. 11, where *N* is the neutral relay and *P* the polar relay e East station. *K* and *K'* are transmitting keys at the West station, key

K operating to alternately weaken and strengthen the line current, and [illegible] operating as a pole changer to reverse the line current. As shown, the line wi[illegible] always have some current flow, the amount being determined by key K and th[illegible] direction by key K'. As the neutral relay will operate on currents of eith[illegible] direction, if strong enough, it will be responsive only to key K; and as the po[illegible] relay will operate on either current strength, if in the right direction, it will b[illegible] responsive only to key K'.

The circuits of the Edison quadruplex are shown in Fig. 12. The windings [illegible] the neutral relays N and of the polar relays P are in each case made different [illegible] for the same reasons as pointed out in connection with the Stearns and pol[illegible]

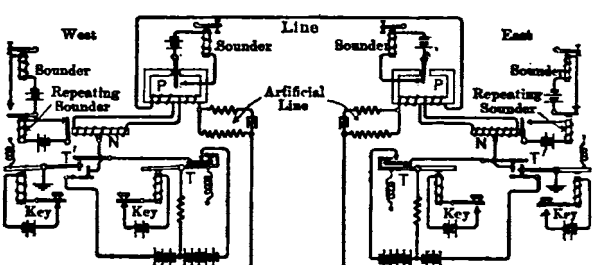

Fig. 12. Edison Quadruplex

duplex systems. At each station of the "quad" system one winding of ea[illegible] relay is in the line, and the other in the artificial line. As will be seen from Fi[illegible] 12, the two transmitters at each station modify the main battery current, [illegible] pointed out in connection with Fig. 11, the continuity-preserving transmitter [illegible] controlling the current strength and the pole-changing transmitter T' contro[illegible] ling its direction.

Key Systems for Quadruplex Working.— In the quadruplex so far de[illegible] scribed, the current was supplied by batteries, and the strength-varying tran[illegible] mitter operated to accomplish its purpose by alternately cutting a portion [illegible] the line battery out of and into the circuit. Where dynamos furnish the cu[illegible] rent, a different scheme is employed. One system, known as the Field key sy[illegible]

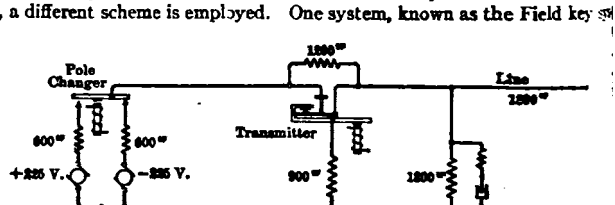

Fig. 13. Field Key System

tem, is illustrated in principle in Fig. 13. Two dynamos are employed, havin[illegible] opposite poles grounded. The pole changer merely chooses between the tw[illegible] live poles for securing its reversals in polarity. The continuity-preservin[illegible] transmitter varies the current strength in the line by changing the resistanc[illegible] relations as shown. Thus, when the key is closed, the 1200-ohm resistance i[illegible] short-circuited and the 900-ohm "leak" resistance to ground is cut off. Th[illegible]

Digitized by Google

these circumstances flows to line at full strength. When the key 1200-ohm resistance is introduced in the line and the 900-ohm ffective. The resistances shown are those for an 1800-ohm line.

EX SYSTEMS. — The term "multiplex" should include duplex ex systems, but practice has been otherwise, and has resulted he term "multiplex" principally to a system wherein two moving switches, one at each end of the line, serve to connect ing sets of telegraph instruments momentarily and successively lation with the line. While each set of instruments, therefore, is the line for only a small fraction of the total time, the successive cur so rapidly as to afford, to all intents and purposes, a practi- s use of the line.

nchronous Multiplex System (Fig. 14). — The principle of the onous multiplex system is shown in diagram in Fig. 14. Six sets , each consisting of a pole-changing key and a polar relay, are end of the line. The two switch arms of the synchronous rotary

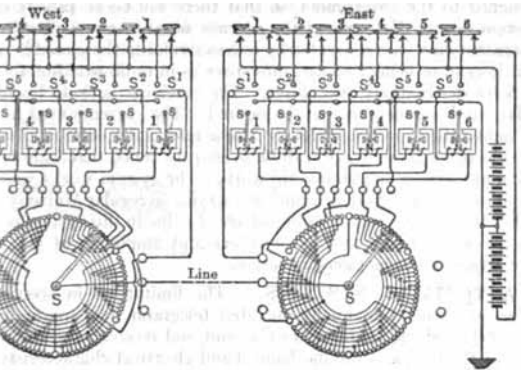

Fig. 14. Delany Synchronous Multiplex

nade to revolve in unison, so that the correspondingly numbered nts at each end will be simultaneously connected with the line. rms make about 180 revolutions per minute, and as each set of onnected with the line twelve times at each revolution, it follows f instruments is connected with the line thirty-six times per a much shorter interval than that required to make the short- erefore, any closure of a key which an operator may make will a time during which at least one connection will be made with particular embodiment of the Delany system shown polarized changing keys are used, the advantage of this being that the will remain in the position to which it was last brought by a in spite of the rapid interruptions caused by the synchronous l switch lever, S^1, S^2, etc., is associated with each key and ed by the operator to one or the other of its positions, accord- e is sending or receiving.

orage batteries is by motor-generator sets, the motor being adapted to the source energy and the generator being shunt wound. Shunt-wound generators driven internal-combustion engines are used as emergency charging equipments.

POLE CHANGERS. — Ringing current in central offices is usually produced by alternating current generators or by pole changers. The latter are vibrating contact-makers having natural frequency corresponding to the frequency of the current desired. They are operated by direct current from a storage battery or other source. The Warner pole changer, Fig. 10, is widely used for ringing ordinary telephone bells at a frequency of from 16 to 20 cycles per second. Pole changers for multiple frequency are also used to ring harmonic bells on party lines.

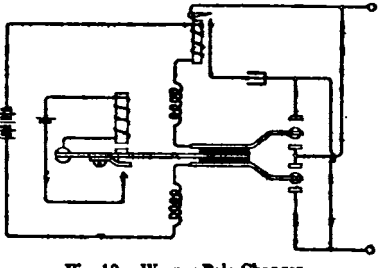

Fig. 10. Warner Pole Changer

IMPEDANCE COIL. — An impedance coil is a single coil of wire wound on an iron core. In telephony the iron core usually is of wires, or occasionally sheets.

INDUCTION COIL. — A step-up transformer used in a telephone circuit called an induction coil in telephone parlance. Fig. 11 shows the use of such transformer in a local battery set. The battery and the carbon button are connected in series with its primary winding; the line and the receiver are connected in series with its secondary winding. The function of the induction coil is to convert the feeble variations of direct current of low e.m.f. into alternating currents of higher e.m.f. in order that it may pass over the line with less loss.

Fig. 11. Induction Coil in Local Battery Set

Local battery induction coils have a large ratio between the two windings. The primary winding is of low resistance and of fewer turns than the secondary winding. Single silk insulated wire is used for both windings; practice varies as to wire sizes and turns; a representative example has 350 turns of No. 20 B. & S. gage wire in the primary and 2400 turns of No. 30 B. & S. gage wire in the secondary. Other examples use from 200 to 700 turns in the primary, 700 to 3000 turns in the secondary, No. 20 to No. 28 B. & S. gage wire in the primary and No. 26 to No. 36 B. & S. gage wire in the secondary.

The induction coils in common battery sets have different functions from those in local battery sets. Figs. 12 and 13 show two forms of common battery telephones using them. In most cases one function of the induction coil is to in-

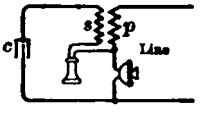

Fig. 12.

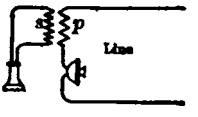

Fig. 13.

sulate the receiver from the direct current of the line, so that its permanent magnetism never shall be opposed by direct current flowing in its coil. In Fig.

e line operates the ringers at all stations. Each station has a particular group periods of bell ringing, which group only it is meant to answer. Up to five ations from one to five short rings per station serve well. Beyond five, long d short rings are combined. Magneto sets, both series and bridging, are used non-selective party lines. The generator of the magneto set at any station n ring all the bells of the line at once, and operate the central office signal also, the line leads to a central office. The bridging system is so used on many ivate lines, farmers' co-operative lines, rural toll lines, and, to a degree, on change party lines in towns.

Non-selective stations should not answer other calls than their own; this tra listening on lines is an extra drain on local batteries in sets having them; also destroys privacy. A receiver off the hook impairs signals unless circuits e specialized; for example, as follows:

If a condenser of low capacity, say one-half microfarad, be placed in series th the receiver, it will obstruct ringing current (frequency 20 per second) nsiderably, but voice currents (mean frequency 800 per second) very little.

Selective Party Lines are equipped with ringers arranged to respond each its own call, the others remaining silent. There are three such methods in e in the United States, and still a fourth method, which has certain very de- led advantages, is coming into use.

Metallic Circuit Two Party Lines (Fig. 20.) — On metallic circuits ective two party working is simple. Fig. 20 is the standard system of the

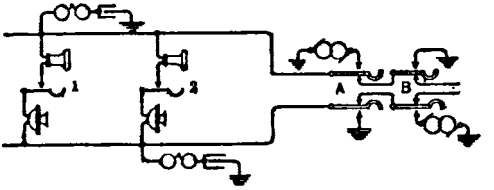

Fig. 20. Two Party System

sociated Bell Telephone Companies in the United States. Each wire of the etallic circuit is used as a private grounded ringing circuit to one station, and e pair of wires is used as a talking circuit by each station. Key *A* connects e ringing generator to the upper wire, ringing station No. 1; key *B* rings ation No. 2. If a station answers while being rung, the other station is not ng falsely, the ground on the non-ringing side of the used key preventing that.

Harmonic Selective Systems (Fig. 21) operate on the principle that ringer having a spring-supported armature will ring for one frequency of cur- nt but not for any other frequency. Frequencies of 16, 33, 50 and 66 per

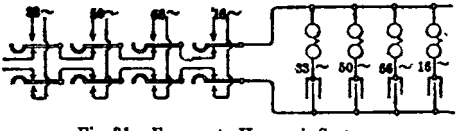

Fig. 21. Four-party Harmonic System

cond are used in the Dean four-party harmonic system. Each calling cord the central office switchboard can be rung upon by one of four keys, as in

Fig. 21. The ringers are alike except as to the cylinders of metal, heaviest for the lowest frequenc for the highest frequency.

The number of selective stations may be made twi by connecting harmonic ringers from each wire to g of across the line as in Fig. 21. This enables eigh line leading to a four-frequency central office.

Biased Ringer Systems (Fig. 22). — The uses unidirectional pulsating current for the selecti party lines. An improvement on that system (Fig

There are three general ways in which direct curre circuits to subscribers' lines. In Fig. 28 current is coils without condensers. Such a plan is suitable where all the lines of a switchboard are of about equal resistance, as in a private exchange. If the lines are of varying resistance, a high resistance line will be denied proper current when connected through such a cord circuit to a low resistance line (low compared to the resistance of the impedance coil). The circuit of Fig. 29, using a repeating coil, is free from this objection and is standard & Telegraph Company. The circuit of Fig. 30, us densers, is as efficient as that of Fig. 28, though e It is widely used in manual and automatic switchbo American Telephone & Telegraph Company.

in the originating district can be completed in the switchboard . Calls for subscribers in all the nine other districts must be accomplish this, the operators in a multi-office exchange have bling them not only to complete calls directly in the multiple it to connect subscribers with trunk lines leading to the other ch office furthermore there are operators and equipments adapted complete calls trunked to them from the offices where they

o answer subscribers are called *A* operators; operators who s incoming from other offices are called *B* operators. The cycle a call for a line not in the office first called is as follows: sub- receiver and his line lamp lights; operator answers and asks g by prefix that call is for a subscriber in a distant office, opera- marked with that prefix, so connecting her telephone set with irectly to a receiver of a *B* operator in the distant office; *A* the number desired, following with the *prefix of her own office;* stant office names back a trunk number; *A* operator inserts multiple jack of that trunk and simultaneously distant *B* the plug of that trunk in the called line; method of ringing e of apparatus; at close of conversation *A* operator discon- lights disconnect lamp before *B* operator, who disconnects in ishing signal.

stributing Frame. — The main distributing frame is a device terminated, usually upon opposite sides, the lines from sub- switchboard apparatus. Between these terminals connect- , called "jumpers," are soldered. The purpose of the main e is to enable a subscriber's line to be connected semiper- given switchboard line. A subscriber may move anywhere of his central office and may utilize any pair of wires entering t relinquishing his particular telephone number, as his switch- be connected by jumper to whatever entering cable wires Protective apparatus, consisting of sneak current arresters and resters, is associated with all lines entering a central office. devices customarily are mounted on the switchboard side of ing frame.

ate Distributing Frame. — The intermediate distributing on which lines to multiple jacks and lines to answering jacks cessible for inter-connection. Its object is to enable a given n an answering jack at any part of the switchboard and this semi-permanent. By this is meant that when a subscriber's ected by jumper to an answering jack on a certain operating lls of that line will be answered at that position until the rmediate distributing frame has been changed. The purpose affic originated by the subscribers of an office to be divided operators. This equalization is not automatically done by stributing frame, as is the intent in the automanual system.

OR MACHINE-SWITCHING SYSTEMS. — There f switching lines in a central office by means of machines. lly known as the automatic system, connects and disconnects ed lines by the agency of central office machines under the g subscriber. The other utilizes machines similar in function he automatic system, but these are controlled by skilled ntral office, and the subscriber gives his call orally to these common battery relay manual system.

Google

The fundamental merit of machine systems
machines over human beings in doing certain thin
line switching has become so fully standardized th
tage to machine methods, with diminution of err
same order as resulted from the adoption of typ
as substitute for script and mental addition.

Such systems are in successful use in many ex
and to a growing degree abroad. Their use lat
rising labor costs and by the difficulty of secu
skilled women operators for the manual system
system managers throughout the world recently
machine switching, principally for economic rea
fuller but perhaps belated recognition of what m
do.

Machine switching systems so far most widely
principle. In the system of the Automatic Elect
wide use, selector and connector switches take as
there are units in the digit called.

In manual multiple switchboards, all the lines of
operator. At the time of making a connection th
of a cord circuit may be considered as a terminal
line and seeking the called line in the multiple o
transfer switchboard or in the trunking of a call fr

This first switch makes as many vertical steps a
digit called, and immediately thereafter seeks out
of that group. On the calling of the next digit
selected trunk takes as many vertical steps as
digit, and immediately seeks out and appropriate
This process is repeated until all but two digits h
the connection to the last switch which will be
"connector" and has vertical and rotary motion
but, unlike them, both vertical and rotary moti
control. As he calls the next to the last (tens) d
vertical steps as there are units in that digit but
matic rotation. It rotates in response to the call
many steps as there are units in that digit and st
tact with terminals of the called line. Ringing o
caused by automatic means or by relays responsiv
ing subscriber's telephone. Disconnection ensue
hangs up his receiver.

Automanual System. — What has just been s
under subscriber control, in which all the digit-m

hes are dictated by the subscriber's turning of a disk attached e. In the second type of machine-switching apparatus, of later t formerly called automatic, there are in the central office opera- e by telephone the orders of subscribers as in the manual system, e those orders wholly by machines. The latter are controlled ike those of an adding machine. Disconnection is instantaneous up of subscribers' receivers. Very high efficiencies are attained s, and operators' labor costs are low, as few operators are required is done under most favorable conditions.

ems share the advantages of the use of machines; one requires o operate a dial, the other requires him to state his wants orally; ermined which shall be properly called the "natural" method n both systems, however, a higher quality of service is attain- manual system, and operating costs are somewhat reduced.

matic System. — The subscriber-controlled system first operates on the step-by-step method within the central office. natic system contains no such devices, but consists almost relays, much like those used for telegraphy or for relay manual urrent impulses resulting from the operation of the sub- uate these relays in the central office, connecting the lines. llows hanging up the receiver of the calling station. Further- ms of this type may be used in connection with dial-less tele- lition of trunk lines leading to operators in automanual central the requirements of many small rural exchanges adjacent to Calls from the rural subscribers are answered by city operators, relay equipment in the rural exchange over signal trunks. onnections are made the trunks are released for other use. the subscribers' lines follows hanging up the receiver of the ny rural exchanges thus can be operated from one city office, th its other work, the rural offices requiring no operators or ace.

CHANGES. — A private exchange is a group of telephone g apparatus subordinate to a central office, and usually on the the uses of a single business. Private exchanges are widely rtment houses, factories and suites of offices.

es are of three types: those using simple switchboards which erators through whom all local and outside calls pass; those ach telephone whereby each user may select the line of any trunk line to a central office, and those having a local equip- switches of the step-by-step or of the relay type.

ject of the private exchange is to enable the telephones within cate with each other directly without using lines through all. A second object is to enable communication from tele- ate exchange through the central office by the use of fewer ere are telephones in the private group. A serviceable ratio cal telephones may be from one-tenth to one-fifth at a con- cost over the providing of a line to the central office from e.

RCUITS (Fig. 32.) — In Fig. 32, four wires join two offices. rs. They are designed to be efficient in transforming both currents. CHARACTERISTICS OF TELEPHONE CABLES. — Telephone bles are groups of pairs of paper insulated wire twisted together and en-sed in a lead sheath. Soft drawn copper is invariably used for the con-ctors. The size wire usually employed ranges from No. 19 to No. 22 B. & S. r long distance underground lines individual wires as large as No. 10 B. & S. ve been employed. For the resistance of the different sizes of conductors see *ires and Cables*. The capacity of any pair of wires and the capacity of any e wire to ground depends largely upon the way in which the cable is made up. hen the wires are twisted tightly together the capacity is greater than when ey are loosely assembled. The mutual capacity ranges from 0.067 to 0.090 icrofarad per mile, and the regular or grounded capacity from 0.10 to 0.12

microfarad per mile for tightly twisted wires, as

Wires smaller than those given in this table should not be used on pole lines, account of their lack of mechanical strength.

ns or fastened directly to the poles. Underground cables are usually run in : or other type of ducts. (*See Conduits and Conduit Lines, Underground; res and Cables.*)

Open Wire Lines. — With the exception of the smaller insulators, usually ss, and the larger number of wires carried on a single pole line (as many 100), the construction of open wire telephone lines differs but slightly from at of pole lines for power transmission. (*See Cross Arms; Distribution Circuits; Poles for Overhead Lines; Transmission Lines.*)

The size of poles and their spacing usually employed for various classes of es through level country are given in the following table:

Type of line	Ultimate number of wires	Height, feet	Diameter of top, inches	Number per mile
Short, local	6	22	5 to 6	30
Important routes	20	25	6 to 7	40
Long distance	30 to 40	30 to 35	7 to 8	40

Where special conditions arise the height and size of poles must be selected ccordingly. The depth to which a pole is set in the ground ranges from one-

fifth to one-eighth of its total height, the larger fig
(25 feet), the latter to tall poles (65 feet).

TELEPHONE TRAFFIC AND RATES.—*ments and Circuits; Telephone Lines.*) For the pu phone users, the unit of telephone traffic is the "con of designing and using telephone equipment the t unit. A call does not always result in a conver subject to general variations closely linked with va Obviously, telephone traffic relative to business i working days; on all days telephone traffic vari fairly uniform from day to day. It is possible to p is a load curve representative of what happens each working day in most regular exchanges. The number of calls which subscribers originate depends on the kind of service rendered, whether residence, business, etc., and on the method of charging. Subscribers will call about twice as often under flat rates as under measured rates.

A knowledge of the amount of traffic in a system, of its distribution as to time and as to divisions of the exchange, is important. By that knowledge the equipment must be designed, modified from time tributed upon it as changing circumstances shall re

Methods of Counting Calls. — Amounts of t are observed in three general ways. A peg-coun operator actuating some counting device for each A second way is to determine a ratio existing, for t between the calls in a given period and the averag use in that period. Knowing these, the probable the cord circuit as counted. The third method is service meters on all lines and is to associate one with all the meters of that position, so that it will cou meter of the position is operated.

In machine switching systems, meters can be ar tabulate any desired part of the traffic automatica themselves are equipped with service meters for charging for the service.

Operator's Speed.— The number of calls an o hour depends on the percentage of total calls whi offices. With standard manual equipment, for exa calls in an hour if none have to be trunked, and 165 them have to be trunked. In machine switchin controlled type, an operator completes a much la per hour. All calls being handled alike, whatever station within the exchange system, the work of t may be as many as 1200 connections per busy ho are average and usual performance, as compared wi 165 per hour.

Prompt disconnection is of great importance. A nect signals shall be given prompt attention by so precedence over a call for connection. A flashing recall should be given precedence over all other calls systems disconnection is automatic and instantaneo

NG. — Traffic studies enable the determination of the number uired for an anticipated traffic. The number of trunks required, central offices, or between a central office and a private exchange the number of calls which must be trunked per maximum or busy lement of the probable coincidence in the time at which the calls must be considered, and for this reason the more trunks installed ill be the number of calls which each trunk may be expected to following illustrate current manual practice:

unked calls per busy hour	35	90	1080
umber of trunks required	5	10	60
lls per trunk	7	9	18

ONE RATES. — Rates for telephone service are of two kinds, nd "measured service rates." Under flat rates, a fixed sum per ed and the subscriber may use his telephone as much as he pleases. ed service rates, the subscriber is charged a certain sum for each e originates. Ordinarily also the subscriber guarantees to pay certain minimum amount per month. Rates for private exchanges up by charging a rate per month for each local telephone, another for each section of local switchboard, another rate for each trunk l further rate for each outward call over the trunk lines leading te exchange, the monthly charge being the sum of all.

elephone service depends on the amount of use, though there is a ost of being prepared to furnish service. There is a tendency to e flat-rate to the measured-rate system. The latter is in opera- ge cities.

ystems. — In flat-rate systems there is no continuous effort umber of conversations. Counting is done from time to time urposes.

ate Systems. — In measured-rate systems it is necessary to ersations as they occur, so that each subscriber may be charged he receives. Sometimes this is done by hand on tickets, but nterferes with the operator's regular work, losing not only perating but wasting switchboard investment by not using it e best way is to equip each line with a meter under electrical uses it to count one unit for each completed conversation. Such xtensive use in the larger cities. In manual systems, when a kes place, the operator presses a meter key associated with the and this makes the record upon the meter. In automatic wering of the called station operates the meter.

ces in London usual calls are charged a penny each and certain wo-pence each. In trunking calls of the latter kind, the operator he higher charge by the lighting of a specially colored lamp as nk order key. Being so reminded, she presses the meter key n a conversation occurs, the result being that the calling sub- -pence for each such special call, because his meter records two

TANCE CALLS are those which occur between cities, as dis- within cities, no matter how large the latter may be. Long- ually are handled by special operators at special switchboards unks to the switchboards which handle city service. Long-dis- ly require that a particular person be found in the called city, such calls includes the name as well as the number of the called ticket is recorded the duration of the conversation in minutes.

TURE AND THERMOMETERS. — (*See also Heat and rties; Pyrometers; Thermodynamics, Principles of; Units and Con-*.) The temperature of a body may be defined as its relative olness referred to some standard substance under standard con- change in some physical property of a standard substance must order to give a number to temperature. Any device which serves called a thermometer; if the device is applicable to the meas- y high temperatures it is also called a pyrometer, q.v.

TURE SCALES. — The standard* temperature-measuring onstant volume hydrogen thermometer, which consists essentially eceptacle containing a constant mass of hydrogen gas kept at e, viz., the volume it would have at a pressure of 1000 millimeters l at the temperature of melting ice, with means provided for variation that may be caused to take place in the pressure of

Scale. — The temperature of melting ice at a pressure of 760 ercury is arbitrarily taken as zero degrees, and the temperature eam at a pressure of 760 millimeters of mercury is taken as alling p_0 the pressure of a constant volume of hydrogen gas tacle is immersed in the melting ice and p_{100} its pressure when e saturated steam, and p_t its pressure when immersed in any (the pressure in each case being measured after the lapse of a or it to reach a constant value), the numerical value of the tem- given substance is defined as

$$t = \frac{p_t - p_0}{p_{100} - p_0} \times 100.$$

ade is abbreviated deg. cent. or °C.

Scale. — The Fahrenheit scale of temperature is derived in r, except that the temperature of the melting ice is taken as ling point of water (at 760 millimeters mercury) as 212°. A degrees Fahrenheit is then equal to

$$t_c = \tfrac{5}{9}(t_f - 32) \qquad \text{degrees centigrade.}$$

perature of t_c degrees centigrade is equal to

$$t_f = \tfrac{9}{5} t_c + 32 \qquad \text{degrees Fahrenheit.}$$

eit is abbreviated deg. fahr. or °F.

le. — This scale, which is used to some extent in Europe and his country, is defined in the same manner as the centigrade t the boiling point of water (at 760 millimeters mercury) is temperature of t_r degrees Réaumur is then equal to

$$t_c = 1.25\, t_r \qquad \text{degrees centigrade.}$$

e. — See article on *Pyrometers*.

TEMPERATURE. — Let p_0 = absolute pressure of a given ° C., p = absolute pressure of this same mass of gas at any as above defined. For all values of t between about $-150°$ e., for all values of t within the experimental range, it is found

e temperature in ° F. corresponding to t_f is

$$T_f = 460 + t_f.$$

Thermodynamic Temperature. — (*See article on Thermo-
ciples of.*) The difference between the temperature scale as
onstant-volume hydrogen thermometer and the absolute thermo-
s less than 0.1° C. at ordinary temperatures, and is less than 1° C.
range from − 150° to 1000° C.

IETERS. — The standard constant-volume hydrogen ther-
om used except for standardizing purposes, and then only for
o to about 500° C. The constant-volume nitrogen thermometer
dardizing purposes for temperatures up to about 1500°. For
ures radiation pyrometers are used as standards (*see Pyrometers*).

Glass Thermometers. — For ordinary temperature measure-
about − 35° C. and 350° C., the ordinary mercury-in-glass
almost universally employed. The temperature may be read
e position of the end of the mercury column as given by a
ed scale on the stem, provided the 0° and 100° points have
cated and the stem has a uniform bore.
neasurements the scale on the thermometer should be checked
ether the 0° and 100° points are properly located and whether
rm. Unless the proper quality of glass is used the bulb does
actly the same volume after successive heatings. Even when
rmometer is employed, the zero should be frequently checked
er is used for high-temperature measurements.
alibrating mercury thermometers are described in text books
the present day it is more convenient to compare the ther-
secondary standard mercury thermometer which has been
entral standardizing bureau, such as the Bureau of Standards

ge Mercury Thermometers. — The mercury thermometer
ery hard glass and filled under pressure with the space above
mn containing some inert gas, like nitrogen, may be used to
tures up to about 550° C. If a considerable length of stem
air, a very considerable error, 25° C. or so, may be introduced
ures. This "stem correction" varies slightly with the kind
be represented very nearly by the formula

ection to be added to reading = $0.00016\, n(t_b - t)$,

atures are all in degrees centigrade and n = number of degrees
ath or furnace, t_b = temperature of bath and t = mean tem-
ent mercury column.

dinary mercury thermometers cost from 50 cents to $5.00 a-
upon the accuracy of their calibration. A 100° C. mercury
ciently accurate (error not over ½ per cent) for ordinary
costs about $4.00. A 400° C. mercury thermometer costs
550° C. mercury thermometer about $12.00.

THERMODYNAMICS, PRINCIPLES (*istry, Principles of; Heat and Thermal Properti Temperature and Thermometers.*) "Thermodyn employed to include all problems involving t one body to another, and the transformations The word "energetics" is a better general term but the term "thermodynamics" is the one ord (Greek, "thermos") is developed in practicall e formation of energy. The transfer of energy f every known instance is found to be consistent w principles or laws:

FIRST PRINCIPLE OF THERMODYNA mental facts are in accord with the principle that given state or condition 1 to any other given state given out by the body is always the same, indepe place.

Intrinsic Energy. — Any given body in a may, therefore, be considered as having associate energy, which, in general, changes when the st changes. This energy is called the "intrinsic e pends solely upon the state or condition of the b in a given state or condition 1 is U_1, and in some U_2, then the total energy given out by the bo state 1 to the state 2 is $U_1 - U_2$, and this diffe initial and final states of the system and is in passes from one state to the other.

Heat and Work. — The energy given out by mechanical work, electrical, magnetic or other fo ience, all other forms of energy given out by the the "external work" done by the body. Hence, W the external work *done by* a body when it chan the total energy given out by the body may be exp the amount of heat evolved and the external w changes from a state 1 to a state 2 depend respecti the change takes place, but the sum of the heat always the same for given initial and final states, takes place.

Mathematical Expression of First Law. — sions given above for the total energy transferred from a state 1 to a state 2, gives the relation

$$U_1 - U_2 = Q_e + W,$$

which is the usual mathematical expression of the If, in the change from state 1 to state 2, heat i positive, while if the heat is absorbed Q_e is negat venient to consider the heat absorbed by the Hence, putting $Q = -Q_e$ the above expression ma

$$W = U_1 - U_2 + Q,$$

in which U_1 is the intrinsic energy of the body i energy in any other state 2, Q is the heat *absorbed* body when it changes from the state 1 to the state

PATH OF CHANGE. — Consider a body or condition 1 to another state or condition 2.

Digitized by Google

l state the body passes through a series of successive states, ring but infinitesimally from the preceding. The given series of hich the body passes is called the "path" from state 1 to state a body may pass from a state 1 to a state 2 by an infinite paths; therefore, a change can be completely specified only path" of the change as well as the initial and final states. e work done and the heat given by a body when it changes from ate 2 depends only upon these states, i.e., upon the ends of the portions of the energy given out as work and heat respectively upon the series of successive states through which the body "shape" of the path), but also upon the relation of the given rnal bodies which may in any way affect it.

PROCESS. — Any process by which a change can be pro- under conditions such that the body neither absorbs nor gives other body is called an "adiabatic" process. Adiabatic pro- be completely realized, since no known substance is a perfect ut such processes can be closely approximated, e.g., the expan- ion of a gas in a cylinder with well-insulated walls when the pression is so rapid that no heat is conducted through the walls.

AL PROCESS. — Any process by which a change can a body without changing its temperature is called an "iso- s. For example, the melting of ice, when the ice and water are is an isothermal process.

E PROCESS. — Whenever a change takes place in a e also takes place in some other body or bodies *B*. If the ystem formed by *A* and *B* are such that the path of each versed in direction without changing by an appreciable amount of the system, then the process by which the change takes "reversible" process.

pass only from a hot to a cold body and never in the reverse on of heat), it follows that, if during any step of a process there it between bodies whose temperatures differ by a finite amount, is irreversible. Hence, a reversible process can take place ions only: either there must be no transfer of heat (adiabatic ransfer of heat must be between bodies which differ in tem- an infinitesimal amount.

g, the last type of process is absolutely reversible only in the n the bodies between which the transfer of heat takes place same temperature. This condition can be only approximated always be a difference in temperature, though this difference small, in order that a transfer of heat may take place.

W OF THERMODYNAMICS. — The so-called second amics involves three distinct principles, which may be stated

v changes from a state 1 to a state 2 by any *reversible* process, n 2 to 1 over the same path, but in the reverse order, then the the body during the change from 1 to 2 is exactly equal to the his body during the reverse change from 2 to 1.

changes from a state 1 to a state 2 by any irreversible process, during this change can never be greater than the heat which re the change from 1 to 2 over the same path produced under would render the process reversible. Similarly, if the body ring an irreversible change, the heat given out can never be

Google

less than the heat which it would give out were t
produced under conditions which would render th

3. The heat (Q) absorbed by a body during any
bears the following relation to the temperature (t)

$$Q = MK\ (t + T_0)$$

where M is the mass of the body, T_0 is a constant
scale on which the temperature is measured, and K
solely upon the nature of the body and its initial and

Absolute Thermodynamic Temperature. —
any known means to produce a negative temperat
perature scale, numerically greater than the cor
T_0 in the above expression (equation (2)). Hence t
of any given scale equal to this constant T_0 is ca
namic zero" of this scale, and the temperatures
called "absolute thermodynamic temperatures."
be written

$$Q = MKT,$$

where $T = (t + T_0)$ is the absolute temperature c
ture t. The value of the absolute thermodynam
as that temperature, as measured on the consta
mometer, at which the pressure of the gas would
in pressure per degree ($= 1/273$ of the pressure
at all temperatures.

On the centigrade scale the absolute zero is, the
and on the Fahrenheit scale $-460°$ (approximat

Entropy. — Since the factor K, in equatio
upon the nature of the body and its initial and
looked upon as representing a change in a proper
ing this property of the body for the initial state
then K may be put equal to $N_2 - N_1$, and equatio

$$Q = M\ (N_2 - N_1)\ T.$$

This equation, which represents the relation betw
temperature, for a reversible isothermal process
adiabatic process, if the property of the body re
assumed to remain unchanged during such a proc
the heat absorbed is zero, by definition, and this, c
in N during such a process, is consistent with equa

In general, the temperature of a body during a
the process may be considered as made up of a
and adiabatic steps, and the above definition of t
to each step. That is, the change in N for each
isothermal "tread" and an adiabatic "rise" is

$$dN = \frac{dQ}{MT},$$

where M is the mass of the body, dQ is the heat a
temperature of the body during this step.

This property N, whose increase during any
equal to the heat absorbed per unit mass divide
of the body during this step, is called the "entro
Since entropy is defined in terms of its change, it

Digitized by Google

of a body may be arbitrarily taken as zero. In steam tables, water at 32° F. and at atmospheric pressure is usually taken as ropy of a body can in many cases be calculated from the other he body. (*See article on Steam.*)

ce with the above definition of entropy the heat absorbed by a hanges from a state 1 to a state 2 by any *reversible* process is then

$$Q = M \int_1^2 T dN, \tag{3}$$

mass of the body, T its absolute temperature during any step of d dN the increase in its entropy per unit mass during this step.

le of the Increase of Entropy. — It can be shown, from the e stated, that the only possible changes which can take place in lies to which no energy is added or subtracted are changes which ase in the total entropy of the system. Reversible changes may ke place without increasing the total entropy, but reversible take place in nature nor can they be realized *absolutely* by any ental means.

I WORK. — The maximum external work which a body changes from a state 1 to a state 2 along a given path (i.e., by a given series of states) is equal to the decrease in its intrinsic maximum amount of heat it can absorb when it changes along maximum external work which a body can do in changing from ate 2 along a given path is therefore

$$W_{\max} = U_1 - U_2 + M \int_1^2 T dN. \tag{4}$$

e last term in this expression depends upon the temperature at change, and this temperature depends upon the "path" along e takes place. If the path is such that *all* the heat is absorbed nperature T, then

$$W_{\max} = U_1 - U_2 - TM(N_1 - N_2). \tag{4a}$$

e written

$$W_{\max} = U_1 - U_2 + T\frac{dW_{\max}}{dT}, \tag{5}$$

the rate of increase of the maximum work done by the body

ture at which the heat is absorbed.

. — The maximum work which a body can do in changing a state 2 is sometimes referred to as the "free energy" of the ing to this change. This free energy depends not only upon nal states of the body itself but also upon the temperature of nal body available as a source of heat; this is apparent from

OCESSES. — In the theory of the steam and other heat ion arises as to what is the maximum amount of external work ained from a body by alternately heating it to a high tempera- ing it do work (e.g., by expanding), thereby cooling to a lower cycle of operations being repeated over and over again. That working substance" changes from a state 1 to a state 2, then then changes again to 2, and so on for any number of cycles. rgy of the body at the beginning and end of any cycle is then erefore, the net work done by the body during any cycle is

Digitized by Google

the difference between the heat actually absorbe
during the cycle.

Thermal Efficiency. — The ratio of the
absorbed during the cycle gives the proportion
converted into external work, and is called th
cycle.

Carnot's Cycle. — From the principles stat
heat absorbed will be a maximum when this hea
manner under conditions such that the tempera
is the same as that of the hottest body availal
the heat given out is a minimum when this hea
manner under conditions such that the temperatu
the same as that of the coldest body available

rail, or third rail, is a conductor supported on insulators near the resenting a continuous contact surface to a collector or shoe ne rolling stock. In its commonest form it is a rail of standard ted at intervals of a few feet by substantial insulators, electrical veen adjacent lengths being obtained by copper bonds across the

LOGY. — The following terms and definitions are used in con- ird-rail systems. See also Standards of the A.I.E.E.

oe. — A third-rail contact shoe is a conductor, fastened to the hich is designed to make electrical contact with the third rail. ter referred to as the "shoe."

face. — The contact surface of a third rail is the surface against presses.

ack. — The minimum clearance between the inside surface of two track rails, i.e., the distance *A* in Fig. 17. The track gage s 4 feet 8½ inches.

age. — The distance measured parallel to the plane of the tween the gage line of the nearer track rail and the inside gage ct surface of the third rail, i.e., the distance *B* in Fig. 17 of this

Third rail locations will be described in terms of the third-rail evation or vertical distance (*C* in Fig. 17) between the normal and the normal top of the track rail. See also Table II below.

Rail. — A top-contact third rail is one on which the contact upper side of the rail.

ct Rail. — An under-contact third rail is one on which the s on the under side of the rail.

sulator. — A third-rail insulator is that portion of the third- h forms the principal electrical insulation.

se or Bracket. — A third-rail insulator base or bracket is a pport the third-rail insulator.

incline is a portion of third rail sloped to gradually bring the e position into contact with the normal surface of the third

— An end incline is an incline at the end of a run of third rail ceive shoes moving in line with the third rail.

Digitized by Google

Offset-end Incline. — An offset-end incline of third rail and is made to receive shoes movi rail.

Cross Incline. — A cross incline is a combin inclines from adjacent third rails which meet at

Side Incline. — A side incline is an incline a made to receive shoes moving laterally towards t

Offset-side Incline. — An offset-side incline standard third rail in order to gain clearance b maximum equipment line of the rolling stock.

Maximum Equipment Line. — The maximun ary which encloses the cross-sectional outlines o all normal operating conditions.

Third-rail Protection. — A third-rail protecti third rail which affords some degree of protectio accidental contact with foreign bodies.

Third-rail Anchorage. — A third-rail anchora third-rail creeping longitudinally.

Tie Motion. — Unless otherwise specified, tie r mean the vertical play of the ties caused by the pa

TYPES OF CONSTRUCTION. — Third-rail fied into the top-contact and under-contact types, of important variations in design, especially with reference to the type of protection.

Interborough Top-contact Type (Fig. 1). — One of the most commonly used types is illustrated in Fig. 1. It is often called the "Interborough Type" on account of its use in the subways of the Interborough Rapid Transit Co., of New York. The rail is a standard T-section and rests on reconstructed granite insulators. A board protection is attached to the rail itself by means of clamps and uprights and is thereby kept in perfect alignment.

Pennsylvania Top-contact Type (Fig. 2). — Another type has the protection supported on separate brackets independent of the third rail itself. It is claimed that this reduces the amount of labor w live rail, when repairs are being made, but it cannot the Interborough type to keep the rail and protectio

London Tube Type (Fig. 3). — The mounting rail and the negative contact rail of the London Tub Fig. 3.

Under-contact Types (Figs. 4, 5, 6 and 7). — W have given first-class service, they are considered to h for exposed locations as they cannot be wholly prot sleet. The lower part is only a few inches from th generally reduce this clearance, increasing the danger o lation of wet snow and ashes and from flooding. Th traffic during sleet and snowstorms and floods, on railr type of third rail, led to the idea of an under-contact

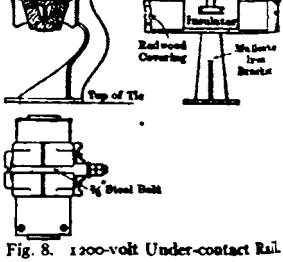
some other forms, and in sleet storms no ice forms on the contact surfa some icicles may form at the edge of the petticoats, but hanging down clear the edge of the rail, are easily broken off by the passing shoe. A special desi using a standard T-rail, is shown in Fig. 8, and is used for 1200 volts.

Where the rail is buried in snow, the passage of the contact shoe breaks snow away, leaving the rail surface clear, instead of ironing the snow down the rail, as may happen with the top-contact type.

Sheathing and Special Work. — The sheathing between the insula blocks, depending upon local conditions and the price of materials, as wel the potential used, is usually formed of three wooden strips, one grooved on under side and inclosing the head of the rail, and the other two, attached to and dependent from it, reaching in toward the web of the rail. Where good wood is not available, an alternative protection costing about the same and having a higher electrical resistance, although not so good mechanically, is a semi-flexible shell of indurated fiber conformed to the rail sections.

The special work, i.e., inclines, jumpers, etc., used with the under-contact rail, is shown in Fig. 9.



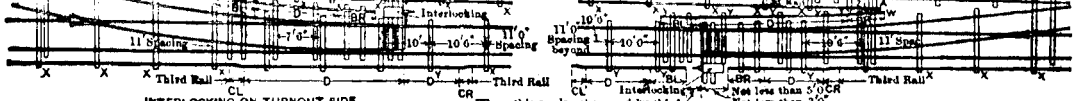


Fig. 8. 1200-volt Under-contact Rail.

Combined Top- and Under-contact Shoes. — The employment of collecting shoes on rolling stock so constructed as to press upwards on the und contact rail and downwards on the top-contact type solves the question interchange between railroads not using the same type.

CONTACT RAILS VERSUS OVERHEAD TROLLEY. — The conta
ail is used as a part of the positive conductor system whenever the current
e collected by each collector exceeds the amount which can be taken safe
rom a trolley wire, or whenever the total current taken by a train exceeds
mount that can economically be carried by conductors of such expensive met
s copper or aluminum.

Positive Contact Rails. — Considered as a part of the positive conduc
ystem, the contact rail and overhead trolley possess the relative qualifica
ions given in Table I.

TABLE I. — RELATIVE QUALIFICATIONS OF THIRD RAIL AND OVERHEAD TROLLEY SYSTEMS.

(*Adapted from Table by C. E. Eucleth.*)

I Protected third rail	II Overhead high-tension bridge, catenary construction	III Overhead side bracket, catenary construction
Interference with track maintenance.	Entirely clear of road bed.	Same as II.
Can be maintained by section gang.	Requires special tools, crews and work trains.	Same as II, but not as important.
Easily cleared up and insulated when derailment occurs.	In the way of boom of derrick car — liable to be knocked down and put all tracks out of service.	Same as II.
Hindrance to coupling freights, etc. With protected rail this is not very serious.	Dangerous to freight brakemen on account of parts hanging down and small bridge clearance. Very difficult to install satisfactory ticklers to warn trainmen when approaching bridges.	This point is of less importance.
Interference with clearing snow between tracks.	Not affected.	Not affected.
Ease of satisfactorily collecting current on account of location, where relative motion between track and rail is small. Collectors may be safely replaced on the road.	Difficult to collect current, as a more complicated mechanism is required on account of the grade of the wire due to low clearances at bridges and high clearances at road crossings.	Similar to II.
May be readily inspected by track walker.	Requires a man with special training.	Similar to II, but of less importance.
Ease of sectionalization. Jumpers may be disconnected at the nearest adjacent road crossings.	Difficult of sectionalization.	Sectionalization not of so much importance.

TABLE I. — RELATIVE QUALIFICATIONS OF THIRD-RAIL AND OVERHEAD TROLLEY SYSTEMS — *Continued*

(*Adapted from Table by C. E. Eveleth.*)

I Protected third rail	II Overhead high-tension bridge, catenary construction	III Overhead side bracket, catenary construction
May be worked on while alive to make track changes or repairs, making system very flexible.	Requires that current be shut off no matter how slight repairs are, making system inflexible.	Similar to II, but not of such importance.
No interference with visual signals.	Signals located and seen with difficulty, as they must be lower than the bridges and even then have the distant bridges as a background. Dangerous to maintain signals in this location, as it must be done from ladders.	Not affected.
Danger of wreck from burning off track rail due to arcing current. This is a possible contingency, but one not very likely to occur.	Danger from dangling overhead work when messenger cable is burned off at a defective insulator.	Same as II.
Little interference with fire-extinguishing apparatus in the car storage yard.	Difficulty in removing cars on account of high-tension wires interfering with firemen.	Will probably have low-tension wires for this type of construction.
Absolute freedom from lightning disturbances.	Very much exposed to lightning.	Same as II.
Entire freedom from telephone and telegraph disturbances, also inductive effects on signal wires.	Difficult problem in connection with these interferences, affecting not only the railroad company's wires, but those belonging to other interests.	Same as II.
No trouble at grade crossings with crossing trolley wires.	Probably trolley crossings will have to be avoided by overhead or undergrade crossings.	Troubles similar to II.
Can add sidings or more tracks with little difficulty.	Can make such additions only at considerable expense.	Difficulty not very great.

Negative Contact Rails. — Negative contact
negative-feeder system when the drop of potential i
such a small amount that it is cheaper to use an
force the track rails with feeders. Considered as
system, the contact rail possesses the following ad
return system. If used in connection with a positi
rail is placed between the track rails.

(I) When properly insulated, it eliminates every
(II) It gives the block-signal system complete in
traction system. Among the advantages which thi
of signal circuits, saving the cost of reactance bo
and increased economy in signal circuits.
(III) It gives greater safety to passengers.
(IV) It reduces the probability of short circuits.
(V) It decreases the cost of track-rail mainter
bonds.
(VI) It halves the first cost of bonds, as one b
usually replaces two track rails.
(VII) It reduces the wear of bonds by saving th

These advantages are usually offset by the first
rail, by the complications it introduces at special tra
bility of protecting a central rail from snow and i
clearance for any kind of covering.

ELECTRICAL DESIGN. — The calculations
resistance, etc., are treated under *Trolley Systems*,
weight, dimensions, resistance and reactance of rail
on *Rails, Track and Third*.

Selection of Suitable Rail. — When the vari
consideration it is well to arrange a table with the
to compare the relative economy of the different
copper equivalent to rail; (2) Additional circular
equal the rail of highest conductivity; (3) Cost of
(4) Cost of additional copper for entire railroad;
additional copper for entire railroad.

MECHANICAL DESIGN. — The general de
been settled, the next step is to secure a set of tra
the special work. When an entirely new railway i
designer and the third-rail designer can work tog
line is being converted, the general track plans ca
dom sufficiently accurate for the electrical engine
the contact-rail engineer has to take measurements
to make drawings of the cross-overs and other com

Location and Weight of Third Rails. — The

t, a dotted line is shown on the diagram located 2 inches distant horizontally and 4 inches distant vertically from the limiting clearance line for uipment.

Turnouts. — (*See also Railways, Location and Permanent Way for.*) A typical nout is shown diagrammatically in Fig. 11 which shows the lengths which uld be measured; *F* is the distance from the point of the switch the point of the frog, and is led the "frog distance"; *D* is the gth between the adjacent frogs, d *Z* the distance apart of the ck centers. In such a diagram- tic view the lines represent the ge lines of the track rails. When, however, a contact rail is represented by ine, it is the center line that is given. Having measured the four distances ecified above, the radius of the turnout curve may be calculated from the following formulas:

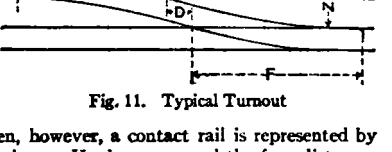

Fig. 11. Typical Turnout

$R = 0.127\ F^2$, when the turnout is from a straight track.
$R = 0.271\ F^2$, when the turnout is from a track of equal radius to the turnout.

Graphical Method of Locating Contact Rail. — The track plans having en drawn from the field sketches, to a scale of say ¼ inch to the foot, the ntact rail may be drawn in, as outlined below. An aid in this work is an oute plan of the electric car or locomotive to the same scale as the track work awings — say ¼ inch to the foot. Such a plan is shown in Fig. 12, in which e points *W* represent the wheels, *S* the contact shoes and *K* the king-pins. This d better be made of celluloid with a large pinhole at ch point *S*. In order to lay out the contact rail the is drawn along the tracks with the points *W* on rails and a pencil stuck in one of the pinholes. The e traced by the pencil represents the center line of the e path, and therefore that of the contact rail. Such a e should be made on each side of the car. In cases ere there are sharp curves, it will not do to run the wheel points *W* along tracks, as an error will arise due to the truck rotation not being represented. such a case the king-pin points must be run along a track center line.

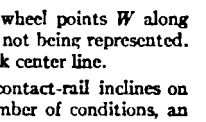

Fig. 12.

Location of Inclines. — The exact location of the contact-rail inclines on ch side of a track-rail intersection depends upon a number of conditions, an portant one of which is the extent to which the equalizer bar and journal box ject outward. If there is a train-bus line connecting all the cars, the end lines may be situated many feet back from the switch point or frog, but if re is no such bus line, the contact rail will probably have to be terminated a cross incline extending near as possible to the itch point or frog.

Isolated Section
Fig. 13.

Sectionalizing the Contact Rail. — Where a train- s line is not used, it is customary to break the third rail in front of substaons and use an isolated section of third rail between the two main sections, as own diagrammatically in Fig. 13. The length of this isolated section and the gaps which bound it should be such that both gaps are never spanned cars at the same time.

Digitized by Google

Let L = car length, feet,
T = distance between shoe centers (usually truck centers),
S = shoe length.

Then,

Total space must be $> L + T$
Rail section must be $< 2L$
Length of each gap must be

For example, on the Manhattan Railway, New was adopted, a short isolated section was used.

$L = 46.37$, $T = 32.27$, S

Total space > 79.64, actually
Section of rail < 59.47, actu
Gap length < 31.27, actually

Cross and End Inclines. — Inclines serve contact shoes to rise (or fall) from their free posi with the rail. They should, therefore, have sufficient slope to prevent any undue shock either to the rail or to the shoes. Low-speed lines and sidings may therefore have shorter inclines than high-speed lines. The usual length of straight slope (i.e., without end nose and flat surface at top) is from 60 to 70 inches for high-speed work and 30 or 40 inches for sidings. The slope ranges from 1 in 45 for high-speed work to 1 in 30 for urban railways. made of cast iron. A typical design is shown in

Fig.

Third-rail Insulators. — Third-rail insulator qualifications. Strength to withstand weight and to moisture; resistance wet shall not be less th drip edge; shall allow free motion of rail laterally to allow for expansion, contraction and tie motion and quick removal without disturbing the rail.

Spacing of Insulators. — A spacing of recommended by the American Street & Interurb rails and represents present day practice.

INSTALLATION OF CONTACT RAIL. railway being electrified, the first step is to replac vals by long ones. A man then proceeds along marks on them the location of the screw holes o followed by an augur gang which drills the holes the case of an under-contact rail) or the stool a top-contact rail) are distributed along the line. gang screws the brackets or stools to the ties.

Where the rails rest on tie plates which hav it is not unusual to place shims under the brack have reached their normal position.

Digitized by Google

se of under-contact rails the brackets must be accurately checked for mensions before being distributed.
and fish-plates, etc., are next distributed along the line on that side where they are to be installed and a gang follows which installs the the case of an under-contact rail, attaches the insulators and hook ne case of a top-contact rail, another gang follows, attaching the ıtever is used to fasten the rail to the insulators. Another gang ıstall the fish plates, expansion joints and anchorages, if any. If o anchorages or expansion joints, expansion and contraction are ıinst by making an allowance at all joints, depending on the temper-ch the rails are installed. This is done by inserting an "expansion e the rails are l together. The shim for different on a 30-foot rail ig. 15.

rails are being materials for the are distributed e and a gang fol-g them. A last the protection ɔriming and then ıg paint.

ve to be carefully located to make sure that the shoes will ride n them.

ON AND MAINTENANCE OF CONTACT RAIL. — The ird rails is negligible and even without painting the deterioration very slow. The principal items of maintenance are the insulators, l bonds. Unless the supports are carefully designed, insulators by "tie motion," i.e., by the depression and rebound of the ties ass over them. Every time a wheel passes over a tie carrying an latter is pounded against the rail and is likely to be broken unless is provided.

ffects due to large currents sometimes causes the third-rail voltage 3 times its normal value. (D. D. Ewing, E. R. J., 1917, Vol. 56,

f Sleet. — The best protection against sleet is undoubtedly the third rail and the next best is a top-contact third rail with a wide rd. Where these are impracticable the deposit of ice on the rail ented and means for its removal have to be adopted. The two ıs are scrapers and hot water. Electrical heating of the rail uggested but found to require too much energy. When the hot-is used, some salt such as calcium chloride, or some other sub-lowers the freezing point of water must be added to the water. ous objections to the hot-water method, especially on elevated e saline solution not only rusts the metal of the structure but chloride is used in the water, damage also occurs to the roofs of , underneath.

OF CONTACT RAILS. — Contact rails have to be tested for ontinuity at the joints, (2) conductivity, (3) insulation from gage.

ntinuity at Joints are described in the article on *Bonds, Rail-*

Digitized by Google

The Conductivity Test is best performed by passing a considerable current through a length, measuring the drop with a milli-voltmeter and calculating the resistance by Ohm's law.

The Insulation Test is best performed by means of a pair of voltmeters, as shown in Fig. 16. The rail A to be tested is connected to a live rail B through a voltmeter, and the voltage V_1 between the two noted. At the same instant the voltage V_2 between the rail B and ground is also read. Let L be the length in miles of the rail A. Then the insulation resistance of the rail A in megohms per mile is

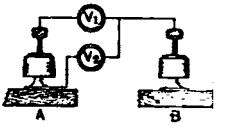

Fig. 16.

$$\frac{rL}{10^6}\left(\frac{V_2}{V_1} - 1\right),$$

where r is the resistance in ohms of the voltmeter on which V_1 is read.

Testing of Gage. — The gage line of a third rail is measured by means of a template which fits over the track rails as shown in Fig. 17.

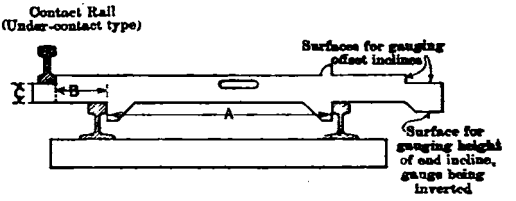

Fig. 17.

COST OF CONTACT-RAIL CONSTRUCTION. — The estimates in Table III include the cost of (1) handling and distributing the material from the storehouse to the place where it is used; (2) the solder, gasoline, etc., used in bonding contact rail; (3) putting three coats of paint on the protection; (4) bending rails on curves; (5) 5 per cent for breakage; (6) foremen's and engineers' salaries. They do not include the cost of tools or of jumpers.

These estimates are approximately correct where existing traffic does not materially impede the work. Under less favorable conditions, the cost may rise 50 per cent or more over the figures given.

The estimate on the top-contact type is based upon the Interborough Rapid Transit Co's. construction, New York (Stillwell-Slater patent), the weight of rail, however, being slightly less than on that railway. The estimate of the under-contact type is based upon construction similar to that used by the New York Central Railroad (Wilgus-Sprague patent). Little third-rail cost data having been published since the Great War, the data from the 1914 edition are reproduced.

TIMBER. — (*See also Structures, Simple; Poles for Overhead Lines.*) The standard names for structural timbers as adopted by the Am. Soc. for Test. Mat. and the Am. Ry. Eng. Assoc. are reprinted below by permission from the present (1913) board of the Am. Soc. for Test. Mat.

Fir, Douglas. — The term "Douglas Fir" is to cover the timber known likewise as yellow fir, red fir, western fir, Washington fir, Oregon or Puget Sound fir or pine, norwest and west coast fir.

Hemlock, to cover Southern or Eastern hemlock; that is, hemlock from all states east of and including Minnesota.

Hemlock, Western, to cover hemlock from the Pacific coast.

Larch, Western, to cover the species of larch or tamarack from the Rocky Mountain and Pacific coast regions.

Pine, Norway, to cover what is known also as "Red Pine."

Pine, Southern Yellow. — This term includes the species of yellow pine growing in the southern states from Virginia to Texas, that is, the pines hitherto known as longleaf pine (*Pinus palustris*), shortleaf pine (*Pinus echinata*), loblolly pine (*Pinus taeda*), Cuban pine (*Pinus heterophylla*), and pond pine (*Pinus serotina*).

Under this heading, two classes of timber are designated: (*a*) dense southern yellow pine and (*b*) sound southern yellow pine. It is understood that these two terms are descriptive of quality rather than of botanical species.

Pine, Western, to cover the timber sold as white pine coming from Arizona, California, New Mexico, Colorado, Oregon and Washington. This is the timber sometimes known as "Western Yellow Pine," or "Ponderosa Pine," or "California White Pine," or "Western White Pine."

Pine, White, to cover the timber which has hitherto been known as white pine, from Maine, Michigan, Wisconsin and Minnesota.

Pine, Idaho White, the variety of white pine from western Montana, northern Idaho and eastern Washington.

Redwood, to include the California wood usually known by that name.

Spruce, to cover Eastern spruce; that is, the spruce timber coming from points east of and including Minnesota.

Spruce, Western, to cover the spruce timber from the Pacific coast.

Tamarack, to cover the timber known as "Tamarack," or "Eastern Tamarack," from states east of and including Minnesota.

A fuller description of the timbers used for transmission line poles is given in the article on *Poles for Overhead Lines.*

DEFECTS IN TIMBER. — The standard names for defects in structural timber as adopted by the above association are the following:

Encased Knot. — An encased knot is one whose growth rings are not intergrown and homogeneous with the growth rings of the piece it is in. The encasement may be partial or complete; if intergrown partially or so fixed by growth or position that it will retain its place in the piece, it shall be considered a sound knot; if completely intergrown on one face, it is a watertight knot.

Large Knot. — A large knot is a sound knot, more than 1½ inches in diameter.

Loose Knot. — A loose knot is one not firmly held in place by growth or position.

Pin Knot. — A pin knot is a sound knot not over ½ inch in diameter.

Digitized by Google

— **A pith knot is a sound knot with a pith hole not more than** meter in the center.

ot. — A rotten **knot is one not** as hard as the wood it is in.

ot. — A round knot is one which is oval or circular in form.

t. — A sound knot is one which is solid across its face and which he wood surrounding it; it may be either red or black, and is so h or position that it will retain its place in the piece.

t. — A spike knot is one sawn in a lengthwise direction; the mean lth shall be considered in measuring these knots.

Knot. — A standard knot is a sound knot not over 1½ inches in

ets. — Pitch pockets are openings between the grain of the wood e or less pitch or bark. These shall be classified as *small, standard* pockets.

tch Pocket. A small pitch pocket is one not over ½ inch wide.

Pitch Pocket. A standard pitch pocket is one not over ⅝ inch es in length.

tch Pocket. A large pitch pocket is one over ⅝ inch wide, or n length.

k. — A pitch streak is a well-defined accumulation of pitch at e piece. When not sufficient to develop a well-defined streak, or between grains, that is, the coarse-grained fiber, usually termed ' is not saturated with pitch, it shall not be considered a defect.

Shakes are splits or checks in timbers which usually cause a ne wood between annual rings.

. — An opening between the annual rings.

ake. — A shake which extends between two faces of a timber.

nd Red Heart. — Any form of decay which may be evident red discoloration not found in the sound wood, or the presence rotten spots, shall be considered as a defect.

ane is bark, or the lack of wood from any cause on edges of

ID PRESERVATION. — Decay is due usually to a fungus revented by cutting off the air by immersing the timber in water, is known is a sure preventive. Decay is retarded by thorough naturally or in the kiln, or by poisoning the food supply of the ical treatment. The latter method usually consists in impreg- with creosote or zinc chloride, the former being more commonly e methods used for preserving timber poles are described in the *for Overhead Lines.*

ESSES FOR STRUCTURAL TIMBER. — The values of structural timber given in the following table are recommended tee on Wooden Bridges and Trestles of the American Railway ociation. See *Manual* of the Association, Chicago, 1911. For vable in various cities of the United States see article on *Build- Unit Stresses in.*

D SIZES. — The commercial sizes of spruce and yellow pine part of the United States are as follows:

Cross-sectional dimensions in inches are:

, 2 by 5, 2 by 6, 2 by 7, 2 by 8, 2 by 10, 2 by 12
, 3 by 8, 3 by 10, 3 by 12
, 4 by 8, 4 by 10, 4 by 12
, 6 by 10, 6 by 12
o, 8 by 12.
ft. are ordinary lengths.
ft. are less common.
ft. are obtained with difficulty.

. — Same cross-sectional dimensions as spruce and also the fol-ons in inches):

by 16	6 by 14, 6 by 16	12 by 14, 12 by 16
by 16	8 by 14, 8 by 16	14 by 14, 14 by 16
by 16	10 by 14, 10 by 16	16 by 16

icks are commonly longer than spruce sticks, frequently exceed.

F TIMBER BEAMS. — Timber beams may be designed by of the ordinary beam formulas (*see Design of Beams in article mple*). Timber is especially weak in longitudinal shear which ng factor in many cases as shown by the preceding tables. It , be noted that the projection of the end of a beam over the en gives the timber a greater resistance to shear than would be strict application of theory and the designer must often use cretion in applying the shear formula.

FOR TRANSMISSION LINES. — (*See also Distribution ators for Transmission Lines; Poles for Distribution Lines; Struc- ; Transmission Lines.*) Steel towers are often used instead of for supporting electrical circuits. They have the advantages over ey can be of as large size as desired and are much more perma- owers are especially advantageous for high voltages (over 50,000) ire spacing is necessary; for long spans, such as river crossings, chanical stresses are exceptionally heavy; and in localities where r forest fires occur.

. FEATURES OF DESIGN. — Towers are composed of two er proper and the foundation. Towers are usually built of stand- steel shapes. Angles are used for most members. Channels are rger members of some towers, usually the cross arms, or for posts wers. Flat pieces are sometimes used for the minimum-sized ht towers. Round rods are used for tension members in some rincipal members of a tower are the corner posts or legs, which approximately vertical, and are usually the heaviest members roper, and the horizontal and diagonal web members which con- together in vertical planes which constitute the sides or faces

of a tower at the base is generally between one-fourth and one- eight. The greatest economy in cost of tower plus foundation es a little wider base than that which gives the least cost for the one.

usually designed for either one or two three-wire circuits, usually wo ground wires above and sometimes with a telephone circuit two circuits are on one tower they are usually located on op- reduce the hazard of repairing the line. The three wires of a asionally arranged to form an equilateral triangular prism, but in a single plane which is usually horizontal for single-circuit rtical for two-circuit towers.

owers. — There are two general types of towers, viz., (1) the only two legs and (2) the rigid, having three or more legs.

Towers (Fig. 4). — The flexible tower is set with face at right e so as to rigidly resist any transverse force, such as a wind blow- line, while bending if necessary to relieve any stress in the direc- e. The stability of the tower in the direction of the line is the conductors which it supports acting as guys. Where con- perform this function, due to being attached by suspension in- ound wires are used as the guys. The flexible tower is especially the smaller sizes, where the line conditions approximate those oles would otherwise be used. On lines of flexible towers, rigid re set at intervals.

owers. — These are usually triangular, square (Fig. 2) or rec- 3). The square tower is probably the most common. Square have the four faces framed with the same size members (even sses in the longitudinal and lateral faces rarely figure the same), economy of manufacture and erection which results from the is feature has an advantage in design in that the torsional e simply determined. Rectangular (including square) towers vantage that the unequal settlement of the foundations may ternal stresses not allowed for in the design. Triangular towers tresses from unequal foundation settlement, but present diffi-

Often no single combination can be found which will maximum stress in all tower members, and therefore several com- ist be used to determine the design.

e anchor tower carrying six wires, three on each side, the maximum e expected in the corner posts when all six wires are pulling in the on; the maximum stress in the web members will probably be pro- ce wires pulling on one side in one direction and the three on the the opposite direction. In the first case the tower is subject to a s and in the second to a torsional stress. In each case the stresses t and wind are to be superimposed. The wind may act as a force e or across the line, but generally its longitudinal effect is negligible al effect is important.

n Tower Members. — The stresses in the several members of a ually determined graphically from the assumed loadings by means grams; see section on *Trusses* in the article on *Structures, Simple.* gns the distribution of stress is not fully determinate.

tal Assumptions. — Certain assumptions are, however, commonly ive a determinate distribution for the purposes of design. Among ions are:

alanced stress on the tower (say a broken wire pulling on one resolved into an equal stress at the axis of the tower and a tor- t.

uivalent stress at the axis of a ower can be considered as bal- n the two faces parallel with it, ng one-half the stress.

rsional moment can be consid- ed between all four faces of a wer.

anced force in pounds applied at each corner post equivalent

to F in bending effect on body of tower,

ssure on a tower is assumed to be uniformly distributed per square foot t which the wind blows, one-half of it consequently being on the wind- windward face and the other half on the windward side (inside) of the or simplicity in calculation this uniformly-distributed force is replaced ncentrated forces, one at each panel point equivalent to the total dis- ending over a half panel above and a half panel below the panel point. is meant a point of intersection of principal members, for example, mbers with vertical members in Fig 4; and by panel is meant the between panel points, a panel usually being bounded by two vertical al members as in Fig 4.

oogle

$f' = \frac{Fa}{8b}$ = torsional force in pounds applied at each corner post equivalent to F in twisting effect on body of tower.

(5) In a tower framed with a double system (i.e., diagonals in duplicate and suitable for compression as well as tension) each system may be considered as taking one-half of the stress as far as possible.

Approximations Made in Calculating Tower Stresses.—The stress diagrams are usually simplified by employing certain approximations:

(a) Faces of towers are usually battered so that they deviate slightly from a true vertical plane, but the stress diagrams usually neglect this inclination and are based on the vertical projection of the face.

(b) Where the face of a tower does not lie in one plane (i.e., has a change batter as occurs frequently at bottom cross arm where a prismatic cage joins pyramidal base) the change of inclination is neglected and the diagrams are based on a single vertical projection as before.

Subject to the limitations of the assumptions and approximations given above, the four faces of the tower can be regarded as four cantilevers, supported at the base and loaded at the top, which are independent except that the four corner posts are each common to two faces and must contain the resultant of both stresses.

Where a face of a tower or any part of a face has any considerable inclination the above approximations may not be used without danger of serious error.

Unstressed Members.—A tower usually contains members no stress in which is shown by the stress diagram, viz.:

(1) Diagonal members in a horizontal plane do not usually appear in the stress diagram when located below the lowest cross arm. These members play an important part in the distribution of torsion among the faces. In a rectangular tower the torsion will usually redistribute between the four faces at each level where there are horizontal diagonals, therefore the failure of the stress diagram to show stresses in them may be taken to indicate that the assumed distribution of torsion is not quite correct rather than a true absence of stress.

(2) Redundant members are braces which carry no determinate stress but perform the important function of supporting the compression members which do carry stress. The unit stress allowable in a compression member diminishes as the unsupported length increases. The weight of compression members is therefore diminished by dividing their unsupported length by braces applied at one or more intermediate points.

Unit Stresses in Towers.—The factors of safety and unit stresses used in tower design have not been standardized. In some cases it has been assumed that the combination of loading taken for tower design represents conditions which would happen so rarely that a tower which would stand these loadings in test without failure would be sufficient. This is equivalent to taking a severe combination of loads and designing for a factor of safety of but one. The result, however, may be as good a tower as one designed for the same conditions individually (but not in combination) with a factor of safety of two or four. It is probable that few towers are designed for the combination of all loadings, each taken at the most severe condition reasonably possible with an actual factor of safety exceeding two.

For a factor of safety of from 2½ to 1½ (as determined by test of complete tower, not of individual members) the following unit stresses have been used:

Tension: 12,000 to 20,000 lb. per sq. in.
Shear: 12,000 to 20,000 lb. per sq. in.
Bearing: 16,000 to 30,000 lb. per sq. in.
Compression: $12{,}000 \div K$ to $20{,}000 \div K$ lb. per sq. in.

$\frac{}{R^2}$,
orted length of member, in inches,
adius of gyration of section, in inches,

so limited that for main members $L + R$ does not exceed 125 to
econdary members $L + R$ does not exceed 150 to 220.

tricity in Stresses at Joints. — As tower members are ordinarily
ether the stresses in them are slightly eccentric, thereby prevent-
rength of the members being developed. The eccentricity should
or reduced as much as possible by having the center of gravity
members at each connection meet at one point as exactly as

ACTING ON TOWER FOUNDATIONS.—Foundation stresses
ses: first, the foundations resist the tendency of the tower to slide
due to the external forces on it considering the tower as a self-
cture; second, the foundations resist certain stresses which would
wer stresses were the tower framed as a complete self-contained
which become external stresses because the ground is depended
tion of certain omitted members. The weight of the tower can
educed by thus substituting the ground for certain members, but
ndation is thereby increased. The amount of these latter stresses
e outline and framing of the tower and their effect should not be
letermining loadings on foundations.
ude and direction of the forces acting on the tower foundations
ated by taking the case of a rectangular tower, and considering
line which runs north and south.

(feet) of base of tower (east and west);
(feet) of base of tower (north and south);
eight (pounds) of tower, insulators, fittings and one span of all
wires, including ice load, if any;
eight (pounds) of any unbalanced load, such as a wire c feet off
r;
nt force (pounds) of the wind on the tower and a complete
of all the wires (with ice coat, if any), acting at a distance of d
above the foundation, wind assumed blowing across line from
to east,
ounds) of any unbalanced force toward the south applied at a
ace of e feet above the foundation and f feet to the west of axis
wer, as for example, a dead-ended wire or when a wire on the
side of the tower is broken.

that the forces divide equally among the four foundations and
al forces are in a circumferential direction, the relations given
table hold. These assumptions are reasonably correct for a
four legs joined at the bottom with a horizontal strut in each
s and with horizontal ties across the diagonals, unless the
usually provided in the other faces is inadequate. Probably
s fully meet these requirements. Therefore, there are usually
s of large magnitude due to the foundations performing the
ng or inadequate members, as pointed out in the notes ap-
ble.

Google

tending to the surface of the earth. The face of this cone is as making an angle of 30° with the vertical.

ontal Overturning Force, Sliding and Indirect Uplift. — The erturning force is also important. Its effect on the base may be two components, one a horizontal force tending to slide the foun- he other a moment tending to rotate the base about a horizontal sistance of the earth to these forces is an obscure subject, especially tion is of irregular shape. The following discussion which neglects able elements may be considered as a conservative view of the earth

nce to sliding may be considered as due to the friction of the base on the earth, and it may further be assumed that any base to resist uplift will also furnish sufficient friction to prevent slid- n of the overturning force is then the same as the height of the ottom of base to top where tower is attached), and the over- nt is equal to the horizontal force multiplied by this arm. The ent may be considered as due entirely to the vertical reaction of the top and bottom of the foundation. These vertical pressures as varying uniformly from zero at a horizontal neutral axis through the base, to a maximum at the edges of the base most remote from e moment of resistance is calculated as for a beam subject to aving a cross-section identical with the area of the base. It may at any unit pressure allowable on the uplift edge will be amply posite edge where the pressure is downward, so that calculations y are necessary. The maximum allowable unit stress on the y be taken as equal to the average unit resistance to uplift of dation, determined as described above under *Direct Uplift*.

g Conditions. — Usually the most severe condition that a tower required to meet consists of a combination of uplift and over- this condition the unit stress of uplift proper must be added to unit stress of uplift due to overturning and the sum must be wable average unit resistance to uplift.

Foundations. — (*See also article on Strength and Elasticity.*) A ubject to stresses from the tower tending to move it and from the he earth preventing motion. The foundation should of course gh not to break when subject to these opposing forces. As the cation of the resistance of the earth and the magnitude of the ransmitted by the earth at any point are subject to great un- foundation should be designed for strength for the distribution nce which is most severe, considering for example that while the is calculated on a uniformly-distributed earth resistance, it may practice by concentrated pressure from stones or timber located edge of the base.

Points Regarding Design of Foundations. — The following are lusions which follow from the above discussion:

erted cone theory of resistance to uplift gives a calculated re- increases at a rapid rate with the depth (eventually increasing as the cube of the depth). It would however be unsafe to ap- for foundations differing much from those of usual dimensions, much exceeding six feet and for foundations where the spread of less than the depth to which it is buried.

of the tower (top of foundation) should be brought as close to he ground as possible to reduce the overturning moment.

Digitized by Google

he tower diagonals of the bottom panel of the tower should intersect
osts as low as possible, because this is the actual point of application
rturning force to the foundation and if this intersection is above
ion this extra length must be added to the arm of the overturn

ly inclining the axis of the foundation approximately in line with
tower leg (i.e., to bring it as near as possible into line with the result
iorizontal overturning force and the vertical pressure or uplift) a
ical use of material may be made to resist the combined uplift and

TING OF TOWERS. — Since towers are generally indeterminate st
iew designs are usually tested. Test loads proportional to the
l for the design are applied until the required factor of safety has
or failure occurs. Towers are usually mounted on a rigid base for
his gives the strength which the tower would develop on an "id
ion. In practice the tower must be expected to develop somewhat
ı, as unequal movement of the foundations will ordinarily overst
members. Test loads may be applied by means of weights suspe
at proper points for vertical loads and applied by means of pulle
to a tower-testing structure ("test tower") for horizontal loads. T
of application makes the determination of the test loads easy, but
nient to have the weights fall any considerable distance if the tow
o failure.

ng of Foundations. — Foundations are occasionally tested, but t
usually more for determining the holding power of the soil than
ı of the foundation. For the former purpose the test result will dep
on the character of the soil and its condition (dry, wet or frozen). Te
ling power are only necessary for uplift and overturning forces. In te
important that the testing machine should not press down on the surf
oil near the foundation. The machine should rest on the ground o
the base of an inverted cone of angle of 45° from the vertical and
g the base of the foundation under test.

CIFICATIONS, CONTRACTS AND PROPOSALS. — Differ
.cturers of towers use different details of construction so that specifi
ritten for the purpose of obtaining proposals should contain only
and requirements. These should state the loadings, factors of saf
ım allowable stresses, and show outline dimensions of the tower as de
from clearances required.

specifications should state whether towers are bolted or riveted, g
l or painted, shipped assembled or partly assembled, tested or not tes
sides containing the usual structural steel specifications; see *Steel*.

proposals should show the arrangement and sizes of members and typ
of connections.

racts are oftentimes let on the basis of furnishing an approximate nu
towers when the exact number required cannot be determined in a
and a unit price per pound is included to cover extensions, spec
tions and modifications that may be required.

galvanizing and sherardizing of towers and parts are usually specified t
ıe American Telephone and Telegraph Co's. Specification for galva
on wire (*see Galvanising for Iron or Steel*). All members of towers th
too heavy, so that there is danger of their buckling in the process, ma
ified to be galvanized by the hot dip process. All bolts, nuts, threade
id turnbuckles may be specified to be sherardized.

Digitized by Google

ATION AND ERECTION. — Towers are generally shipped en-
mbled, all of the members for one tower being bundled together.
usually assembled lying on its face on the ground adjacent to the
When assembled it is temporarily braced when necessary (usually
ween the legs at the base of the tower) and up-ended onto the foun-
r the latter operation temporary hinges connecting the two legs
ground to the two adjacent foundations are convenient. Towers
up-end and towers in inaccessible places are built up in place.
d connections the nuts should be prevented from working loose by
ads on bolts, riveting over the end of the bolt, or by lock-nut or

r member should have a number which should be shown on the
ings and marked on the corresponding member of each tower.
rs should be cut, bent and punched to template so that the parts
nangeable and the assembled tower will fit the foundation prepared

n of Foundations. — Foundations should be set with their bases
st line. The hole should not be excavated deeper than necessary,
undation may rest on undisturbed earth. If any of the several
f a tower rest on loose backfill, unequal settlement may be ex-
may greatly weaken the tower. The hole should not be larger
y, as the backfill will be less effective than undisturbed earth in
t. The resistance of concrete foundations can sometimes be in-
gging a hole smaller in diameter than the base and undercutting
om, while with structural steel foundations large stones can some-
ed against the steel to increase its resistance to motion, either
eral. The backfill should be well tamped in place and especial
used if it is probable that the foundation will be subject to heavy
he earth has had time to settle. On sloping ground filling may be
e low side to give the designed weight of earth against uplift. In
the floating power of hydrostatic pressure beneath the foundation
ed for. Where towers are raised on extensions the increased
esses due to increased moment must not be overlooked.
foundations of a tower should be set accurately by template
ls spacing and elevation so that towers stand trully vertical and
stresses due to distortion.

ANCE OF TOWERS. — All bolted connections on towers
ully watched and kept tight, and the galvanizing or paint should
gularly and towers must be repainted before any deterioration
ccurs. Foundations are the most likely source of trouble in
ese should be kept properly backfilled and should be watched
tlement of legs.

ONS, WEIGHTS, COSTS. — Data on these items for a number
given in the following table. Galvanized towers cost from 2½
pound, f.o.b. factory. Galvanizing costs from ½ to 1 cent per
t of galvanizing is included in the figures just given.

General Description. — The electrical transformer, commonly called the tic transformer, is a piece of stationary apparatus used to transform alter- ting-current energy at one voltage to some other higher or lower voltage. e single-phase transformer consists of two electrical circuits, usually of a ge number of turns, interlinked with a common magnetic circuit of iron. ice the power is approximately the same in both windings, the currents in e two windings are inversely proportional to the voltages in the windings. e polyphase transformer is essentially two or more single-phase transformers ide into a single piece of apparatus, but so designed that at least a part of e magnetic circuit is common to all the phases. A three-phase transformer s three high-tension and three low-tension windings arranged on a single n core; see Figs. 1 and 2. The auto-transformer is treated in a separate ticle, viz., *Auto-Transformers.*

Terminology. — The winding by which the energy enters the transformer logically the "primary" and the one by which the energy leaves the trans- rmer is called the "secondary." Since either winding of the transformer ay be connected to the source of energy, these terms are not definite unless e manner of connection is also stated. When referring to the transformer as separate piece of apparatus the terms "high-tension" winding and "low-ten- on" winding are used to distinguish the two windings, the high-tension winding ing the one with the greater number of turns. When the high-tension winding connected to the source of supply it is the primary, and the transformer is id to be used as a "step-down" transformer; when the low-tension winding connected to the source of supply, the high-tension winding is the secondary, id the transformer is said to be used as a "step-up" transformer.

CLASSIFICATION. — Transformers may be classified according to their perating characteristics, to their construction, or to the method of cooling.

Constant Potential and Constant-current Transformers. — Transformers ay be either constant potential, such as are intended to give an approximately onstant potential on the secondary side, or constant current, intended to give n approximately constant current on the secondary. Both types are intended o operate on a supply circuit of a constant potential.

Series Transformers are connected in series with the main circuit and re- ceive a variable voltage and current in the primary. The secondary circuit is

Digitized by Google

closed through a path of low impedance and thus the secondary current will be proportional by the ratio of turns to the load current flowing in the primary or supply circuit. They are usually used to supply low-reading ammeters and wattmeters from circuits carrying very heavy currents.

Auto-Transformers or Compensators, sometimes called single-circuit transformers, consist of one electric circuit interlinked with the magnetic circuit and a tap brought off from some part of the winding. The voltage between the tap and either terminal of the electric circuit will be a fraction of the total voltage and thus a fractional voltage may be secured from this piece of apparatus. It is customary to proportion the windings on each side of the tap in accordance with the current to be carried. Auto-transformers are generally used where the ratio of voltages is quite near to unity as in this case they can be constructed with much less copper than the regular transformer. See article on *Auto-transformers.*

Potential Regulators are a form of transformer in which the voltage of one member may be varied from zero to a fixed maximum either by changing the direction of the magnetic flux or by changing the phase of the electromotive force of the secondary with respect to the electromotive force of the primary.

Core and Shell Types.—Two methods of arranging the electric and magnetic circuits are in use, the corresponding construction being designated as the "core type" or the "shell type." At present a large number of lighting transformers of small and medium capacity are constructed in a manner which is a composite of the core and shell types.

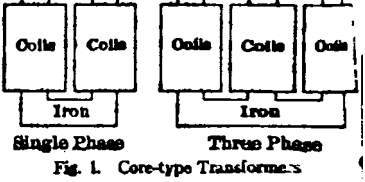

Fig. 1. Core-type Transformers

Core Type (Fig. 1).—The single-phase core-type transformer consists of a single magnetic circuit interlinked with two electric circuits, each consisting of a group of coils as shown in Fig. 1. The three-phase core-type transformer is also shown in Fig. 1.

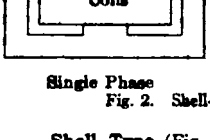

Fig. 2. Shell-type Transformers

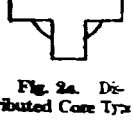

Fig. 2a. Distributed Core Type

Shell Type (Fig. 2).—In the shell type of transformer each electric circuit is interlinked with two magnetic circuits having a common path inside the coils but branching outside of the coils as shown in Fig. 2.

Distributed Core Type (Fig. 2*a*) is a compromise between shell and core type and is much used for small lighting transformers because it economizes in iron and distributes the heat. It consists of the two electric circuits wound concentrically about one central core which divides at the top and bottom into four radiating magnetic circuits surrounding the coils on four sides. It is shown in Fig. 2*a* in plan view.

Comparison of Core and Shell Type.—The core type of construction is best adapted for high-voltage low-capacity transformers and the shell

e for low-voltage high-capacity transformers. This arises from the fact that most economical disposition of material in the core type demands a large ıber of turns and small cross-section of iron, while in the shell type a large ıs-section of iron and small number of turns may be used to advantage. In shell type the coils are usually wound in flat "pan-cakes," this type of struction being particularly well suited to the use of heavy copper rib- or straps. In the core type the coils usually consist of two or more ›ls, long in comparison with their diameter. The use of the core type is easing both in number and size of transformers as it is found possible to nge the coils so they will better withstand the mechanical strain due to 't circuits.

lassification According to Method of Cooling. — (*See also below.*) nsformers may be subdivided into classes in accordance with the method l for dissipating the heat due to their internal losses. As a transformer is a compact piece of apparatus the problem of carrying away the heat is important and various ingenious means have been devised for the purpose.

Naturally Cooled Transformers. — As this name implies this type of sformer has no special means of cooling but relies upon the ordinary circu- ın of the air. It is only used in transformers of very small sizes, such as ıe intended to supply meters.

Oil-cooled Transformers. — In this type of transformer the core and lings are submerged completely in oil in a tank and the windings and core subdivided by ducts in order that the oil may circulate and carry off the from the internal parts. The heat is carried to the surface of the tank ch contains the transformer and from there carried off by the surround- air. The tank is specially designed to provide large air-cooling surfaces, provided with deep corrugations, or with projecting vanes or tubes.

Air-blast Transformers are designed with special passages through ch a current of air is forced by means of a blower, the heat being carried off he atmosphere in this manner.

Water-cooled Transformers consist of a construction similar to that he oil-cooled type and in addition a coil of pipe carrying running water is nerged in the oil.

Forced-oil Transformers. — Transformers artificially cooled by cir- tion of oil are used when the size is too great for the self-cooling oil type no cooling water is available. The oil circulates through external coils or cs which give a greater cooling surface.

IETHODS OF RATING. — The *Standardisation Rules of the A.I.E.E.* ify that the continuous rating of a transformer is that load in kilo-volt- ıeres which when applied continuously will cause a rise in temperature of C. as measured by a thermometer, or 55° as measured by resistance of the dings. The iron of transformers takes a long time to reach a constant perature, that of oil-cooled transformers in particular requiring from 10 to 12 rs. Thus a transformer will stand a considerable overload for a short time ›out overheating, the principal danger being excessive mechanical stresses.

'RANSFORMER PRINCIPLES. — (*See also Electricity and Magnetism, nciples of.*) The essential features of a transformer consist of a primary ding having a number of turns interlinked with a magnetic circuit, and a ›ndary winding also interlinked with the same magnetic circuit, as shown ig. 3.

Simple Theory, Neglecting Leakage Reactance. — In the following dis- sion the assumption will first be made that all the flux links both primary l secondary windings; the effect of the leakage flux will be discussed later.

In Fig. 3, S_1 is the primary winding, M the magnetic circuit (of iron) and the secondary winding. If an alternating current is caused to flow in S_1 it will set up a flux in M which at any instant is proportional to the current i_1. Thus

$$\phi = \frac{4\pi S_1 i_1}{10 R},$$

where S_1 is the number of turns, i_1 the instantaneous value of the current and R the magnetic reluctance of the path in M.

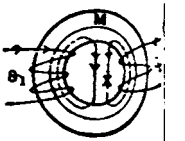

Fig. 3. Elementary Transformer

Thus ϕ alternates with i_1 and since it interlinks with S_2 it will induce a voltage in S_2 at any instant equal to

$$e_2 = -S_2 \frac{d\phi}{dt} 10^{-8} \quad \text{volts}$$

in which S_2 is the number of turns. The negative sign means that any current due to e_2 will tend to diminish ϕ.

No-load Conditions. — When there is no current in the secondary the vector relations are as shown in Fig. 4. Let E_1 be the voltage impressed on S_1, then the maximum value of the alternating flux will be

$$\phi = \frac{10^8 E_1}{4.44 f S_1},$$

where f is the frequency of alternation of E_1. Strictly, the numerator is $10^8(E_1 - r_1 I_\omega)$, where I_ω is the exciting current and r_1 the resistance of the primary, but the term $r_1 I_\omega$ is practically negligible. This flux will lag 90° behind E_1 or 90° ahead of the counter electromotive force E_c which it induces in S_1. The true magnetizing current I_m will be in phase with the flux and the hysteresis component of current I_H will be in phase with E_1. Hence the total no-load current I_ω will assume some phase a little less than 90° behind E_1.

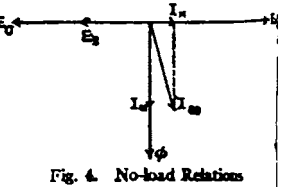

Fig. 4. No-load Relations

The flux ϕ will induce in the secondary turns S_2 an e.m.f. 90° behind the flux, hence 180° behind E_1 or in phase with the primary counter e.m.f. The effective value of this e.m.f. is

$$E_2 = 4.44 f S_2 \phi \, 10^{-8}.$$

Load on Secondary. — When the secondary is closed through a non-inductive external circuit a current will flow. This current will tend to demagnetize the iron, that is, to reduce the flux and hence the counter e.m.f. of the primary. This action, however, allows the current in the primary to increase until the secondary m.m.f. is balanced and there is left an excess m.m.f. in the primary to give sufficient flux to induce the counter e.m.f. E_1'. The vector relations are as shown in Fig. 5, again neglecting the leakage flux.

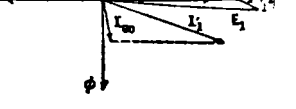

Fig. 5. Full Load, No Leakage

Leakage Reactance. — Due to the fact that a part of the lines of induction set up by the currents in the two windings pass through the air space (Fig. 3), the m.m.f.'s set up by the secondary current and the load current

(the current I_1' in Fig. 5) cannot neutralize each other, since the es established by the two currents are in the same direction, and ition as are the fluxes in the iron. The primary leakage flux is in he total primary current and the secondary leakage flux is in phase condary current; these leakage fluxes are therefore not in phase eful flux (i.e., the flux which links both primary and secondary). that the leakage fluxes cause a decrease in the secondary voltage ifting of its phase with respect to the primary voltage.

t " Circuit of Transformer. — In practice it is not possible to ately the primary and secondary reactances. They must be ther and treated as one quantity, called the total reactance x_t rmer, which may be expressed in terms of either the primary condary turns.

proximate method which is sufficiently accurate for all practical ed on the equivalent circuits shown in Fig. 8. This method is

used in calculating the characteristics of a transformer from constants obtained from tests.

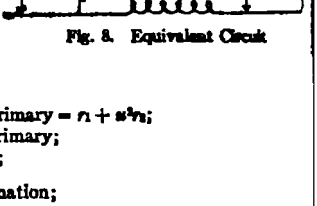

Fig. 8. Equivalent Circuit

Let E_2 = terminal e.m.f. of secondary;
$\cos\theta_2$ = power factor of load;
I_2 = secondary current;
u = ratio of transformation = $\frac{S_1}{S_2}$;
E_2' = uE_2;
I_2' = $\frac{I_2}{u}$;
R = total resistance in terms of primary = $r_1 + u^2r_2$;
X = total reactance in terms of primary;
I_M = primary magnetizing current;
I_H = $\frac{\text{core-loss}}{uE_2}$, to a close approximation;
E_1 = primary impressed e.m.f.;
I_1 = total primary current;
$\cos\theta_1$ = power factor of transformer with load, i.e., power factor at primary terminals;
P_1 = watts input at primary terminals;
η = per cent efficiency.

Then

$$E_1 = \sqrt{(E_2'\cos\theta_2 + RI_1)^2 + (E_2'\sin\theta_2 + XI_1)^2};$$
$$I_1 = \sqrt{(I_2'\cos\theta_2 + I_H)^2 + (I_2'\sin\theta_2 + I_M)^2};$$
$$P_1 = E_2I_2\cos\theta_2 + R(I_2')^2 + E_2'I_H;$$
$$\cos\theta_1 = \frac{P_1}{E_1I_1};$$
$$\eta = \frac{100\,P_2}{P_1};$$
$$P_2 = E_2I_2\cos\theta_2;$$
$$\text{Per cent regulation} = \frac{100\,(E_1 - uE_2)}{uE_2}.$$

Constant-current Transformers are used for supplying current to arc lamps connected in a series circuit which requires from 4 to 10 amperes and about 2000 volts. The principle of operation for this type of transformer is based on the existence of the leakage or useless flux which causes a repelling force between the primary and secondary windings. One winding is arranged so that it may move with respect to the other. As the current in the windings increases the repelling force increases and the windings move apart. This allows more flux to leak or pass between the windings and less to thread the secondary. Therefore the voltage induced in the secondary decreases as the current tends to increase. A counterweight is attached to the movable winding to regulate the amount of movement. The current in the primary remains fairly constant but the power factor decreases with decreasing load on the secondary so that power in the primary is approximately proportional to the output of the secondary.

Series Transformers operate under conditions similar to those in a constant-potential transformer with short-circuited secondary. Under operating conditions the flux is small as the only voltage to be induced in the secondary is that required to overcome the impedance drop in that winding and the instrument which it supplies. The only counter e.m.f. in the primary is that due to impedance drop. The series transformer must be operated with the secondary

rt circuited by a low impedance. If the secondary circuit is open there is counter m.m.f. to balance the primary turns, which, being in series with the in line, carry a current irrespective of the secondary circuit. The primary pere-turns would then set up a magnetic flux of considerable magnitude. the transformer is not designed for this condition, the density would become y high in the magnetic circuit of small cross-section, and the transformer is ble to burn up from the heat due to core-loss.

TRANSFORMER CONNECTIONS. — The various transformer connecns which are commonly used in lighting and power services are described ow; see also section on *Operation* below.

Single-phase System with Three-wire Secondary (Fig. 9). — Standard ictice in residence lighting with the a-c. system involves grounding the neuwire on the low-tension side, the primary side not being grounded. Lamps motors operating at 110 volts are connected between the neutral and either

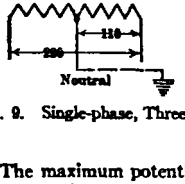

Fig. 9. Single-phase, Three-wire

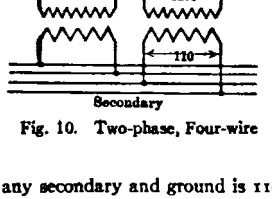

Fig. 10. Two-phase, Four-wire

le. The maximum potential between any secondary and ground is 110 volts it if either of the outside wires becomes grounded it constitutes a short-circit on that half of the transformer.

Two-phase or Quarter-phase Four-wire System (Fig. 10). — The standd two-phase or quarter-phase system is essentially two independent singlease systems which are usually independent electrically throughout. When e two phases are not electrically connected inside the generator, either wire one phase may be connected to either wire of the other phase, without any ow of current resulting. In certain two-phase generators, however, the windgs are interconnected, in which case any interconection of the wires coming from the generator will ause a flow of current through this connection.

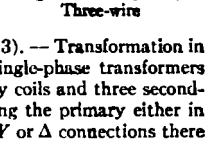

Fig. 11. Two-phase, Three-wire

Two-phase Three-wire System (Fig. 11). — his connection is occasionally used for the distriution of power in small systems. There is a possiility of a slight saving in copper, but the chances f unbalanced voltage and bad regulation, particlarly with an inductive load, render it objectionable.

Three-phase Y and Δ Connections (Figs. 12 and 13). — Transformation in three-phase system with either three independent single-phase transformers r with a three-phase transformer, having three primary coils and three secondry coils on one iron core, is accomplished by connecting the primary either in *Y* or in Δ and the secondary either in *Y* or in Δ. With *Y* or Δ connections there re the following relations between voltage per transformer winding and voltge between lines, and between current in transformer windings and current n lines. The power in the three transformers in any case is $3 \times 0.58 \times EI = 1.73\,EI$.

Digitized by Google

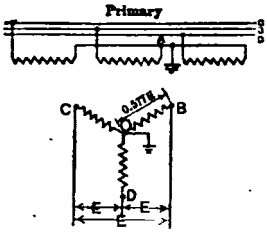

Fig. 12. Three-phase Y

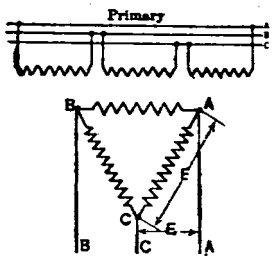

Fig. 13. Three-phase Delta

Connection	Volts bet. lines	Volts per winding	Current per line	Current per winding
Y	*E*	0.58 *E*	*I*	*I*
Δ	*E*	*E*	*I*	0.58 *I*

There are four combinations of these connections which may be used on any bank of transformers. These connections are given in the following table, and also the ratio of the voltage between lines for the low-tension and high-tension sides for a given ratio (u) of transformation in each individual transformer connection.

Connection		Low-potential volts bet. lines	High-potential volts bet. lines
Low pot.	High pot.		
Δ	Δ	*E*	*uE*
Y	*Y*	*E*	*uE*
Δ	*Y*	*E*	1.73 *uE*
Y	Δ	*E*	0.58 *uE*

Parallel Connection of Three-Phase Banks. — If there are several banks of transformers in the same system connected in parallel on one side, then to connect the other sides in parallel the connections must be such that the voltage between any two lines on this side will have the same phase in all the banks. From this relation result the following rules:

With ΔΔ on one bank, the other bank must be ΔΔ or *YY*.
With *YY* on one bank, the other bank must be ΔΔ or *YY*.
With Δ*Y* on one bank, the other bank must be Δ*Y* or *Y*Δ.
With *Y*Δ on one bank, the other bank must be *Y*Δ or Δ*Y*.

Even when these relations are satisfied a short-circuit will result unless the three phases of each bank are connected in the proper sequence. This can be

ermined by the polarity test described below in the section on

tive Advantages of Y and Δ Connections. — There has been ssion as to the relative advantages of *Y*- and Δ-connected trans- high-tension transmission and as to the value of a grounded neu- eneral and fundamental arguments may be summed up as follows: Δ-system the advantages are that if one transformer becomes dis- stem may be operated from the other two, operating on open delta If the load is unbalanced the voltages do not become unduly un- Resonance cannot occur. On the other hand, each transformer ulated for full line voltage as there is no neutral to ground, and if omes grounded the voltage strain on the rest of the system becomes he normal strain, and this strain may extend to the low-tension the generator which is connected to the transformers.

Y-connection there is a very unstable neutral and a possible ex- ge strain on one phase, unless the neutral is grounded.

Y arrangement for step-up transformers, the neutral on the high- may be grounded. The voltage strain on any transformer is then 3 per cent of the line voltage. There is a possibility of operating g two transformers, if one becomes damaged, by using the neutral conductor. However, there is the possibility of resonance under mstances and the danger of causing disturbances in nearby tele- elegraph circuits. Any accidental ground on the system makes a t-circuit on one phase.

gement of *Y*Δ for step-up transformers is not desirable on account ble neutral with unbalanced load, but is permissible with a balanced a good connection from neutral of transformers to neutral of genera- onnection, however, is frequently used for step-down transformers when connected to a balanced load.

nded Neutral vs. Ungrounded Neutral. — In any system rounded neutral there are numerous possibilities of disturbances a high voltage strain on the various parts of the insulation of the th the high voltages now in use for transmission systems these may give a great deal of trouble by breaking down the insulation, always possible to employ a large margin of safety and lightning not always protect from these disturbances. On the other hand, l is grounded, most of these disturbances will merely result in an rent, and if the circuit breakers are installed in the proper places n the circuit, so that the only adverse result will be a temporary of service.

e is then between a system with ungrounded neutral and a large fety in the insulation, and a system with grounded neutral, mod- ion and the possibility of occasional interruption of service.

t of Higher Harmonics. — Many alternators generate an e.m.f. shape contains higher harmonics (*see Wave Analysis*) and the mag- ent of transformers operating at high magnetic densities has a ve shape which contains a prominent third harmonic. If these re present in a *Y*-connected machine they cause the voltage be- ine and the neutral to vary so that there exists an unstable neu- voltage strain on any one phase is indeterminate. If the neutrals s of apparatus in which these harmonics exist are grounded or ier, a high-frequency current will flow in the neutral connection. er hand these pieces of apparatus are Δ-connected a third harmonic circulate inside the apparatus. This may be measured by con-

Digitized by Google

necting an ammeter in the Δ between two phases. This current heats the apparatus, does no profitable work, and is therefore to be avoided. High frequency current in the line will cause high voltages to occur at certain points if a large amount of capacity is present, as is the case in any underground line even of moderate length, and also in long overhead lines. All possible means both in the design of the generators and the connection of the apparatus should be taken to prevent the occurrence of, or to diminish the effect of, these higher harmonics.

Three-phase Open Δ or V Connection (Fig. 14). — This system consists in omitting one transformer from the delta connection, and is used to save expense, particularly in temporary installations or in new installations where the load is not great at first but is expected to increase in time. Thus the

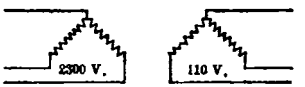

Fig. 14. Three-phase, Open Delta

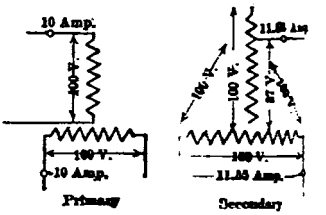

Fig. 15. Two-phase to Three-phase

purchase and installation of the third transformer is postponed until the load requires it. This connection can only be recommended for low voltages, such as 2300, as it is liable to produce dangerous potentials due to electrostatic unbalancing. The regulation and efficiency are also poor, as one phase of the load receives its power from two transformers in series. The aggregate capacity of the two transformers should be 15 per cent greater than the load.

Two-phase to Three-phase Transformation (Fig. 15). — The Scott or T connection, the standard method of transforming from two-phase to three-phase, consists of two transformers which on the two-phase side may be connected in the normal two-phase manner either independently or interlinked. On the three-phase side one transformer has a tap at the middle point and the other a tap giving 87 per cent of full-transformer voltage. Fig. 15 shows the method of connecting and the currents in primary and secondary with balanced loads. Since the total power is $2 E_2 I_2 = \sqrt{3}\, E_3 I_3$, it follows that $I_3 = \frac{2}{\sqrt{3}} \frac{E_2}{E_3} I_2$, or the three-phase current is 16 per cent greater than it would be for straight single- or two-phase transformation. Thus one of the windings of one transformer must carry 16 per cent more than its share of the volt-amperes of the load and is overloaded in that proportion.

In commercial practice it is customary for the sake of interchangeability to make the capacity of both transformers 16 per cent greater than the load and to put both a 50 per cent and 87 per cent tap on both transformers. For this connection of transformers each half of the main transformer winding must be distributed over both legs of the core in order to prevent flux (and therefore voltage) unbalancing. If this precaution is taken both the primary and secondary voltages are balanced if the load is balanced. Any unbalancing of the secondary causes a like amount of unbalancing on the primary; thus if this connection is used to transform from 3-phase to 2-phase and all the load comes on one phase of the secondary it will also come on one phase of the primary.

Transformer Connection for Synchronous Converters.—For a tv
onverter the connections are simple as shown under *Converters*. For
hase converter there is a choice between Δ or *Y* secondaries, which is
ecided in deference to the conditions in
he high-tension line. The delta connection
s customary in railway substations. A
iagram of the connections is given in the
rticle on *Converters, Synchronous*. When
ie converter is to supply a three-wire d-c.
ghting system, the "distributed" *Y* con-
ection for the secondary should be used
s shown in Fig. 16. By this arrange-
ient the unbalanced current from the d-c.
eutral is divided, and sent through the two
alves of each transformer in opposite di-
ections. Thus it does not increase the magnetic densities in the tr
rs, and avoids the excessive core-loss which would occur with a s
onnection.

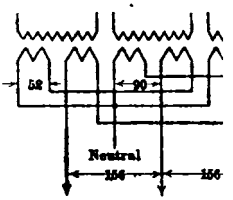

Fig. 16. Distributed Y for T
Converter

For six-phase converters there is the choice between the "diametri
double delta" connections as shown in Figs. 17 and 18. The diam

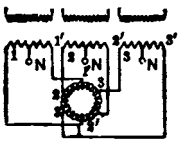

Fig. 17. Six-phase Diametrical

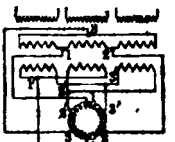

Fig. 18. Six-phase Delta

ommon with railway converters, or where the conditions are such
elta is not needed to prevent an unstable neutral.

For regulating pole or split-pole converters certain special conditions
orne in mind in choosing between the diametrical and the doubl
ections. With the variation of the direct voltage of the converter t
ape of the alternating e.m.f. is distorted and this introduces harm
ther the counter e.m.f. or current waves, among which the third
ominent. If the delta connection is used a local harmonic current c
the converter armature and transformer secondaries, which incre
sses and heating and lowers the efficiency. If the diametrical conn
ed the higher harmonic voltage gives an unstable neutral, and in
tra potential strains in the high-tension windings and line if *Y*-co
his may be obviated by grounding the neutral, but then a consider
nt may flow in the neutral connection, which may interfere with nel
rcuits. The best solution is to use the diametrical connection in the
y and ungrounded *Y* in primary, and use transformers having a gooc
safety in the insulation of the high-tension side.

THREE-PHASE TRANSFORMERS. — Considerable space, wi
st cost may be saved by the use of a three-phase transformer in
ree single-phase transformers. This saving is warranted in large inst
it not in small installations where the convenience of having one inte
le single-phase transformer as a spare for several banks of three tran
ch is an important item.

Digitized by Google

Core of Three-Phase Transformer. — Three-phase transformers may have of the core type as shown in Fig. 1, in which case all the magnetic paths are of the same cross-section, or of the shell type shown in Fig. 2. In the latter type the horizontal cross pieces and outside vertical pieces may have one-half the cross-section of the central vertical core, providing the coil on the central leg is connected with a definite polarity with respect to the other two coils in order to have the fluxes differ in phase by 60 degrees.

Operation of Damaged Three-phase Transformer. — In a shell-type three-phase transformer if the primary and secondary are delta-connected it is possible to operate with only two phases in open delta at reduced capacity in case of trouble in the third phase of the system. This is accomplished by separating the third phase entirely from the system and short-circuiting both the primary and secondary windings.

DESIGN. — (*See also section below on Cooling of Transformers.*) The methods of design for single-phase and polyphase transformers are similar, the chief difference being that of the magnetic circuit. In the design of polyphase transformers each leg is treated as an independent single-phase transformer. The number of turns is adjusted to the voltage per phase and the cross-section of the conductors to the current per phase. All legs are wound alike and the phases are connected up as described in the preceding section.

The alternating-current transformer is the most efficient piece of electrical apparatus. Its efficiency at full load is usually better than 95 per cent and frequently better than 98 per cent. For this reason it is very small in volume and light in weight for a given output compared to other pieces of electrical apparatus and hence the chief difficulty in design is the necessity of providing sufficient surface and a proper means to carry off the heat developed.

The difference in mechanical construction between the core and shell types is that the winding of the core type usually consists of two or more long spools (in which the length is considerably greater than the diameter) surrounding each leg of the transformer. The shell type consists usually of large flat "pancake" coils, laid alongside of each other on the central core with proper separating devices to permit ventilation. See Figs. 1 and 2.

The following discussion applies alike to both core and shell types except where specific mention to one or the other is made.

Preliminary Calculation of Main Dimensions. — Let

E_1 = primary voltage, effective value;
I_1 = primary full-load current, effective value;
E_2 = secondary voltage, effective value;
I_2 = secondary full-load current, effective value;
f = frequency in cycles per second;
S_1 = number of primary turns;
S_2 = number of secondary turns;
ϕ = maximum value of flux;
$C = \dfrac{\phi}{S_1 I_1}$ = ratio of total flux to full-load primary ampere-turns;
e = volts per turn, effective value;
B = maximum value of magnetic flux density in lines per square inch;
A = cross-section of core in square inches;
f_1 = space factor of winding space;
D = total section of copper in square inches;
U = current density in amperes per square inch;
σ = ampere-conductors per inch length of core.

ermination of Flux (ϕ) and Number of Primary Turns (S_1).— estimate a desirable value of the flux to be used there is employed which is defined by the relation

$$C = \frac{\phi}{S_1 I_1}. \qquad (1)$$

value of this factor C depends upon the type, capacity and voltage former, and the relative weights of copper and iron.* Usual values the accompanying table.

VALUES OF C

f transformer	Voltage	Core type	Shell type
		Value of C	Value of C
ft.....	0–6000	55–70	500–700
	6000 up	70–75	500–700
.....	0–10,000	75–100	
	10,000 up	100–150	
water-cooled...	0–10,000	110–160	600–1000
	10,000 up	160–240	600–1000

n between the effective value of the primary voltage and the ue of the flux is

$$E_1 = 4.44 f S_1 \phi \times 10^{-8}. \qquad (2)$$

equations (1) and (2) the proper values of the primary voltage ncy f, the constant C and the primary full-load current I_1, and o equations for ϕ and S_1, reasonable values for the flux ϕ and primary turns S_1 are obtained.

minary estimation of the full-load primary current I_1 it is suffi- e to ignore the efficiency and power factor and to take the current utput divided by primary voltage.

per Turn (e). — The above value of ϕ should be checked by ts per turn,

$$e = 4.44 f \phi \times 10^{-8},$$

it with values used in practice. In large transformers a greater n turns is permissible than in ners. The accompanying table transformers is based on the t double-cotton-covered wire is ndings. With special insulation ay be used. For the shell type es as great are customary.

Kilowatt rating of transformer	Allowable volts per turn for core type
10	2.5
20	3.5
50	5.5
100	7
200	9
500	13

of Secondary Turns (S_2). — ned in a preliminary way the ry turns, the number of turns in $S_2 = \frac{E_2}{E_1} S_1$. It will considerably anical arrangement of the coils if 4. The nearest multiple of 4 is l value of S_2 and then S_1 and ϕ correspond to this value of S_2.

f this factor C will be found in Arnold's *Transformers* and in S. P. *mo Electric Machinery*, Vol. II.

Digitized by Google

Cross-section of Core (A) and Magnetic Flux Density (B). — The cross-section is determined by the magnetic density which it is desirable to use, which in turn is determined by the core-loss. It is found that in average practice a loss of one watt per pound of iron can be dissipated without excessive rise in temperature. The corresponding flux densities in iron having a thickness of 14 mils are given in the following table. These values are approximate only since the quality of the steel used is exceedingly variable. It should also be noted for a transformer intended for supplying a load of low power factor that the iron loss should be less than 1 watt per pound for the best distribution of material.

VALUES OF FLUX DENSITY

Size of transformer	Kind of steel	Lines per sq. in.	
		25 cycles	60 cycles
Small	Ordinary transformer sheet	50,000	40,000
Small	Special; silicon-steel	70,000	60,000
Large	Ordinary transformer sheet	75,000	65,000
Large	Special; silicon-steel	90,000	75,000

The proper cross-section of core in square inches is then

$$A = \frac{\phi}{B}.$$

In the core type this cross-section may be assumed as a square whose side is d. Since the core is made up of laminations whose effective length one way is 0.9 d, the value of d is

$$d = \sqrt{\frac{A}{0.9}}.$$

In the shell type this cross-section is a rectangle whose length is from 2 to 3 times its width.

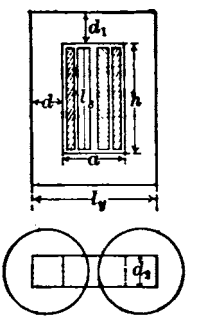

Fig. 19. Dimensions, Core Type

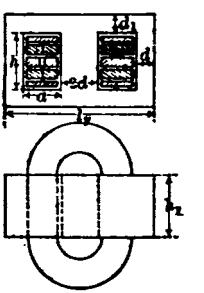

Fig. 20. Dimensions, Shell Type

Dimensions of Winding Space (Figs. 19 and 20). — The area or cross-section of the "window" or winding space depends upon the amount of copper

sulation and ventilating space. The first can be determined accurately by e chosen current density in the copper. The second and third are allowed : by a space factor (f_1) which gives the ratio of the actual total cross-section copper (D) to the cross-section of the window. Usual values of f_1 are given the following table.

SPACE FACTOR IN TRANSFORMERS (f_1)

Size of transformer, Kw.	Core type		Shell type		
	Up to 10,000 volts	33,000 volts	Up to 2000 volts	2000 to 10,000 volts	33,000 volts
0–50	0.22	0.15	....	....	....
50–1000	0.33	0.25	0.40	0.33	0.18
Above 1000	0.38	0.33	0.45	0.36	0.21

In the core type there is one window and it contains $S_1I_1 + S_2I_2$ ampere conctors; in the shell type there are two windows and each contains $S_1I_1 + S_2I_2$ ipere conductors. The cross-section of copper in one window in either case is

$$D = \frac{S_1I_1 + S_2I_2}{U} = \frac{2\,S_1I_1}{U},$$

here U, the current density in amperes per square inch, has the following lues:

Condition of transformer	U = amperes per sq. in.
Poorly cooled	850–1200
Ordinary oil cooled, air blast, etc.	1100–1600
Large, well cooled	1500–1900

Then the height h and width a of the window, see Figs. 19 and 20, must be ich that

$$ha = \frac{D}{f_1}.$$

Height of Core. — In the core type this depends upon the ampere-turns or npere-conductors per inch length of core, which in turn is related to the heatg. The ampere-conductors per inch length of core is

$$\sigma = \frac{S_1I_1 + S_2I_2}{2h} = \frac{S_1I_1}{h},$$

here h is the height of core.

For a maximum rise in temperature of 50° C. σ will have values as given in he accompanying table. A reasonable value of h can then be found.

Digitized by Google

Form of transformer	σ = amp. conductors per inch of core
Natural cooled	500–750
Oil cooled or air blast	750–1250
Water cooled	1250–2000

In the shell-type transformer the practice is to make the height (h) from 1.5 to 3 times the width of window (a) and the width of window from 0.75 to 1.25 times the width of the central iron core, $2d$ in Fig. 20. See also paragraph above on *Cross-section of Core.*

Details of the Winding.—

$$\text{Cross-section of primary conductor in square inches} = \frac{I_1}{U}.$$

$$\text{Cross-section of secondary conductor in square inches} = \frac{I_2}{U}.$$

For minimum loss the copper density should be the same in both members but to save space the copper density in the high-potential winding is sometimes greater than that in the low-potential winding.

The low-potential winding is usually placed between the high-potential winding and the iron.

Each coil is now laid out in detail, placing as many turns in a layer as the height and insulation will allow. The voltage per layer must not exceed 150 to 200 volts. A space of 10 mils is to be allowed for insulation between layers when insulated wire is used and 8 mils when insulated strip is used. The space between coils is from 0.04 to 0.30 inch, depending upon the voltage per coil. Space for the air or oil ducts is also provided. Each duct is from ¼ to ⅜ inch wide and there should be one on each side of each coil. No part of the winding should be more than ⅝ inch from the surface of a duct.

Insulation of Windings.— The insulation of each turn usually consists of the cotton covering if the coils are wound with wire, or mica paper if the coils are wound with strip copper. This is proportioned to withstand the potential between turns as given above. The voltage between conductors on adjacent layers may be equal to twice the voltage per layer. To prevent breaking down between layers, a layer of Fuller board is used as a separator and this should project beyond the windings at the ends to prevent creepage. The maximum voltage between layers should be kept below 400 and to accomplish this it is customary to limit the voltage per coil to about 5000 volts. Between the windings and the core a layer of pressboard and sometimes wood is placed while between primary and secondary windings a layer of pressboard and micanite may be used. For very high voltages the end turns of the high-tension winding for about 75 feet from the terminals is given a special insulation to withstand the sudden high potentials which occur when there is a sudden change in the potential applied to the transformer. These high potentials result from the distributed capacity of the transformer, between the high-tension winding and the core, frame and other winding.

Terminal Bushings. — At the point where the high potential leads pass through the case there is a very great dielectric stress which must be taken care of by the use of a proper kind of insulation and a proper disposition of the

Digitized by Google

o prevent a concentration of the dielectric flux at a few points. For ow 40,000 a porcelain bushing is customarily used.
r voltages it is necessary to supply a large creepage distance and to face submerged in oil to prevent corona effect. This is accomplished of bushing, known as the "condenser type," by surrounding the th layers of insulation and putting sheets of tinfoil between the is arrangement is equivalent to a series of condensers. By properly ig the area of the successive layers of tinfoil the drop in potential nsulation is kept uniform. The whole terminal is inclosed in an ng. Another form of bushing known as the "oil-filled type" consists ylinder of composition insulation which surrounds the lead and is oil. The cylinder is divided into compartments to keep the oil tributed, and disks or collars project outward from the outside to creepage distance.

Coils of Shell Type. — With the flat coils customarily used in e transformer the subdivision of the windings is usually such that lf coil of the low-potential winding at each end of the winding space). This is to reduce the leakage flux. In order to further reduce flux all coils may be divided into halves with a ventilating duct ves. The space between a primary and secondary coil is then iat necessary for the insulation.

nt of Core Dimensions. — After the final details of the windings the cross-section and length of core is finally settled. Sometimes tion of core in the core type is made cruciform instead of square se more effectively the area inside of circular coils.

ERMINATION OF THE PERFORMANCE OF A TRANS- — From the above calculations a drawing to scale of the trans- e laid out. The next step is to calculate its performance, i.e., to the values of the efficiency, regulation and temperature rise. ture is treated in the following section on the *Cooling of Trans-*

ng Current (I_M). — The final flux density will probably differ a from the value assumed earlier in the calculation. The cross- e is usually proportioned to give the same magnetic density in all condition gives minimum core-loss for a given weight of iron. ength of path in the iron is measured or calculated. If H (found netization curve of the iron, see article on *Magnetic Properties of* ampere-turns per inch for the given density the magnetizing transformer will be

$$I_M = \frac{H \times (\text{length path})}{\sqrt{2}\, S_1}.$$

it is desired to allow for the minute air gaps at the joints of the rnold finds that under practical conditions each joint represents 2 inch. Thus if there are n joints (usually 4) there should be in amount

$$\frac{0.313 \times 0.002\, Bn}{\sqrt{2}\, S_1}.$$

— The core-loss consists of hysteresis and eddy losses in the s. These losses have been considerably reduced in recent years

by improvements in the manufacture and quality of the steel (*see article Magnetic Properties of Iron*).

$$\text{Core-loss} = k_1 f V \left(\frac{B}{1000}\right)^{1.6} 10^{-6} + k_2 V \left(t f \frac{B}{1000}\right)^2 10^{-6} \text{ watts,}$$

where f = frequency in cycles per second;
V = volume of iron in cubic inches;
B = magnetic density in lines per square inch;
t = thickness of laminations in inches;
k_1 = a constant, ranging from 8 in ordinary transformer steel to 4 silicon-steel;
k_2 = a constant, ranging from 4 in ordinary transformer steel to 1.5 silicon-steel.

The core-loss may be calculated more easily by the method and curves given in the article on *Magnetic Properties of Iron*.

Copper Loss. — The mean length of turn of both primary and secondary windings is obtained from a sketch to scale. The direct-current or ohmic resistance of each member at 60° C. is obtained by substituting the proper values in the formula

$$R = \frac{0.0093\, lS}{12{,}000\, as},$$

where l = mean length of turn of primary or secondary respectively in inches
S = number of turns in series,
a = cross-section of conductor in square inches,
s = number of conductors or coils in multiple.

To allow for eddy currents caused by the leakage flux, the above resistance is increased by 15 per cent to give the effective resistances r_1 and r_2. The total copper loss is then $I_1^2 r_1 + I_2^2 r_2$.

Transformer Reactance. — As explained in the section above on *Transformer Principles*, the leakage of flux between the primary and secondary windings of a transformer causes a component of voltage in each member which is out of phase with the current; if the current lags very much this voltage may have a considerable component opposed to the useful voltage and cause a loss of voltage or poor regulation. It is, therefore, necessary in designing to estimate the amount of this flux and calculate the voltage it would produce. In practice empirical formulæ are usually used, but a logically deduced formula is desirable as it is more easily adapted to unusual cases.

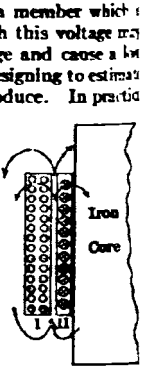

Fig. 21. Leakage Flux

The phase of the current in the secondary coil is nearly opposed to that in the primary and may be assumed to be exactly opposed without any great error. The result as shown in Fig. 21 is that all these ampere conductors, both primary and secondary, tend to set up a flux in the same direction in the space between the windings and to a lesser degree in the windings themselves. A part of the flux in the intervening space interlinks with the primary turns and another part with the secondary turns. In addition the flux in the windings themselves interlinks with some of the turns. The flux in each part is proportional to the ampere turns producing it and to the permeance of the path. In this case since the path is in air, the permeance is the area divided by the length, where the length is the average length of the flux lines.

he leakage flux passes between the windings and one part closes its path he iron inside the inner coil and the other part in air outside the outer coil the core type). The reluctance of the path between the two coils is large ıpared to that of the other two portions, because the inside path has a high neability and the outside path has a large cross-section. The reluctance he path between the coils is therefore accurately (and easily) calculated and ınstant used to allow for the rest of the path.

ı order to calculate the inductance it is necessary to have a cross-section he windings showing their thickness, length and arrangement, as in Figs. 19 20.

wo cases must be considered:

A) Where there are as many primary coils as secondary coils, and all coils are full size (usual core type).

B) Where there is a "half" secondary coil at each extremity of the group of windings (the usual arrangement in the shell-type transformers).

ırnold's Method of Calculating Reactance. — Arnold calculates the intance of a single primary coil and its secondary mate or mates, and multiplies by the number of primary coils in series or divides by the number in mul-. This gives the total "short-circuit" inductance of the transformer in ns of the primary voltage or turns.

eferring to Figs. 19 and 20 for the core and the shell type respectively, let various quantities be represented as follows, all dimensions being in inches:

q = number of primary coils in series,
p = number of primary coils in parallel,
s_1 = number of turns in one primary coil,
s_2 = number of turns in one whole secondary coil,
l_a = height of coils in cylinder type,
l_a = depth of coils in flat type,
t_1 = thickness of a whole primary coil,
t_2 = thickness of a whole secondary coil,
t = distance between coils,

l_1 and U_2 = mean length of primary and secondary turns respectively,
U_m = average of U_1 and U_2,
k = an empirical constant, varying from 0.95 with flat coils to 1.06 with cylinder coils.

Reactance of Core Type (Fig. 19). — In a core-type transformer with ndrical coils and an equal number of full-sized primary and secondary coils, permeance of the path of the flux in the duct which interlinks with a primary is $\frac{tU_1}{2l_a}$ and the permeance of the path in the winding itself is $\frac{t_1U_1}{3l_a}$.

: inductance of one primary coil is

$$L_1 = \frac{3.2\,ks_1^2U_1}{l_a}\left(\frac{t_1}{3}+\frac{t}{2}\right)10^{-8}.$$

: inductance of one secondary coil is

$$L_2 = \frac{3.2\,ks_2^2U_2}{l_a}\left(\frac{t_2}{3}+\frac{t}{2}\right)10^{-8}.$$

lucing the latter to terms of the primary turns by multiplying by $\frac{s_1^2}{s_2^2}$, adding ether and multiplying by $2\pi f$, the total reactance of the transformer in ns of the primary is

$$X = 2\pi f\,\frac{3.2\,qks_1^2U_m}{pl_a}\left(\frac{t_1+t_2}{3}+t\right)10^{-8}.$$

Digitized by Google

Reactance of Shell Type. — If, as in the
in Fig. 20, there is a half secondary coil at each en
mixing, then

$$X = 2\pi f \frac{3.2\, qks_1^2 U_m}{2\, pl_g}\left(\frac{l_1 + l_2}{6} + \right.$$

Efficiency and Regulation. — The efficiency a
lated as described above under "*Equivalent*" *Cir*
or by the following method, which is sufficiently
purposes.
Let

E_2 = secondary terminal voltage,
I_2 = secondary current,
$\cos\theta_2$ = power factor of load on secondary,
$P_2 = E_2 I_2 \cos\theta_2$ = secondary output in watts,
A = core-loss in watts = input for no-load on
u = ratio of number of primary to number of
$R_2 = \frac{r_1}{u^2} + r_2$ = total resistance in terms of se
actual resistances of primary and seco
$X_2 = \frac{X}{u^2}$ = total reactance in terms of secon
reactance in terms of primary.

Then the per cent efficiency is

$$\eta = \frac{100\, P_2}{P_2 + A + R_2 I_2^2}.$$

Secondary voltage at no load is

$$E_{20} = \sqrt{(E_2\cos\theta_2 + R_2 I_2)^2 + (E_2 \sin$$

and the regulation is then

$$\frac{100\,(E_{20} - E_2)}{E_2} \text{ per cent.}$$

All-day Efficiency. — The all-day efficiency is
between the readings of a watt-hour meter connec
similar meter on the primary. It is of importance
formers, particularly for lighting, operate at full lo
day, but the core-loss or iron losses are just as grea
or when there is no load at all. Hence these tran
deal of energy, although their efficiency at full load
To calculate the all-day efficiency multiply each
for efficiency by the number of hours per day that

$$\text{All-day eff.} = \frac{100\, P_2 \times h}{P_2 \times h + h_1 A + h R_2}$$

where h = hours per day of secondary load; h_1 = ho
is on line, and the other symbols as above. Since
a day and P_2 only 2 or 3 hours, the importance of
transformer for this class of service is apparent.
However, there is another side to the question, si
as much during the day when there is little dema
in the evening when the demand is great.

COOLING OF TRANSFORMERS. — It is necessary to keep the tem
ature of the various parts of a transformer within such limits that the ma
ials of which it is constructed do not become damaged and deteriorate to
idly. When subjected to too high a temperature the insulating materia
integrate and lose their mechanical and dielectric strength, and the iro
eriorates in its magnetic qualities so that the core-loss becomes greater fo
iven density. This so-called ageing of the iron may cause an increase of a
ich as 50 per cent in the loss in the iron. The effect varies with the charact
the iron and is practically negligible in silicon-steel.

Digitized by Google

Maximum Rise in Temperature.—The maximum rise in temperature above a room temperature of 25° C. at which the various materials of a transformer should be operated are given in the table.

To guard against this possibility of damage the Standardization Rules of the A.I.E.E. recommend that the windings shall not increase in temperature more than 50° C., as measured by resistance, above the surrounding air, and the other parts shall not increase more than 50° C. as measured by thermometer.

Material	°C
Iron	70–75
Cotton	60
Paper	75
Mica, asbestos	90

Means of Dissipating Heat.—The problem is to provide a path of low thermal resistance by which the heat energy may pass to the surrounding air. To accomplish this it is necessary, first, to provide sufficient surface in the subdivided transformer to transfer the heat to the cooling agent, air or oil, without too great a difference in temperature; second, to so subdivide the transformer that no part of the iron is more than one inch, and no part of the copper more than ⅝ inch, from a cooling surface; third, to provide a sufficient quantity of the cooling agent, air, oil or water to carry away the heat at the same rate as it is generated; and fourth, to provide sufficient surface of the containing case or tank to transfer the heat from the internal oil to the external air without too great a difference in temperature.

Calculation of Exposed Surface of Transformer.—The practical method of estimating the rise in temperature consists in calculating the drop in temperature in the successive media through which the heat must pass to be dissipated. The first step is to calculate the exposed surface of the transformer coil, core ducts, coils and coil ducts. In accordance with design practice the surface in the ducts is only rated at half the effectiveness of the outside surface (*Generators, Alternating-current*), and therefore only half the duct surface is included in the figure for "Effective Radiating Surface, A_t." Having found a value for A_t in square inches, the following criteria apply to the respective types.

Naturally-cooled Transformers should have from 4.75 to 5.3 square inches of surface (A_t) for each watt loss for 50° C. rise in temperature.

Oil-cooled Transformers.—(*See also Oil, Transformer.*) The transformer is submerged in oil in a tank so that the level of the oil is from 2 to 3 inches above the top of the transformer. The quantity of oil is from 6 to 10 pounds per kv-a. rating, or in small sizes 500 pounds per kilowatt loss. There should be from 1.5 to 2.3 square inches of transformer surface (A_t) per watt loss. The oil ducts should be ¼ inch wide and run vertically. If the tank is smooth there should be from 4 to 8 square inches of tank surface (not including top or bottom) for each watt loss. For sizes greater than 25 kilowatts it is customary to use fluted or corrugated sides to the tank. In this case there should be from 6 to 10 square inches of radiating surface per watt loss because the air does not circulate as rapidly in the grooves as over a smooth surface and consequently radiation is poor.

For a rise of 50° C. of the transformer there is an average rise of 30° of the oil. The maximum rise of the oil is 1.3 to 1.5 times the average.

The rise in temperature of the windings by resistance or of the iron by thermometer is

$$T = \frac{2W}{A_t} + \frac{fW}{S} + h,$$

Digitized by Google

otal watts lost;
adiating surface of transformer in square inches;
adiating surface of tank in square inches;
om 160 to 200 with smooth tanks.
o to 270 with corrugated tanks;
aximum difference of temperature in oil, usually 40 to 45° C., depending upon circulation.

Transformers. — This type of transformer is usually set over a in the floor which is supplied by a blower with air at a pressure of ounce (¼ to 1 ½ inches of water). The air enters the transformer at nd is divided into two streams, one passing vertically through the the other transversely through the iron. There is a damper or stream so that the proper amount of air is provided to each part . Ducts ½ inch wide are provided every 3 to 4 inches. For 50° g surface of the transformer (A_t) should be from 1.5 to 2.3 square t loss. A liberal amount of air for 50° C. rise is 150 cubic feet per owatt loss. The air is expected to rise from 15° to 20° C. in its gh the transformer. The theoretical quantity of air in cubic feet

$$Q = \frac{1.65W}{Ta},$$

e rise in temperature of the air, which is usually about half as e of the transformer.

d Transformers. — The cooling coils are suspended in the il near the top, usually above the transformer, and carry a ulating stream of water. It is customary to provide ⅓ gallon inute for each kilowatt of loss and to allow the outgoing water above the incoming. Other requirements are from 1 to 1.5 f surface (A_t) per watt loss for 50° C. rise and 1 square inch coils per watt loss. This assumes a temperature drop of 20 to ulation and oil, 2 to 3° between oil and water and 20 to 25° in

SINGLE-PHASE TRANSFORMERS. — The customary s on transformers and the best order of making them are: cold ity, ratio and checking of taps, impedance, core-loss and exciting run, heat run, insulation tests. The efficiency and regulation om the results of these tests.

nsformers should never be tested or subjected to potential unless filled with oil from which all moisture has been removed.

est results are given below.

ce Measurement. — The cold resistance must be very care- t is used as a basis of calculating the temperature after the r the transformer has been standing in one place long enough arts to have reached the same temperature as the surround- current of from 10 to 15 per cent of the rated current of hrough the windings and the drop measured with a volt- ame time the temperature of the windings is measured by a

ity. — This test gives information necessary for connecting ers in a bank and have them operate in parallel or on poly- Direct current is sent through one winding of a transformer eter connected across the other winding. If the current is

Google

stopped, the voltmeter will give a deflection either positive or negati For similar connection and direction of current on all the transformers o bank the deflection should be of the same sign. A small current should used as otherwise the throw of the voltmeter needle may be sufficient bend it.

Ratio of Turns. — With no load on a transformer the ratio of voltage the same as the ratio of the turns. Thus, with a known voltage applied to low-tension winding, the ratio of turns of the two main windings and of sections between taps can be checked up by connecting across the other minals another voltmeter of proper range (using a potential transforme necessary).

Impedance Test. — This test is important in order to calculate the regula and in order to determine whether transformers will run in parallel with e other. One winding of a transformer is short circuited and a voltmeter, amme and wattmeter are connected in the circuit of the other winding. A voltag from 1 to 8 per cent of the rated voltage of this winding and of the proper quency is impressed. The voltage is regulated so that readings are take values of current from 50 to 125 per cent of the rated current of the windi The wattmeter reading will be in the neighborhood of 2 per cent of the ratin the transformer. The total impedance of the transformer will be $Z = \frac{E}{I}$. T total effective resistance will be $R = \text{Watts}/I^2$, which will include the effec eddy currents, and the total reactance will be $X = \sqrt{Z^2 - R^2}$. This reac cannot be separated into primary and secondary reactance. The results o test are usually plotted in two curves, one between volts and amperes and other between volts and watts.

Core-loss and Exciting Current Test. — The alternator supplying the po for this test should give a sinusoidal e.m.f. wave, as any distortion in the sha may cause a variation of from 5 to 10 per cent in the core-loss. A peaked wa gives a lower core-loss than a sine wave. For this test the high-tension win ing is left open and rated voltage at the proper frequency is impressed on t low-tension winding. A voltmeter, ammeter and wattmeter are connected i the low-tension circuit, the voltmeter having a range including the rated vo age of the transformer and the ammeter a range of approximately 15 per ce of the rated current of the machine. Readings are taken with a voltage from 50 per cent to 125 per cent of the rated voltage of the transformer. Bo ampere-volt and watt-volt curves are then plotted. If extreme accuracy desired, the RI^2 loss should be subtracted to give true core-loss.

Separation of Eddy and Hysteresis Losses. — In certain special ca it is desired to investigate the iron of a transformer by separating the hysteres from the eddy loss. Let

W_1 = the core-loss at normal voltage and frequency.
W_2 = the core-loss at half voltage and half frequency.
W_e = eddy-current loss at normal voltage and frequency.
W_h = hysteresis loss at normal voltage and frequency.

Then

$$W_e = 2W_1 - 4W_2$$
$$W_h = 4W_2 - W_1$$

Parallel Run Test. — The test for polarity and ratio having sho nothing wrong in the transformers, they are connected two at a time. T

windings being connected in parallel to a generator and the
n windings in parallel with each other with an ammeter of about
t the capacity of the transformer connected in one lead between
voltage of the alternator is gradually increased from zero and the
he ammeter noted. This current should not be greater than 5 per
rated current of that winding at rated voltage. If a transformer
vindings in either member the same test should be made on these
parallel.

n. — The heat run is made at the rated load of the transformer
nes at an overload of 25 per cent or 50 per cent, depending
uarantees. The run may be made by connecting the trans-
oad such as a water rheostat (*q.v.*) but as there are other equally

Temperature Rise by Resistance is calculated from the formula

$$T = (234.5 + t)\left(\frac{R_h}{R_c} - 1\right),$$

where T = temperature rise in ° C.;
t = temperature in ° C., by thermometer, at which the cold resistance is measured;
R_c = resistance in ohms at temperature t;
R_h = "hot" resistance in ohms at end of heat run.

The number 234.5 is the reciprocal of the resistivity temperature coefficient referred to 0° C.), of 100 per cent conductivity copper, i.e., the reciprocal of 0.00427. For any other conductivity, C per cent say, divide 234.5 by C. (*See article on Resistance and Conductance.*)

Temperature Rise by Thermometer.—In an air-blast transformer it is desirable to measure by thermometer the temperature of the incoming air and the outgoing air (from iron and coils), of the primary windings, and of the secondary windings. Spirit thermometers and not mercury thermometers should always be used for measuring the temperature of transformer windings.

In an oil-cooled transformer the temperature, by the thermometer, of the tank at top and bottom and of the oil in two or three places near the top should be taken.

Insulation Tests.—To test the insulation between turns and sections of coils double the rated voltage per section is impressed on each section for one minute. This test should be made at a high frequency, preferably at double the rated frequency. After this one and a half times normal voltage at rated frequency is applied for five minutes, to discover the effects of the double voltage test. These voltages should be applied and removed gradually.

High-potential Test on Complete Transformer.—To test the dielectric strength of the insulation as a whole the following high-potential test is made. Connect both terminals of the high-tension winding to one terminal of the high-potential transformer. Ground both ends of the secondary winding to the core and frame and connect to the other terminal of the high-potential transformer. Adjust a needle gap to arc at the desired test voltage and increase the voltage gradually until the gap arcs over. Decrease the voltage till the arcing ceases and hold the voltage as near as possible to the arcing point for a minute. The voltage should then be decreased gradually. The proper test voltages and spark-gap adjustments are given in the Standardization Rules of the A.I.E.E. (q.v.).

Calculation of Efficiency and Regulation from Test.—From the results of the preceding tests the efficiency and regulation of the transformer for various loads may be calculated by the methods given above, p. 1625 in the paragraph on *Efficiency and Regulation*, using the test data instead of the calculated quantities.

TESTING OF THREE-PHASE TRANSFORMERS.—In testing three-phase transformers the same methods are followed as with single-phase units. The only difference is in testing for polarity; owing to the mixing of the magnetic circuits special care must be exercised. The direct current must be sent in one direction through one primary phase and in the opposite direction through the other two, so that they will not neutralize one another. With a voltmeter similarly connected on the primary and secondary of each phase in turn, break the direct current; if the connections are right the voltmeter on the secondary will deflect in the same direction as the steady deflection on the primary.

with the No. 3 terminals.

LES OF PERFORMANCE. — Usual values of the performance
:s of transformers are given below.

urrent ranges from 2 to 6 per cent of full-load current in lighting
of the core type and from 5 to 10 per cent in power transformers.
inges from 0.5 per cent to 1.25 per cent of the rated output.
anges from 0.75 per cent in large sizes to 2 per cent in small sizes
utput.

ance drop ranges from 1.25 to 5 per cent of the voltage, being less
type than for the core type. The value depends largely on the
: transformer, methods of construction and opinion of the designer.

nd Regulation. — The variation of the efficiency with the load of
cycle transformers for lighting purposes is shown in Fig. 24. The

the top, and also flows transversely through the iron, passing
Separate dampers at each outlet are provided in order to
currents independently. The dampers are regulated so that
as a temperature 20° above the incoming air.

Digitized by Google

Since the transformers are so dependent on the air blast for their operat and safety, it is customary to provide a reserve blower set.

Location. — Care must be exercised to protect the transformers fr moisture and dirt and particularly, since they are open at the top, to place th where water and dirt cannot drop in the open top. All terminals of the blast type of transformer are usually brought out below so that the primary secondary cables may be laid in the air duct and all connections and insp tion may be made from below. It is therefore desirable that the air d be sufficiently large to enable a man to move about therein.

Drying and Cleaning. — In putting the transformer in operatio moisture must be removed before applying potential. This may be a.. plished by running the blower set and forcing air through the transform which will be sufficient if the air is dry. Another method is to short-cir one winding of the transformer and apply a low voltage of from 1 to 2 per of the rated voltage to the other winding, so that 75 per cent of full-load cur flows through the windings. This is maintained for from 24 to 36 hours transformers of this type should be cleaned once a month by means of co pressed air at 20 pounds pressure.

Measurement of Temperature. — In determining the temper of the windings only that calculated from a resistance measurement is depe able, as the coils are so thickly wrapped in insulation that a thermometer not show the true temperature.

OPERATION OF TRANSFORMERS. — Single-phase transform may be used singly or in parallel on single-phase circuits, and in various co binations on polyphase circuits as described above. The polarity should determined before making the connections.

Parallel Operation on Single-phase Circuits. — Single-phase transfo ers are very generally operated with the primaries in parallel on the supply cuit and their secondaries in parallel on the load circuit. In order to successf operate in this manner two or more transformers, the transformers must ha (1) the same ratio of transformation; (2) the same regulation; and (3 same value of X/R, where R and X are the total resistance and reactan respectively of any one of the transformers. Transformers divide the l inversely proportional to their reactances, provided the ratio of reactance resistance is the same in both cases. If transformers are purchased to op in parallel with others, proper provision must be made in the design of t transformers, and this fact should be stated in the specifications.

In general, a 50-kilowatt transformer will have about twice the resista and twice the reactance of a 100-kilowatt transformer of the same commerc line, and therefore these transformers will divide the load in proportion to th capacity. But this is not likely to be true of transformers of different bra made at widely different times.

If transformers not satisfying the above conditions are to be run in paral an impedance coil having a proper resistance and reactance may be connec in the circuit of one of them, thus establishing the necessary conditions for proper distribution of load, provided the ratios of transformation are the sa

ORMERS, INSTRUMENT. — (*See also Transformers.*) In-
ansformers are either potential transformers or current transform-
ial or voltage transformers are transformers of comparatively small
ıged for shunt connection to the primary lines, designed to produce a
oltage which represents the primary voltage with sufficient accuracy
on to instruments. Current transformers are transformers of com-
nall output arranged for series connection in the primary lines,
produce a secondary current which represents the primary current
nt accuracy for application to instruments. The insulation of
: and potential transformers is designed with reference to the
e circuit on which the transformer is to be used. The most com-
for the secondary of the potential transformer is 115 volts. The
ı current for secondary full load on the current transformer is 5
ıe secondary voltage of the current transformer is usually very
erating conditions, being only sufficient to force the secondary
gh a few instruments of low impedance.

TIONS. — Instrument transformers are used for three principal
to supply current and voltage to measuring apparatus; (2) to
ting devices; (3) to operate circuit protective devices. In each
: two principal advantages to be attained by the use of trans-
:o protect the devices in the secondary circuit against the incon-
ınger of a direct application of the primary voltage or current;
the use of measuring, regulating and protective devices designed
rd current and voltage for the entire range of currents and volt-
ler various operating conditions, thus simplifying design and
ncreasing reliability and accuracy and lowering cost.

nd Reliability Required. — Of the three applications given
olving measuring instruments, requires the highest accuracy in
r; in the operation of regulating devices the certainty of con-
ion is more important; in the operation of circuit protective
moderate degree of accuracy is satisfactory, but certainty of
the highest importance. It is, therefore frequently desirable
transformers for the several purposes, even where convenience
would suggest the use of a single transformer.

)F CURRENT TRANSFORMER. — The current transformer
imary winding in which the line current flows, a magnetic circuit,
y winding for connection to a load of instruments and other
ed in series. The current flowing in the primary is usually
ıe characteristics of the transformer or by the amount of second-
ı the secondary winding short-circuited, the secondary ampere-
equal to the primary ampere-turns, the slight difference being
tively small exiciting current (*see Electricity and Magnetism*,
This exciting current is always of low power factor, while the
the secondary current depends on the resistance and induc-
ondary circuit. While the reversed secondary ampere-turns
ıe primary ampere-turns less the exciting ampere-turns, the
ıe exciting ampere-turns is not usually arithmetical but vecto-
ulting secondary ampere-turns are less than and not in exact
to the primary ampere-turns. This is expressed by stating
mer current ratio varies from the ratio of turns, and that there
between the primary and reversed secondary currents. Since
nd on the relative amount of the exciting current and its phase
pect to the secondary current, they will vary with the imped-

Digitized by Google

ance of the secondary load and the current flowing
ary load impedance increases, the voltage across
consequently the flux density in the
magnetic circuit, grows larger.
When the impedance becomes so
great that the transformer magnetic
circuit approaches saturation, the
exciting current becomes so large
that the secondary current is no
longer proportional to the primary
current and also differs from it ap-
preciably both in wave form and
phase position.

Ratio and Phase Angle. — For accurate cu
of a current transformer the exact ratio of the pri
must be known. For power measurements the
currents must also be accurately known. Refer t

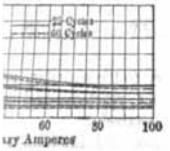
u = ratio of the number of secondary to the nu
I_p = primary current,
I_s = secondary current,
k = ratio of exciting current (referred to second
α = phase angle between the exciting current a
θ = phase angle between the secondary current
(positive for lagging current).
β = the "phase angle" of the transformer, i.e.,
current and the secondary current revers
secondary impedance load is higher tha
the secondary current (reversed) leads
positive; if the power factor of the seco
than that of the exciting current, the sec
behind the primary current and β is neg

Then the ratio of transformation is

$$\frac{I_p}{I_s} = u\sqrt{(\cos\theta + k\cos\alpha)^2 + (\sin$$

and the phase angle is

$$\beta = \tan^{-1}\frac{k\sin(\alpha-\theta}{1+k\cos(\alpha-}$$



The value of the ratio k for a given primary cur
ance of the load connected to the secondary; t
greater the value of k and therefore increasing th
connected load tends to increase the difference b
the true ratio of the primary and secondary curre
of the secondary also tends to increase the phas
The true ratio $\frac{I_p}{I_s}$ and the phase angle β also dep
the load.

In order to use these formulas for numerical r
the amount and power factor of the exciting cur
ditions of load. Since this is difficult to predete

terminal voltages must be known. For power m
between the two voltages must also be accurately
The relations of the quantities involved are sh
Fig. 6.

$$\text{Ratio} = \frac{E_p}{E_s} = u\left[1 + \frac{IR\cos\theta + IX\sin\theta}{uE_s} + \frac{(}{}\right.$$

$$\left. + \frac{I}{}\right.$$

$$\text{Phase angle in minutes} = \frac{3438}{E_p}[IR\sin\theta - IX\cos$$

Where u = ratio of the primary to the
R, X and Z = equivalent resistance, reac
transformer, respectively
R_p, X_p and Z_p = resistance, reactance and
winding;
E_p = primary impressed voltage;
E_s = secondary terminal voltage
E = secondary induced voltage;
I_s = secondary current;
$I = \frac{I_s}{u}$ = load current in the pri
I_0 = exciting current.

It is assumed that,

$$\frac{R_p}{R} = \frac{X_p}{X}$$

because the reactance of the primary and sec
directly determined. The third term in the expre
brackets, is very small and can be omitted with
variations in the true ratio $\frac{E_p}{E_s}$ with the power fac
of the load on the secondary, see Figs. 7 and 9.

The phase angle ϕ of a potential transformer,
primary terminal voltage and the secondary ter
range from a positive angle (secondary voltage l
age) to a considerable negative angle (secondary
age), depending on the exciting current, power
secondary load and the impedance of the transf
no-load condition this angle is nearly always negati
where the exciting current is large and of very low
large. The general tendency of non-inductive sec
vary in the positive direction (secondary voltage to
current) loads to cause it to vary in the negative
to lead). It is frequently possible to bring ϕ pr
voltage and load by adding a non-inductive loa

he operation of protective devices. When so used the failure nsformer may cause destruction of expensive apparatus, and e designed to stand a higher insulation test than other types

Again, the exciting current of the current transformer has the phase angle and errors of ratio. The flux density in the s therefore kept very low for the ordinary metering conditions, errors within satisfactory limits. The resistance and leakage primary winding do not affect the ratio of the transformer nor between primary and secondary currents; their only effect is dance in the primary line. Resistance and leakage reactance

Ratio

Special Designs of Current Transformer poses special designs are useful. In stations wher bus-bars while small power circuits, such as statio the same bus-bars, current transformers must be operate on small current, while under enormous e formers must at least remain in service long enou devices. Where the currents are not too low, trans bar as primary may be used. These resist me circuit, but the number of ampere-turns under th limited to the number of amperes flowing in the transformers have an accuracy suitable for meteri rated current of the line is comparatively large. are too low for satisfactory operation with a single formers of large size, great primary current capaci sometimes used.

A somewhat similar case arises where the cost of in high-tension circuits is prohibitive. A transfo bushing of an oil switch, the lead inside the bushi secondary being wound on a core which encircles t current is usually small, while the length of the tively large, the accuracy of these transformers is narily confined to tripping devices or specially cali

Design of Potential Transformers. — The desi is very similar to that of a small distribution or po accuracy of ratio and small phase angle between pri the flux density in the core should be kept compar and leakage reactance of the primary and secondar these transformers are ordinarily connected to t insulation is sufficient if it equals that of good distri for the same voltage. The exciting current is us full-load current than in power transformers, bec no moment, and good regulation is necessary. Th ever, is roughly dependent on the product of the ex resistance; hence too large an exciting current undesirable.

RATING AND PRECISION. — The volt-a transformers as given by many manufacturers is the most distant relation to the characteristics is no general correspondence between accuracies various manufacturers for the same load. Wher with oil immersion for high-voltage circuits, thei poor than in the small types without oil, because in cost of manufacture between good and poor tr tively small.

Standard Voltage Ratings. — The following ar for which the manufacturers usually list separate l 2300, 4600, 6900, 11,500, 23,00, 33,000, 44,000, 66,

quency of Test Current. — In all current-transformer work where est are to be used for correction, the frequency used in test should e as that of the circuit in which the transformer is to be employed. ntention is only to check the condition of the transformer, any com- quency may be used.

Methods of Testing Current Transformers. — The following is a of the details of one of these methods which has been found satis- se.

ratus. — Referring to Fig. 11 a three-phase supply is used to excite fting transformer with a single-phase secondary. The supply of he transformer under test is obtained from one phase of the same ugh a control resistance R_1 and a step-up current transformer. ios the step-up transformer is omitted. Its input side is wound to he voltage of the supply (125 volts). The high-current winding eavy loose cable, of which one or more turns may be wound through re opening. By suitably selecting the number of turns, currents 4000 amperes are obtained. The primary shunt has a resistance ll rated current gives a drop of 0.5 volt. It is arranged to carry

overload current for a short time for testing purposes. The sec- is adjustable, and is marked in percentage of a normal resistance. several interchangeable scales the normal resistance correspond- cent may be made 0.06, 0.075, 0.08, 0.12, or 0.125 ohm. These of a primary 100-ampere shunt of 0.005 ohm resistance for trans- :: 1, 15: 1, 16: 1, 20: 1, 24: 1 and 25: 1 rated ratios, while still irect reading on the secondary scale of the $\frac{\text{true ratio}}{\text{marked ratio}}$ of the

A set of primary shunts rated 5, 10, 20, 50, 100, 200, 500, 1000,) amperes will thus cover all probable ratios from 1: 1 to 1250: 1. table calibrated mutual inductance whose current coil is in series ndary of the transformer under test, and whose potential coil is he potential element o the sensitive electrodynamometer D, whose nt in turn is supplied from the secondary of the phase-shifting ientioned above. Z is a double-throw single-pole switch. L is ondary loads suitable to represent the instrument combinations in practice.

Digitized by Google

Procedure. — The proper load is connecte former, and the primary current is adjusted to th resistance R_1. This current may be read by ammeter at A_4 which is short-circuited after re to the right. The mutual inductance then ac supplying to the dynamometer potential elem with the secondary current of the transformer field current of the dynamometer is then adj dynamometer reads zero for all positions of th the position of maximum sensibility to changes in shunt. The switch Z is then thrown to the left, secondary shunt is adjusted by moving the drop reads zero. The phase of the dynamometer field go electrical degrees by moving the handle of th definite distance. This is the position of maxi variation. The mutual inductance is then adj reads zero. The phase of the field current is th position, and a slight readjustment of the secon necessary.

Calculations. — From the reading of th angle is determined by the formula

$$\beta = \tan^{-1} \frac{2\pi fM}{R_s},$$

where f is the frequency of the circuit in cycle inductance in henries, and R_s the resistance of Then the true ratio is expressed by the formula

$$\text{Ratio} = \frac{R_s}{R_p} \times \frac{1}{\cos}$$

where R_p is the resistance of the primary shunt.

The correction factor $\frac{1}{\cos \beta}$ for $\beta = 1^\circ$ is 1.000

At these values it is negligible in comparison measurement work involving transformers an angle is so great that this correction becomes in inferior that it should not be used for any purpo ment.

Speed of Operation. — By this means a 30 points of ratio and the same number of p helper to perform necessary calculations and a su ing transformers in the circuit, it is quite practica of transformers including from 6 to 12 points each of determinations of phase angle in an eight-hou can be made practically as fast as the transfor current and secondary load adjusted.

Standardized Transformer Method for D Transformer. — A portable transformer with f series-multiple connection, giving ratios of 5 : 1 practically everything up to 100 amperes. A without primary, so arranged that one turn th ratio of 200: 1, and more turns a corresponding 100 to 1000 amperes. In testing, the primary

t and the standardized portable transformer are connected in ither ammeters, wattmeters or watthour meters may be used ng instruments, the last being susceptible of giving the higher

of Ammeters with Standardized Transformer. — The of the standardized transformer is connected to a standard- ere ammeter, and that of the transformer under test to a similar nd a suitable secondary load. With a sufficient current flowing atisfactory readings on the ammeters, readings are made; the are interchanged, and readings are repeated, to eliminate dif- ween the instruments. From the mean of the results and the standardized transformer, the ratio of the transformer under test

of Wattmeters with Standardized Transformer. — The two secondaries are connected to the current coils of the wattmeters tential elements are placed in multiple and supplied with a definite n a phase-shifting transformer. The phase shifter is adjusted at to cause the wattmeter connected to the standardized transformer naximum. The instruments then are read as ammeters, using a made with the same voltage applied to the potential element. By larger deflection is obtained for low-current values, and consequently racy. If only transformers of moderate-current rating are tested, current may be kept nearly in phase with the supply voltage by the resistance, the phase-shifting transformer may be omitted and the otential circuits excited from the supply voltage.

nod requires little apparatus or care beyond that necessary for ruments and transformers in good condition. It does not test but gives a check on ratio, whose error may readily be kept within . This includes the error of comparison, using ordinary care, and the standard transformer. It is reasonably convenient and rapid, dapted for use in the laboratories maintained by most companies ht and power.

amometer Method of Determining Phase Angle of Current rs. — Phase angle may be determined (where primary currents are) by the use of similar types of dynamometer wattmeters whose ents are connected in the primary and secondary circuits, and ial elements are supplied in multiple by a phase-shifting trans- phase of the voltage is shifted until the primary wattmeter in- showing a quadrature relation of its current and voltage. If W eading of the secondary wattmeter, E the voltage applied to its ent, and I the current in its current coil

$$\beta = \sin^{-1}\frac{W}{EI}.$$

y of this method is very low with ordinary portable wattmeters, sfactory with sensitive reflecting dynamometers. It is the best for the accurate determination of phase angle.

-hour Meter Method of Determining Ratio and Phase rent Transformers. — This method is used by many operating checking their current transformers. It consists of comparing r under test with another of known characteristics. The advan- ethod are:

no special apparatus required.
atus is simple and rugged.

Digitized by Google

3. No special skill required to operate.
4. Transformers may be tested where they are installed.
5. Ordinary variations of voltage, frequency and load during the test do n affect the results.

Apparatus.—The primaries of the standard transformer (S) and t transformer (T) being tested, are connected in series with a variable resistan as shown in Fig. 12. The secondaries are connected through the desired lu

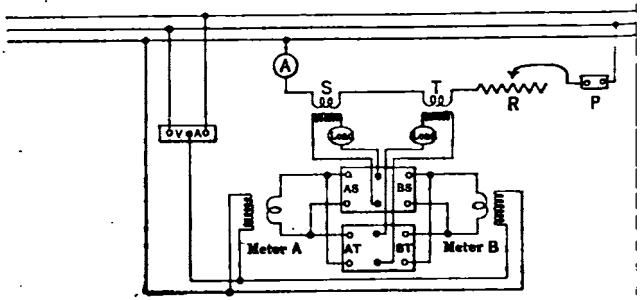

Fig. 12

to the current coils of the two watt-hour meters which are calibrated so th they can be read to $\frac{1}{100}$ of a revolution. Ordinary portable standard watt-hou meters are generally used. In making the ratio test the voltage coils of the wat hour meters are excited from the same phase which supplies the primaries the current transformers, and in making the phase angle test, from one of th other two phases.

Procedure.—The double pole double throw switches are thrown to A and BT and loads of the desired value are connected in the secondary circui of the two transformers. Switch P is then closed and the primary curre adjusted to the desired value. The switch V is now closed and the meter allowe to run until a reading is obtained. Then the switches V and P are opened, an the other switches thrown to AT and BS. Another reading is taken wit switches V and P closed. For convenience in calculation, the meters shoul be stopped when the one connected to T shows an even reading, say 10 com divisions. These readings give the data for calculating the ratio. For th phase angle measurement the same procedure is followed, except that th voltage switch is thrown to A instead of V, and the meters should be stopp when the one connected to S shows an even reading.

Calculations.—

Let R_S, R_T = ratio of the standard transformer and the transformer under test respectively;

α_S, α_T = the respective phase angles (positive for reversed secondary leading primary);

a_S, a_T = reading on meter A when connected to transformer S and T respectively;

b_S, b_T = ditto for meter B;

eter Method of Testing Potential Transformers. — The fol- escription of the apparatus and method of procedure which has tory results.

atus. — The general connections of such an outfit are shown in supply is 3-phase for the excitation of the phase-shifting trans- ne phase is connected through a voltage regulator Q to the low- f the step-up transformer T_1, which has a sufficient number of

connections to provide the range of voltages required for testing. This supply excites the high-tension side of the transformer T_2 which is under test. r_2 and r_1 are placed across the high-tension circuit in multiple with the high-ten-

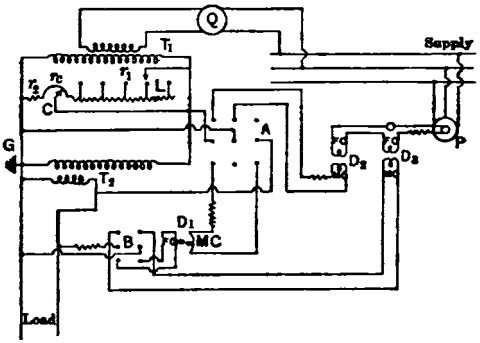

Fig. 13. Connections for Potentiometer Method

sion side of the transformer under test. They consist of non-inductive resistances, containing a non-adjustable portion constituting the greater part of r_2, a middle portion r_c subdivided into equal steps on which a contactor C travels, and a third part constituting the greater part of r_1 on which taps are brought out at points suited to the various voltages to be used in test. One side of the secondary winding is connected to the end of r_2 and the ground G; the other is connected (for ratio test) through switch A, which is in the downward position, through a resistance and the moving element of the dynamometer D_1 to the contactor C. By suitably proportioning the resistances r_1, r_2 and the steps of r_c, the outfit is made direct reading in terms of $\frac{\text{true ratio}}{\text{marked ratio}}$ of the transformer.

Precaution. — Balance can only be secured by a proper connection with regard to polarity of the secondary of the transformer under test to the primary. If the reversed connection is used, double the secondary voltage is applied to the circuit through contactor and dynamometer. A sufficient resistance to protect the dynamometer should therefore be inserted when trying out each transformer to be tested. As soon as an approximate balance is obtained, this resistance may be reduced to secure sensitiveness.

Determination of Ratio. — The fixed coil of the dynamometer D_1 is excited from the low-tension terminals of the transformer under test through the switch B in the downward position. Other secondary load may also be applied to the secondary terminals. With this load and the voltage and frequency suitably adjusted, and with the high-tension lead L connected to the proper tap on r_1, the contactor C is moved until the dynamometer D_1 indicates nearly zero. If the resistance at which the dynamometer indicates zero lies between two steps of the contactor, the nearest may be taken or the readings of dynamometer on both steps may be noted and the result obtained by interpolation. If r_1 and r_2 are respectively the resistances from the contactor C to the high-tension and to the grounded lines, then

$$\text{True ratio} = \frac{r_1 + r_2}{r_2},$$

subject to a small error due to phase angle between primary and secondary voltages, which is negligible for a phase angle of a degrees or less, provided

ce of the circuit from the contactor C through the dynamometer is ely equal to r_3.

ermination of Phase Angle. — To obtain the phase angle the and B are thrown upward. The drop of primary voltage across r_3 is l to the potential element of dynamometer D_3, while the secondary pplied to the potential element of dynamometer D_3, both through nductive resistances. The current elements of the dynamometers n series and excited from the phase-shifting transformer P. When f the excitation is shifted so that dynamometer D_3 indicates zero, ngle between primary and secondary voltages is

$$\gamma = \sin^{-1} \frac{W}{VA},$$

the watts indicated by the dynamometer D_3, V is the voltage and it applied to its potential and current elements respectively.

d of Operation. — Ratio points may be taken at the rate of one while operating, and phase-angle points at a somewhat slower -point checks can be made practically as rapidly as the trans- be connected and the voltage, load and frequency adjusted. One equired for ratio test, two for phase-angle test.

zed Transformer Method for Determining Ratio of Potential r. — The transformer to be tested should be placed in multiple dard transformer of the same rated ratio on the high-tension side, ized portable voltmeters should be connected to the two second- should be read, interchanged and read a second time to elimi- calibration of the voltmeters. It is not difficult to maintain an bout 0.2 per cent on ratio test by this method with carefully stand- ratus near the rated voltages of the transformer. More accurate ts of ratio and determinations of phase angle if desired should thoroughly equipped laboratory, and the check results used simply unchanged condition of the transformer.

and Resistance Method of Determining Ratio. — Where ers of the same rated ratio and a voltmeter with suitable multi- ailable, good checking according to the method . 11. T_1 is a step-up furnish the voltage for T_2 and T_3 are potential of similar ratio, T_3 being er under test. V_2 is a eter. V_1 is a good port- or a laboratory stand- t. M is a multiplier of e R_m that closing the ses the voltmeter and read nearly the same ary supply as the volt- ads from the secondary

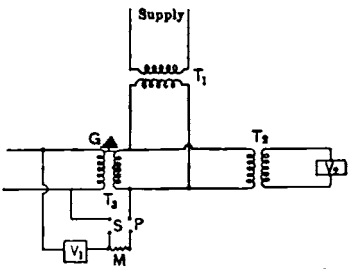

Fig. 14. Connections for Voltmeter and Resistance Method

S closed. In operation the switch P is closed, and readings made Then the switch P is opened and S is closed. V_2 is held at the and V_1 is read. If the resistance of V_1 is R_v, its first reading E_1 reading E_2,

$$\text{True ratio} = \frac{E_1 (R_m + R_v)}{E_2 R_v}.$$

Digitized by Google

If the two readings are close together in the scale of V_1, no specially standardized instrument is necessary. The reading of V_2 does not enter into the result, as it is only used to hold the primary voltage at the same point for the two readings. The accuracy of the method depends on the accuracy of reading of the instruments used, although the absolute values of the readings do not affect it. With care the error should not exceed 0.2 per cent.

Mutual Inductance Method of Determining Phase Angle of Potential Transformer. — The phase angle may be determined by the addition to the ratio-testing outfit described above of a mutual inductance whose primary is placed in series with r_1 or r_2 and whose secondary is in series with the circuit from the contactor C through the dynamometer D_1 in a way similar to that described under current transformers. The primaries of two similar transformers may be placed in multiple, and the difference in their secondary voltages read on a low reading instrument. Where the phase angle is the same in both the transformers, this is an excellent method of comparison if the current drawn in the voltmeter is kept small by the use of a high-resistance instrument.

Two Watt-hour Meter Method of Determining Ratio and Phase Angle of Potential Transformers. — This is similar to the method used for current transformers (see page 1745) and consists in comparing the transformer to be tested with one whose characteristics are known. It has advantages similar to the method for current transformers and in addition all instruments are on the low-voltage circuit.

Apparatus. — In Fig. 15 the standard transformer is shown at S and the one under test at T. The connections to the two watt-hour meters and the

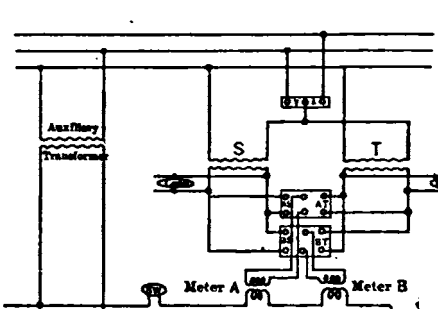

Fig. 15

loads are also shown. The watt-hour meters can be read to 1/100 of a revolution, portable standard watt-hour meters being most frequently used. The auxiliary transformer supplies current for the current coils of the watt-hour meters, and may be one of the main power transformers. The switch SW is a convenient means of starting and stopping both meters simultaneously. If ratio only is desired, the whole power supply may be taken from a 115-volt circuit, the auxiliary transformer being used to step up the voltage for the primaries of the instrument transformers.

Procedure. — The primary switch is thrown to V and the loads on the secondaries are adjusted to the desired values. The current in the current

meters is adjusted to about 5 amperes by means of the resistance R. -throw switches are now thrown to AS and BT and a reading is taken. ouble-throw switches are thrown to BS and AT and another reading For convenience in calculation it is well to stop these readings when onnected to T shows an even number of divisions, say 10,000. These re the data for calculating the ratio. For the phase-angle measure- ame procedure is followed except that the primary switch is thrown l of to V, and the meters should be stopped when the one connected an even reading.

ulation. — The equations are the same as given for current trans- page 1747, namely,

$$R_T = R_S \sqrt{\frac{a_S b_S}{a_T b_T}},$$

$$\frac{R_T - R_S}{R_S} = \frac{1}{2}\left[\frac{a_S - a_T}{a_T} + \frac{b_S - b_T}{b_T}\right] \text{ (approximately),}$$

s and b's are readings taken with the primary switch thrown to V,

$$\tan \alpha_T - \tan \alpha_S = \frac{1}{2 \tan \theta}\left[1 - \frac{a_T b_T R_T^2}{a_S b_S R_S^2}\right]$$

nutes) $= \alpha_S \pm \frac{3438}{\tan \theta}\left[\frac{a_S - a_T}{2a_S} + \frac{b_S - b_T}{2b_S} - \frac{R_T - R_S}{R_S}\right]$ (approximately),

s and b's are readings taken with the primary switch thrown to A. ave the same meaning as given on page 1746. In the last expression, efore the bracket should be used when the meters, with the primary n to A, are working on lagging current, and the $-$ sign when the ading. Or the sign may be determined experimentally from the ing a non-inductive load to a voltage transformer always tends to lary voltage.

of Operation. — The speed of operation is about the same as current transformers by the same method as shown on page 1747.

ATIONS. — Heating limits, insulation test, etc., should be in th the Standards of the A.I.E.E. (*q.v.*).

phase angle under definite conditions of secondary connected the highest class of commercial product, be defined substantially with Figs. 2, 3, 7 and 8. Even better accuracy than that shown s can sometimes be secured with considerable increase in cost and aterial. For less exacting service transformers of lower cost racy can be procured. The conditions to be fulfilled vary so inite general specifications cannot well be given.

IS. — In general, replacement or repair by the maker is to be pre- pairs made by the user where anything more than broken leads or rnal injuries are to be remedied. If repairs to magnetic circuit or e attempted, care should be exercised to duplicate as exactly as original construction especially in regard to number of turns and f windings and exact assembly of punchings. After repairs are he transformer should be carefully tested both for accuracy and for rength.

TS, DIMENSIONS AND COSTS. — Current transformers in for circuits from 115 to 110,000 volts range from 4 pounds to 1500 ht with oil, and from a maximum dimension of 6 inches to a height th a diameter of 30 inches, depending on the quality of the trans- he voltage of the circuit on which it is to operate. Potential trans- nearly the same range of sizes.

f instrument transformers depends on the circuit voltage for which igned, and is also affected in the case of current transformers by he transformer. There is a considerable range between the prices arious manufacturers for transformers of the same rating; the are, however, associated with less accuracy or with less insulation oth.

ximate cost of an instrument transformer of high grade represent- s as per Figs. 2 and 3 for current transformers and Figs. 7 and 8 transformers is as follows:

F VOLTAGE AND CURRENT TRANSFORMERS (1922)

Voltage of circuit	Insulation test voltage	Price in dollars

TRANSIENT ELECTRIC PHENOMENA AND OSCILLATIONS.

- (*See also Alternating Currents; Capacity and Charging Current; Electricity nd Magnetism, Principles of; Inductance and Inductive Reactance; Transmis-on Lines.*)

Establishment of a Direct Current in a Coil. — Let E be a constant rect electromotive force, r the resistance of the coil, L the inductance of the il (assumed constant); then t seconds after closing the circuit (placing the coil id e.m.f. in series) the current in the coil is

$$i = \frac{E}{r}\left(1 - \epsilon^{-ut}\right), \tag{1}$$

here ϵ is the base of the natural logarithms and $u = \frac{r}{L}$. See *Exponential unctions* for values of ϵ^{-x}.

Time Constant of a Coil. — The time required for the exponent $ut = \frac{rt}{L}$ reach the value unity, and therefore for the current to reach 63.2 per cent of s final value, is called the time constant of the coil, and is equal to $\frac{L}{r}$. The rger the time constant the longer the time required for the current to reach its eady value $\frac{E}{r}$.

Decay of Current in a Coil when Coil is Short-circuited. — Using e same notation as above, the current in the coil t seconds after short-circuit-g it is

$$i = I_0 \epsilon^{-ut}$$

here I_0 is the current in it at the instant the short-circuit is made.

Charging a Condenser Through a Resistance from a Source of Constant E.M.F. — Let E be a constant e.m.f., C the capacity of the condenser, the resistance in series with it, and let the condenser be originally uncharged. Then if the conductance of the condenser and the inductance of ie circuit are both negligible, the voltage across the condenser, the current the circuit and the charge on the condenser t seconds after the circuit is osed (thereby connecting the condenser, resistance and e.m.f. in series), are spectively

$$\left.\begin{aligned} v &= E(1 - \epsilon^{-ut}), \\ i &= \frac{E}{r}\epsilon^{-ut}, \\ q &= CE(1 - \epsilon^{-ut}), \end{aligned}\right\} \tag{2}$$

here $u = \frac{1}{rC}$. For values of ϵ^{-x} see *Exponential Functions*.

Time Constant of a Condenser and Resistance in Series. — The me required for the exponent $ut = \frac{t}{rC}$ to reach the value unity, and therefore e the voltage and charge on the condenser to reach 63.2 per cent of their final alues, is called the time constant of this circuit, and is equal to rC. The larger ie time constant the longer the time required for the voltage across the conenser to reach the value of the e.m.f. impressed on the circuit.

Discharge of a Condenser Through a Resistance. — Using the same notation as above, and assuming negligible conductance in the condenser and negligible inductance in the circuit, the voltage across the condenser, the current

in the circuit and the charge on the condenser i
it through a resistance r, the condenser being ch
instant of short-circuit (but no current flowing),

$$\left.\begin{aligned} v &= V_0 \epsilon^{-ut}, \\ i &= -\frac{V_0}{r}\epsilon^{-ut}, \\ q &= CV_0 \epsilon^{-ut}, \end{aligned}\right\}$$

where $u = \frac{1}{rC}$.

GENERAL EQUATIONS FOR LUMPE CAPACITY. — Let the various quantities be as d ferential equations for this circuit are

$$\left.\begin{aligned} i &= gv + C\frac{dv}{dt}, \\ v &= e - ri - L\frac{di}{dt}, \end{aligned}\right\} \qquad (4)$$

where i is the instantaneous current in the impe dance coil (equal to the total displacement an conduction current through the condenser), v is th potential drop through the condenser in the directi impressed voltage, constant or varying. g repre condenser, i.e., the power dissipated in the conde

At any given instant, say at $t = 0$, let the imp any previous value to a new value $E \sin \theta$, and this instant vary sinusoidally, i.e., at any insta $(\omega t + \theta)$, where $\omega = 2\pi f$ and f is the frequency of t (The solution for a constant impressed e.m.f. E $f = 0$ and $\theta = \pi/2$ in the equations below.) Let values of the current i and of the potential dro time $t = 0$. I_0 and V_0 may or may not be zero, of the circuit previous to the change in the impre

Steady State Relations. — The complete so that the current and voltage at any instant afte circuit are each composed of two terms, (1) a t and (2) a term, added to the first, which represe nating) state of the current and voltage respe solution of (4) is readily effected by the ordi current calculation (*see Alternating Currents*), and

$$i_2 = \frac{E}{Z}\sin(\omega t + \theta - \phi),$$

$$v_2 = \frac{E}{yZ}\sin(\omega t + \theta - \phi - \eta$$

where

$$Z = \sqrt{R^2 + X^2} \qquad \text{and} \qquad \phi$$

$$R = r + \frac{g}{g^2 + b^2}, \qquad X$$

$$b = \omega C, \qquad x$$

$$y = \sqrt{g^2 + b^2}, \qquad \eta$$

scillations. — The transient terms in the complete solution of equa- re as follows:

$$\left.\begin{aligned} i_1 &= \epsilon^{-\alpha t}\left[D\cos\omega_0 t - \left(\frac{D'}{\omega_0 L} + \frac{qD}{\omega_0}\right)\sin\omega_0 t\right], \\ e_1 &= \epsilon^{-\alpha t}\left[D'\cos\omega_0 t + \left(\frac{D}{\omega_0 C} + \frac{qD'}{\omega_0}\right)\sin\omega_0 t\right], \end{aligned}\right\} \quad (7)$$

$$\left.\begin{aligned} \alpha &= \frac{1}{2}\left(\frac{r}{L} + \frac{g}{C}\right) \quad \text{and} \quad q = \frac{1}{2}\left(\frac{r}{L} - \frac{g}{C}\right), \\ \omega_0 &= \sqrt{\frac{1}{LC} - q^2}\,. \end{aligned}\right\} \quad (8)$$

e constants, α, q and ω_0 are constants of the circuit, and are inde- the manner in which the transient oscillation is set up. The fre- his "natural" oscillation is

$$f_0 = \frac{\omega_0}{2\pi} = \frac{1}{2\pi}\sqrt{\frac{1}{LC} - q^2}.$$

small compared with $\frac{1}{LC}$ the natural frequency is $f_0 = \frac{1}{2\pi\sqrt{LC}}$.

resistance of the coil and leakance of the condenser, these natural die out with time proportionally with $\epsilon^{-\alpha t}$, or the amplitudes of ansient current and the transient voltage decrease by the fraction cond.

tants D and D', which determine the amplitudes of the transient tions 7) are given by the following relations:

$$\left.\begin{aligned} D &= I_0 - \frac{E}{Z}\sin(\theta - \phi), \\ D' &= V_0 - \frac{E}{yZ}\sin(\theta - \phi - \eta), \end{aligned}\right\} \quad (9)$$

he current in the coil and V_0 the voltage across the condenser at $(t = o)$ at which any change is made in the circuit conditions, i.e., d or closed, or e.m.f. short circuited.

when Damping is Great. — When q^2 is greater than $1 \div (LC)$, maginary and the oscillation therefore has an imaginary frequency, that the transient terms die out without oscillating. Equations 9) still hold in this case and will give the *real* solution *provided* that in "cos" is changed to "cosh" (hyperbolic cosine), and "sin" is changed rperbolic sine) and for ω_0 is taken the value $\sqrt{q^2 - \frac{1}{LC}}$. See *Hy- tions* for tables of "sinh" and "cosh." The expressions for α, q, nain unaltered.

amping. — Where $\omega_0 = o$, that is, when $q^2 = 1 \div (LC)$, equations ansient current and voltage become

$$\left.\begin{aligned} i_1 &= \left[D\left(1 - q\ell\right) - \frac{D'\ell}{L}\right]\epsilon^{-\alpha t} \\ e_1 &= \left[\frac{D\ell}{C} + D'\left(1 + q\ell\right)\right]\epsilon^{-\alpha t} \end{aligned}\right\} \quad (10)$$

D' are given by equations (9).

Digitized by Google

Complete Solution. — The complete expressions for the current and voltage at any instant are in all cases

$$\left.\begin{aligned} i &= i_1 + i_2, \\ v &= v_1 + v_2, \end{aligned}\right\} \qquad (11)$$

where i_2 and v_2 are given by equations (5) and i_1 and v_1 are given by equations (7), the latter changed as noted above when q^2 is greater than $1 + (LC)$ or reducing to equation (10) when $q^2 = 1 + (LC)$.

Discharge of a Condenser through an Impedance Coil. — The above equations may be used to obtain the solution of the special case of a condenser charged to a voltage V_0 and short-circuited at time $t = 0$ through a coil having both resistance and inductance. Assume that at time $t = 0$ the current through the condenser is zero. The "steady state" terms in this case are zero, and only the transient terms appear, viz.,

$$\left.\begin{aligned} i &= -\frac{V_0}{\omega_0 L} \epsilon^{-ut} \sin \omega_0 t, \\ v &= V_0 \epsilon^{-ut} \left(\cos \omega_0 t + \frac{q}{\omega_0} \sin \omega_0 t \right), \end{aligned}\right\} \qquad (12)$$

where the values of u, q and ω_0 are as given above, equations (8). When $1 + (LC)$ is greater than q^2, equations (12) apply directly; the current-time curve in this case is shown in Fig. 2. When $1 + (LC)$ is less than q^2 the circular functions become hyperbolic functions and $\omega_0 = \sqrt{q^2 - \frac{1}{LC}}$ and the current-time curve is as shown in Fig. 3. When $q^2 = 1 + (LC)$, equations (12) reduce to

$$i = -\frac{V_0}{L} t\epsilon^{-ut} \qquad \text{and} \qquad v = V_0 \epsilon^{-ut}(1 + qt). \qquad (13)$$

Fig. 2. $q < \frac{1}{\sqrt{LC}}$

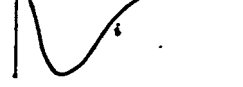

Fig. 3. $q > \frac{1}{\sqrt{LC}}$

OSCILLATIONS IN TRANSMISSION LINES. — Oscillations similar in nature to those discussed above occur in a transmission line when any change takes place in the load connections and particularly when high voltages are suddenly induced in the line by lightning discharges or when heavy currents are suddenly interrupted. The mathematical analysis of such cases is extremely involved, since account must be taken of the distributed nature of the inductance and capacity, and also of the fact that the possible periods of oscillations depend not only upon the line constants but also upon the constants of the apparatus at the two ends of the line. See article on *Transmission Lines*.

IONS AND FUNDAMENTAL RELATIONS. — The follow- ns and relations apply to all types of transmission and distribution

r End and Load End. — By the generator end of the line is meant h is connected to the source of power (either directly or through), and by the load end is meant the end which is connected to the ation which is supplied with power over the line.

Power Loss (Q). — By per cent power loss as used in this article percentage ratio

$$Q = 100 \cdot \frac{\text{total power lost in the line}}{\text{total power delivered at load end}}. \quad (1)$$

Digitized by Google

Hence if P is the power delivered, then the total power supplied to the line and load is

$$P_s = P\left(\frac{100+Q}{100}\right). \qquad (5)$$

Per cent Voltage Loss (D). — By per cent voltage loss as used in this article is meant the percentage ratio*

$$D = 100 \cdot \frac{\text{(voltage at generator end)} - \text{(voltage at load end)}}{\text{voltage at load end}}. \qquad (6)$$

Hence calling E the voltage at the load end, the voltage at the generator end is

$$E_s = E\left(\frac{100+D}{100}\right). \qquad (7)$$

The per cent voltage loss allowed under various conditions is discussed in detail in the article on *Distribution and Transmission Systems;* the allowable voltage loss is usually between 2 and 20 per cent, the most common figure being 10 per cent.

In the case of a direct-current line with a single load at its far end, the per cent power loss and the per cent voltage loss are always equal, but in the case of an alternating-current line the per cent voltage loss may be either greater or less than the per cent power loss, depending upon the constants of the line and the power factor of the load, or may even be negative, i.e., there may be an actual rise of voltage at the load end above the voltage at the generator end; see below.

Efficiency of Transmission. — By the efficiency of transmission is meant the percentage ratio

$$100 \cdot \frac{\text{power output of line at load end}}{\text{total power input to line at generator end}}. \qquad (8)$$

The per cent efficiency is related to the per cent power loss Q as follows:

$$\text{Per cent efficiency} = \frac{10{,}000}{100+Q}. \qquad (9)$$

ELECTRICAL DESIGN OF DIRECT-CURRENT LINES. — Two types of problems arise: (1) given a definite line with known constants, what is the power loss and voltage loss for a given load, and (2) to transmit a given amount of power a given distance with a given allowable loss, what will be the size and weight of the conductor required? In the following paragraphs are given the necessary formulas for the several cases.

Two-wire Line; Concentrated Load at Far End. — Let

E = volts between wires at the load end of the line,

$P = \frac{EI}{1000}$ = kilowatts taken by load,

$I = \frac{1000\,P}{E}$ = amperes taken by load,

l = length of each line wire in feet,

r = ohms per 1000 feet of conductor; see tables in article on *Wires and Cables, Bare,*

$R = \frac{rl}{500}$ = total resistance of line (both conductors), in ohms.

* In the case of an alternating-current line the difference in the numerator of this ratio is the algebraic difference between r.m.s. values of the two voltages, not the vector difference.

Digitized by Google

ving relations then hold:

ilowatts lost $= p = \frac{RI^2}{1000} = \frac{rlI^2}{500{,}000} = \frac{2\,rlP^2}{E^2}$, (7)

olts lost $= v = RI = \frac{rlI}{500} = \frac{2\,rlP}{E}$, (8)

t power loss $= Q = \frac{100\,p}{P} = \frac{rlI^2}{5000\,P} = \frac{200\,rlP}{E^2}$, (9)

voltage loss $= D = \frac{100\,v}{E} = \frac{rlI}{5\,E} = \frac{200\,rlP}{E^2}$, (10)

ce of each conductor per 1000 feet $= r = \frac{500\,v}{lI} = \frac{QE^2}{200\,lP} = \frac{DE^2}{200\,lP}$. (11)

lation of Size and Weight of Conductor for Concentrated m the value of r calculated from any one of the relations given in , the size of wire may be found from the tables in the article on *bles, Bare;* the next larger size of wire (next smaller gauge number) y be chosen when the calculated resistance lies between that of two zes. The wire selected must also have sufficient current-carrying *Wires and Cables, Bare; Wires and Cables, Insulated;* and *Wiring* For outside lines, however, the current-carrying capacity will in ple unless the allowable voltage loss is excessive. For an outside wire smaller than No. 6 A.W.G. (or B. & S.) gauge is seldom used, ount of its lack of mechanical strength.

ght per 1000 feet of the wire finally selected, then

Total weight of conductor in pounds $= W = \frac{wl}{500}$. (12)

Calculation of Total Weight of Conductor (W); Two-wire reliminary estimates it is sometimes convenient to calculate the conductor directly, without reference to a wire table. The total uctor for a two-wire line with concentrated load at its end is given

$$W = \frac{KP}{Q}\left(\frac{l}{E}\right)^2 \text{ pounds}, \quad (13)$$

power taken by the load, l the length of the line (length of each ltage at the load, Q the per cent power loss (= per cent voltage d-c. line) and K a constant depending upon the material of the he units in which P, l and E are expressed, viz.,

VALUES OF K IN FORMULA 13

Material	E in volts, l in feet, P in kilowatts	E in kilovolts, l in miles, P in kilowatts
cent conductivity).....	13.5	380
per cent conductivity)...	6.5	185
specific gravity δ having of c per cent at 20° C...)	$\frac{141\,\delta}{c}$	$\frac{3940\,\delta}{c}$

lues of K given for copper and aluminum are about 5 per cent greater ical values to allow for stranding, higher working temperature, etc.; uctivity corresponds to 1.724 microhms per centimeter cube at 20° C.

Google

Example: Two-wire D-C. Line, Conc 100 kw. is to be transmitted over a two-wire lin volts, the motor being 1000 feet from the pow 10 per cent power loss or voltage drop in the line of copper required is, from equation (13),

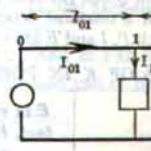
$$W = \frac{13.5 \times 100}{10}\left(\frac{1000}{230}\right)^2 = 25$$

From equation (11) the resistance per 1000 feet i

$$r = \frac{10 \times (230)^2}{200 \times 1000 \times 100} = 0.0264 \text{ oh}$$

The nearest even circular mil size is 400,000 circ a resistance of 0.0270 ohm per 1000 feet at 77° F and a weight of 1240 pounds per 1000 feet. From of conductor is then

$$W = \frac{1240 \times 1000}{500} = 2480$$



This wire, if bare, weather-proofed, or insulated wi will safely carry the required current of 100,000/23 insulated and mounted indoors, a larger wire shoul cular mils, according to the National Electric Co

Calculation of Two-wire Direct-current L Generator End.—When the volts E_0 at the gen the volts E at the load end, the calculations for of R ohms with a concentrated load of P kilowatt in the same manner as above by first finding t formula

$$E = \frac{E_0}{2}\left[1 + \sqrt{1 - \frac{4000}{E_0^2}}\right.$$

For an efficiency of transmission of less than 50 radical should be − instead of +, but an effici practically never occurs in power transmission. for an efficiency of 50 per cent $P = E_0^2 \div (4000 R$ which can be delivered at the far end of the line at the generator end.

When E has been calculated by this formula (14), the formulas (7) to (13) above may be applied directly.

Two-wire Line; Distributed Load. — When a line supplies a number of loads at different distances from the generator end, the voltage loss to the far end of the line is the same as would be produced by a load, concentrated at the "center of gravity" of the line and taking a current equal to the t The center of gravity of the line is defined as follows: taken from the line by the various loads, Fig. 1, and le resistances (both wires) from the generator end to the

$$I = I_1 + I_2 + I_3 + \ldots$$

Digitized by Google

en the center of gravity is that point between which and the generator end of the line total line resistance is

$$R_g = \frac{R_1 I_1 + R_2 I_2 + R_3 I_3 + \dots}{I}. \tag{16}$$

ien the line conductor has the same cross-section throughout its length, then the ter of gravity is at the distance,

$$l_g = \frac{l_1 I_1 + l_2 I_2 + l_3 I_3 + \dots}{I} \tag{16a}$$

m the generator end, where l_1, l_2, l_3, etc., are the distances of the respective loads from generator end.

The total voltage loss to the far end of the line is then

$$v = R_g I = \frac{r l_g I}{500}, \tag{17}$$

ere the distance l_g is in feet and r is the resistance of the conductor per 1000 feet, the ond relation in (17) holding only when the conductor has the same cross-section through- its length.

The total kilowatts lost in the line are

$$p = \frac{1}{1000}\left(R_{01} I_{01}^2 + R_{12} I_{12}^2 + R_{23} I_{23}^2 + \dots\right), \tag{18}$$

ere, referring to Fig. 1, R_{01} = total resistance (both wires) from 0 to 1, R_{12} = total stance (both wires) from 1 to 2, etc., and $I_{01} = I_1 + I_2 + I_3 + \dots$ = the current in the from 0 to 1, $I_{12} = I_2 + I_3 + \dots$ = the current in the line from 1 to 2, etc. When cross-section of the line conductor is the same throughout its length equation (18) y be also written

$$p = \frac{r}{500{,}000}\left(l_{01} I_{01}^2 + l_{12} I_{12}^2 + l_{23} I_{23}^2 + \dots\right), \tag{18a}$$

ere the distances l_{01}, l_{12}, l_{23}, etc., are as shown in Fig. 1, and are measured in feet, and the resistance of the line conductor per 1000 feet.

Calculation of Size and Weight of Conductor for Distributed Load. — For onductor of the same cross-section throughout, the required resistance per 1000 feet a given voltage loss of v volts to the end of the line may be calculated from the formula

$$r = \frac{500\, v}{l_g I}, \tag{19}$$

ere l_g, expressed in feet, and I are given by formulas (16a) and (15). The size and ght of conductor can then be found by reference to the wire tables in the article on *ires and Cables, Bare.*

When the loads are far apart and the smaller loads are farthest from the generator, s sometimes advisable to use different sizes of conductors for the various portions of line. For a given voltage loss v to the end of the line, the minimum weight of conduc- is obtained when the volts lost per unit length of conductor in each section of the line roportional to the square root of the current in this portion of the line. For minimum al weight of conductor then, referring to Fig. 1, the resistance per 1000 feet *of wire* the section between 1 and 2, may, must be

$$r_{12} = \frac{1}{\sqrt{I_{12}}} \cdot \frac{500\, v}{l_{01}\sqrt{I_{01}} + l_{12}\sqrt{I_{12}} + l_{23}\sqrt{I_{23}} + \dots}, \tag{20}$$

ere the lengths are in feet; and similarly for the other sections. The weight of wire each section may then be found by reference to the wire tables in the article on *Wires l Cables, Bare*, and the total weight W can then be computed. Vice versa, for a line portioned in this manner the voltage loss to the end of the line for a given total weight copper will be a minimum.

A line proportioned in this manner, however, does not give minimum power loss for total weight of conductor used. For a given total weight of conductor the total wer loss will be a minimum when the power loss per unit length of conductor in each tion of the line is directly proportional to the current in this section, i.e., when the

voltage loss per unit length in each section is the same, unit length of each section must be proportional to the li letting W be the total weight of the conductor in pou minimum when the section from 1 to 2, say, has a we

$$w_{12} = I_{12} \frac{500\,W}{l_{01}I_{01} + l_{12}I_{12} + l_{23}I_{23}}$$

where the lengths are in feet; and similarly for the ot each section may be obtained from the wire tables in *Bare*. When the sizes as found by the two formulas the choice will depend upon which is the more important voltage loss.

Three-wire Direct-current Line. — When balanced, i.e., when the loads between each of th tral are the same and are connected to the neutr no current flows in the neutral wire. The formu line then apply directly to the case of a balanc ever that the E (= volts between wires) in the the volts between the *outer* wires, and that the above formulas is the weight of the two outer usually made equal in size to each outer wire, but as expected it is sometimes made smaller. When size to the outer wire the total weight of the three more than that given by formula (13), when E to the volts between the outer wires.

The exact calculation of the voltage loss and po two sides of the system are different and are c somewhat complicated, but can always be effecte hoff's Laws for an electrical network; see *Electric of*.

SIZE AND WEIGHT OF CONDUCTOR CURRENT LINES. — As a rough guide in fixi the following facts should be noted; complete for tions required are given later.

1. A power loss of approximately 10 per cent of allowed.

2. A line voltage of approximately 1000 volt practice for long-distance lines not over 150 miles l line a line voltage of 10,000 volts would be emplo voltage of 100,000 volts would be used. The ma (1914) employed is 150,000 volts and the maximu 240 miles.

3. On the basis of 1000 volts per mile of line, u a 10 per cent power loss, and copper at 15 cent copper required for a three-phase line is $4.00 per single-phase or two-phase four-wire line $5.33 per k

Calculation of Total Weight of Conductor and total weight of the conductor required for any delivered, power factor, line voltage and power loss

* These formulas are based on the assumption that in comparison with the load current, which condition is longest high-voltage lines; formulas for power loss tak count are given later.

Digitized by Google

et

E = voltage between wires at the load end of the line,
P = total power taken by all phases of the load,
$\cos \phi$ = power factor of load, as a decimal,
l = length of line (= length of each line wire),
Q = allowable total power loss in per cent of delivered power.

hen the total weight of all conductors is given by the formula

$$W = \frac{KP}{Q}\left(\frac{l}{E \cos \phi}\right)^2 \quad \text{pounds,} \qquad (22)$$

here K is a constant depending upon the number of phases and wires, the mate-ial of the conductor and the units in which the various quantities are expressed, iz.,

VALUES OF K IN FORMULA 22

Material and units	Single-phase or balanced 4-wire 2-phase*	Balanced 3-wire 3-phase
Copper (98 per cent conductivity):		
E in volts, l in feet, P in kilowatts ...	13.5	10
E in kilovolts, l in miles, P in kilowatts	380	280
Aluminum (61 per cent conductivity):		
E in volts, l in feet, P in kilovolts....	6.5	4.9
E in kilovolts, l in miles, P in kilowatts	185	140
Any material of specific gravity δ having a conductivity of c per cent at 20° C.:		
E in volts, l in feet, P in kilowatts....	$\frac{141\,\delta}{c}$	$\frac{106\,\delta}{c}$
E in kilovolts, l in miles, P in kilowatts	$\frac{3940\,\delta}{c}$	$\frac{2950\,\delta}{c}$

NOTE. — The values of K given for copper and aluminum are taken about 5 per cent reater than their theoretical values to allow for stranding, higher working temperatures, c. 100 per cent conductivity corresponds to 1.724 microhms per centimeter cube at 0° C.

* For a 3-wire 2-phase system with the middle conductor having a cross-section equal $\sqrt{2}$ times the cross-section of either outer wire multiply these constants by 0.85, tak-g for E the voltage (volts or kilovolts) between the middle wire and either outer wire.

Calculation of Commercial Size of Conductor and Corresponding Total Weight. — Formula (22) takes no account of the available commercial sizes f wire. These sizes differ successively by approximately 25 per cent in cross-ection. The weight can also be determined by calculating the resistance of ne required conductor per 1000 feet or per mile, and taking from the wire ables in the article on *Wires and Cables, Bare*, the nearest commercial size. Neglecting the charging current, the required resistance per unit length of wire

$$r = \frac{K_1 Q (E \cos \phi)^2}{lP} \quad \text{ohms,} \qquad (23)$$

here K_1 is a constant depending on the number of phases and wires and the nits in which the other quantities are expressed, as given in the table below.

From the wire table the corresponding weight (w) per unit length of conductor having a resistance nearest to that calculated by formula (23) is obtained; the total weight of conductor, including all wires, is then

$$W = K_2 wl \quad \text{pounds,} \tag{24}$$

where K_2 is a constant depending upon the number of phases and wires and the units in which w and l are expressed, as given in the table below.

VALUES OF K_1 AND K_2 IN FORMULAS 23 AND 24

Units	Single-phase	Balanced 4-wire 2-phase*	Balanced 3-wire 3-phase
E in volts, l in feet, P in kilowatts, r in ohms per 1000 feet and w in pounds per 1000 feet.	$K_1 = 0.005$ $K_2 = 0.002$	$K_1 = 0.01$ $K_2 = 0.004$	$K_1 = 0.01$ $K_2 = 0.003$
E in kilovolts, l in miles, P in kilowatts, r in ohms per mile and w in pounds per mile.	$K_1 = 5$ $K_2 = 2$	$K_1 = 10$ $K_2 = 4$	$K_1 = 10$ $K_2 = 3$

* The values of K_1 given in this column when used in formula (23) will give the resistance per 1000 feet or per mile of either outer wire in a 3-wire 2-phase system; the middle wire should, for the same energy loss per pound, have a cross-section 41 per cent greater than either outer, but when commercial sizes (B. & S. gage) are used, either a wire one gage number smaller (25 per cent greater cross-section) or two gage numbers smaller (60 per cent greater cross-section) may be used; in the first case the corresponding value of K_2 is 0.81 times the values given in this column and in the second case 0.90 times the values given in this column.

Current per Wire; Heating of Line Conductors. — The size of wire as determined from formula (23) must be ample to carry the required current without overheating. Heating of the line conductors is seldom a limitation in outside overhead lines, but for inside wiring or underground cables the temperature rise may set a limit to the size of wire which may be used. It is therefore always wise to determine the current which the conductor must carry, and make sure that the wire is sufficiently large not to overheat; see articles on *Wires and Cables, Bare; Wires and Cables, Insulated;* and *Wiring of Buildings*, for tables of current-carrying capacity under various conditions.

The current per line wire in amperes may be calculated from the following formulas, in which E *is the kilovolts* between wires at the load end, P *the kilowatts* (all phases) delivered to the load, and $\cos\phi$ the power factor of the load as a fraction.

$$\left.\begin{aligned} &\text{Single-phase:} && I = \frac{P}{E\cos\phi}. \\ &\text{Two-phase,* 4-wire, balanced:} && I = \frac{P}{2E\cos\phi}. \\ &\text{Three-phase, 3-wire, balanced:} && I = \frac{P}{\sqrt{3}E\cos\phi}. \end{aligned}\right\} \tag{25}$$

Example: Calculation of Weight and Size of Conductor for a Three-phase Line. — A load of 20,000 kilowatts is to be transmitted by means

* E is here the volts between the two wires of the same phase. This formula also gives the current in each outer of a balanced 2-phase 3-wire line, E being the kilovolts between either outer and the middle wire; the current in the middle is $\sqrt{2}$ times the current in each outer.

rhead three-phase line of copper wire to a substation 50 miles away at 60,000 volts between wires, the frequency being 25 cycles per nd the power factor of the load 80 per cent with the current lagging; ss of 10 per cent of the delivered power to be allowed. From formula equired total weight of copper is

$$W = \frac{285 \times 20{,}000}{10}\left(\frac{50}{60 \times 0.8}\right)^2 = 607{,}000 \text{ pounds.}$$

ula (23) the required resistance per mile of conductor is

$$r = \frac{10 \times 10(60 \times 0.8)^2}{50 \times 20{,}000} = 0.231 \text{ ohm per mile.}$$

t commercial size is 250,000 circular mils (stranded), which has a f 0.328 ohm per mile at 77° F. (*see Wires and Cables, Bare*), and a 080 pounds per mile. From formula (24) the total weight is then

$$W = 3 \times 4080 \times 50 = 612{,}000 \text{ pounds.}$$

t corresponding to the given load is, from formula (25),

$$I = \frac{20{,}000}{\sqrt{3} \times 60 \times 0.8} = 241 \text{ amperes,}$$

ive a negligible temperature rise in the wire. See section on *Current-pacity* in article on *Wires and Cables, Bare.*

on of Size and Weight of Conductors for a Given Per cent ss. — The voltage loss in an alternating-current line depends not e resistance of the line, but also upon the line reactance, and in the lines upon the electrostatic capacity of the line. It is therefore o express directly in a simple formula the size or weight of the wire ie voltage loss. The most practical method of making such calcula- sume first that the per cent power loss is equal to the given per cent and calculate the size by formula (23); then using this size of wire per cent voltage loss by the formulas given below. If this cal- ge loss differs appreciably from the given voltage loss, choose the r smaller size of wire (accordingly as the calculated loss is greater he given loss) and recalculate the voltage loss, and so on, until the wire has been found.

S WHICH AFFECT THE VOLTAGE AND POWER LOSS NES. — Due to the inductance and electrostatic capacity the per oss in an alternating-current line is not so easily calculated as the n a direct-current line and is in general different from the per cent r an amount dependent upon the inductance and capacity of the iency and the power factor of the load.

tion of Line Constants. — The four fundamental line constants nce (r) and inductance (L) of the line conductors per unit length ity (C) and leakage conductance (G) per unit length. For all but ransmission lines the mile is usually the most convenient unit of is unit will be used throughout the remainder of this article unless ted otherwise. Tables of resistance, inductance and capacity and per 1000 feet are given respectively in the articles on *Wires re; Inductance and Inductive Reactance;* and *Capacity and Charging* n the inductance and capacity per mile or per 1000 feet may be any given frequency the reactance x ($= 2\pi fL$) and the capacity

Digitized by Google

susceptance* b ($= 2\pi fC$) for the corresponding unit of length. In the last two articles just mentioned are given full tables of reactance and of capacity susceptance per mile for frequencies of 60 and 25 cycles per second; dividing the numerical values given in these tables by 5.28 will give the corresponding quantity per 1000 feet. For any other frequency of f cycles per second, multiply the numerical values given in the tables for 25 cycles by the ratio $f/25$; i.e., for 40 cycles the reactance is 1.6 times the reactance for 25 cycles.

Allowance for Skin Effect in Conductors. — For non-magnetic wire the increase in the conductor resistance due to the so-called skin effect is equal to 2 per cent when the quotient

$$\text{(cycles per sec.)} \div \text{(ohms per mile of conductor)} = 485. \qquad (58)$$

For smaller values of this quotient the increase of resistance due to skin effect diminishes very rapidly; see article on *Skin Effect*. The skin effect is therefore practically negligible at 25 cycles for all copper conductors smaller than 1,000,000 circular mils, and at 60 cycles for all copper conductors smaller than 450,000 circular mils. The corresponding limiting sizes for aluminum are about 30 per cent larger. The skin effect is quite appreciable in copper or aluminum cables with a steel core; it is usual to neglect the conductivity of the steel core entirely in calculating the resistance of such cables.

Apparent Resistance and Reactance in Unsymmetrical Arrangements of Wires. — When the three wires of a three-phase line are so arranged that they form the three edges of an equilateral prism the reactance of each wire is the same as for one wire of a two-wire line. However, when the wires are arranged all in one plane, as is frequently done, the unequal mutual induction sets up a reactive electromotive force in each outer wire which is not in quadrature with the current in this wire; see equation (20) in the article on *Inductance and Inductive Reactance*. As a result, both the apparent resistance and the apparent reactance of each outer wire is different from its true resistance and reactance. Let r = the true resistance per mile of each wire in ohms, x = the reactance per mile of each wire in ohms, as given in the tables in the article on *Inductance and Inductive Reactance;* and f = the frequency in cycles per second, then the apparent resistances and reactances per mile of the three wires, No. 2 being the middle wire, are

$$\left.\begin{array}{lll} r_1 = r + 0.00121f, & r_2 = r, & r_3 = r - 0.00121f, \\ x_1 = x + 0.00070f, & x_2 = x, & x_3 = x + 0.00070f. \end{array}\right\} \qquad (59)$$

The changes in the apparent resistances do not indicate any change in the power dissipated as heat in the wires but a transfer of energy from one wire to the other by the magnetic field surrounding the wires. These relations are deduced from equations (20) in the article on *Inductance and Inductive Reactance*, assuming sine-wave currents equal in effective value and differing in phase by exactly 120°. The assumption that the currents are exactly balanced cannot be strictly true, since the inequality in the apparent resistances and reactances of the three wires tends to unbalance the system, but the values just given may be taken as a fair approximation when the voltage loss in the line is not over 10 per cent, say. When the line wires are transposed these mutual inductive effects are eliminated from the line as a whole, though the apparent impedances of the three wires in any one "exposure" of the transposition will be different; the transpositions, however, keep the currents balanced.

Similar effects take place in a two-phase three-wire line, see p. 1773.

Leakage Conductance. — The leakage current, even at very high voltages, is usually negligible in power transmission lines, but for telephone lines, the leakage is much greater, due to the large number of small insulators used, and has a very appreciable effect on both the attenuation and distortion of the voice currents. McMeen (*see article on Telephone Lines*) gives the following

* The capacity susceptance to neutral as given in the tables (i.e., in microsiemens per mile) is equal to the charging current in amperes per mile per million volts between wire and neutral; the charging current for any other voltage to neutral is in proportion.

alues of the leakage conductance of telephone lines, the conductance
m one wire to neutral,

dry	$g = 0.004$ micromhos per mile.	(28)
age	$g = 0.08$ micromhos per mile.	
wet	$g = 1.0$ micromhos per mile.	

ge conductance from one wire to the other is one-half these values.
A megohms per mile equals $1/A$ micromhos per mile.
he voltage is sufficiently high on a power line to cause the formation of
e article on Corona), an appreciable leakage current passes from one
e other. Even for a sine-wave voltage this leakage current is by no
usoidal, since its instantaneous values are practically zero except
peak of the voltage wave, and consequently the corona loss cannot
ely represented by a constant leakage conductance. Roughly, how-
g p_c the average value of the corona loss from each wire in watts per
sponding to the given line voltage, the leakage conductance to neutral
hos per mile due to the corona may be taken equal to

$$g_c = \frac{p_c}{V^2}, \tag{29}$$

the effective (r.m.s.) kilovolts to neutral.

Voltage at Load End of Line on Open Circuit. — In every current transmission line the voltage at the load end when this end higher than at the generator end, although in short low-frequency e is inappreciable. In overhead lines for which the product

$$(\text{cycles per sec.}) \times (\text{length of line * in miles}) < 10{,}000, \tag{30}$$

rise as a percentage of the delivered voltage is, to a close approxima-
e resistance of the wire is less than that of a No. 0 B. & S. copper

to $\left(\frac{fl}{40000}\right)^2$, where f is the frequency in cycles per second, and l the
line in miles. For example, in a 25-cycle line 160 miles long this
is 1 per cent of the delivered voltage, in a 60-cycle line of the same
-load rise in voltage is 5.8 per cent of the delivered voltage. The
essed by the above formula under the conditions stated is inde-
he value of the delivered voltage and of the size and spacing of
least for all practical cases.
hich is due to the charging current taken by the line, may be looked
nt at all loads, but when the load is appreciable the voltage drop,
ad current, unless leading, more than offsets this voltage rise. A
it may increase the rise in voltage at the load end as the load

nchronous Condensers (or Phase Modifiers) to Maintain ltage at Load End. — By making the line current at the load lead the line voltage by the proper phase angle, it is possible to ntirely for the change in the load voltage which normally takes oad current increases. An overexcited synchronous motor con-lel with the load is sometimes used for this purpose, as described e article on *Motors, Synchronous*. A synchronous motor so used alled a synchronous condenser, since the current taken by it leads pressed on its terminals. A striking example of the use of syn-s for this purpose is in connection with the 150,000-volt, 240-mile

* Length of each conductor.

line from Big Creek, Cal., to Los Angeles, constructed in 1913. Two separate lines are used, the total generator output is 70,000 kilovolt-amperes, and the voltage at the load end is controlled by two 15,000-kilovolt-ampere overexcited synchronous motors.

METHODS OF CALCULATING VOLTAGE AND POWER LOSS IN A-C. LINES. — The absolutely rigorous calculation of an alternating-current line requires that the distributed nature of the inductance and capacity be considered, i.e., that the line be considered as made up of an infinite number of sections such as shown in Fig. 7. However, simpler approximate methods may be employed for nearly all power lines such as are now used, and give results sufficiently accurate for all practical purposes. The accuracy of these approximate methods depends primarily upon the frequency and length of the line; the less the value of the product of these two quantities the simpler is the method which may be employed. Accurate calculation of even a short a-c. line with distributed load can be effected only by rather complicated network equations; see under *Kirchhoff's Laws* in the article on *Alternating Currents*.

Limitations of Approximate Methods of A-C. Line Calculations. — The approximate methods of calculating a-c. lines, in the order of their simplicity, may be designated as (1) the simple impedance method; (2) the single end-condenser method; (3) the middle condenser or "T" method and (4) the split condenser or "π" method; the "π" method is also called the "U" method. For short low-voltage lines, the simple impedance method, which neglects entirely the charging current, is usually sufficiently accurate. The single end-condenser method takes the charging current into account in a manner usually sufficiently accurate for all but the longest high-voltage lines. The "T" and "π" methods are still more accurate, but for exact calculations the rigorous method given on p. 1681ff should be used. In fact, it is always well to check an approximate solution by this exact method.

Fundamental Assumptions on which Formulas Given Below are Based. — All the formulas given below are based on the assumptions of pure sine-wave currents and voltages and a perfectly balanced * system. By using the voltage to neutral instead of the voltage between wires, the formulas are also put in such shape that they may be applied directly to either a single-phase, a two-phase four-wire line or to a three-phase three-wire line, a two-phase four-wire line being considered as two separate single-phase lines. The fundamental idea in this method of treatment is that each line wire is considered as a separate circuit. The return wire shown in the various diagrams is therefore to be considered as having no impedance. This method of treatment of *balanced* polyphase circuits is strictly accurate (*see Alternating Currents*), but when the system is not balanced the circuit must be treated by the more general methods of network calculations; see section on *Kirchhoff's Laws in Symbolic Notation* in the article on *Alternating Currents*. Also, when the voltage and current waves are not sinusoidal, each harmonic must be treated separately as described in the article on *Alternating Currents*. The calculation of a two-phase three-wire line is treated separately, p. 1773.

SIMPLE IMPEDANCE METHOD. — This method is based upon the assumption that the electrostatic capacity of the line may be neglected entirely, and that the line may be considered simply as an impedance in series with the load, this impedance having a resistance equal to the total resistance of the line conductor and a reactance equal to the total inductive reactance of the line

* The meaning of a "balanced" system is fully explained in the article on *Alternating Currents* (q.v.).

$\overline{AB} = V \cos \phi$, $\overline{DE} = xI$, $\overline{FE} = V_0 - V$

volts to neutral at load end of the line (= volts between wires divided by 2 in case of a single-phase line, and volts between wires divided by $\sqrt{3}$ in the case of a three-phase line),
amperes per wire; see formula (25) above,
length of each line wire in miles,
$\frac{V}{lI}$ = "equivalent" impedance of the load per mile of line,
power factor of the load at end of line,
$\sqrt{1 - \cos^2 \phi}$ = the reactive factor of the load; $\sin \phi$ is to be taken positive for a lagging and negative for a leading current,
volts to neutral at the generator end of the line,
conductor resistance per mile of line in ohms; see tables in article on *Wires and Cables, Bare*,
conductor reactance per mile of line, in ohms; see tables in article on *Inductance and Inductive Reactance*,
$\sqrt{r^2 + x^2}$ = conductor impedance * per mile of line, in ohms,
per cent power loss, as a percentage of delivered power,
per cent voltage loss, as a percentage of delivered voltage.

tor diagram it is evident that the voltage at the generator end is

$$V_0 = \sqrt{(V \cos \phi + rlI)^2 + (V \sin \phi + xlI)^2}, \qquad (31)$$

---

nt way of calculating an expression of the form $\sqrt{a^2 + b^2}$ is to write it
or $b \sqrt{1 + \left(\frac{a}{b}\right)^2}$ accordingly as a is greater or less than b; the expression
al will then always lie between the numbers 1 and 2, and no difficulty
ced with decimal points. When b/a is less than 0.3, then the expression
$- \frac{b^2}{2a}$ with an error of less than 0.1 per cent, and when a/b is less than 0.3,
$= b + \frac{a^2}{2b}$ with an error of less than 0.1 per cent. The error in the ap-
sions, diminishes very rapidly as the ratio of b/a or a/b, as the case may
ing only 0.02 per cent when the ratio is 0.2.

Digitized by Google

which may also be written

$$V_0 = V\sqrt{\left(\cos\phi + \frac{r}{Z}\right)^2 + \left(\sin\phi + \frac{x}{Z}\right)^2}, \tag{32}$$

where r and x are per mile of line.

The current at the generator end is the same as at the load end.

The per cent power loss is

$$Q = \frac{100\,rlI}{V\cos\phi} = \frac{100\,r}{Z\cos\phi}, \tag{33}$$

and the per cent voltage loss is

$$D = \frac{100\,(V_0 - V)}{V} = 100\left[\sqrt{\left(\cos\phi + \frac{r}{Z}\right)^2 + \left(\sin\phi + \frac{x}{Z}\right)^2} - 1\right]. \tag{34}$$

The power factor at the generator end is

$$\cos\phi_0 = \left(\frac{100 + Q}{100 + D}\right)\cos\phi. \tag{35}$$

Relation between Impedance Drop and Voltage Loss. — The total impedance drop, which is zI volts, should be carefully distinguished from the voltage loss, which is $v = V_0 - V$ volts. The vector diagram, Fig. 2a, will make the difference clear. For a given impedance drop of, say, A per cent, the voltage at the load end of the line may be anything from A per cent less than the voltage at the generator end to A per cent greater than the voltage at the generator end. The determining factor is the difference between the power-factor angle (ϕ) of the load and the power-factor angle $\left(\epsilon = \tan^{-1}\frac{x}{r}\right)$ of the line; only when $\epsilon - \phi = 0$ are the voltage loss and impedance drop the same. When $\epsilon - \phi$ is greater than 90° (which may occur for a leading current, since ϕ is then negative) the voltage at the load end will in general be higher than at the generator end although the impedance drop in the line may be very large. As a fair approximation, when the impedance drop is less than 20 per cent, that is, when z/Z is less than 0.2, the percentage voltage loss may be written

$$D = \frac{100\,z}{Z}\cos(\epsilon - \phi), \tag{36}$$

z and Z being the impedances of the line and load respectively, and ϵ and ϕ the power-factor angles of the line and load respectively.

Example of Calculation by Simple Impedance Method. — Take the case of a three-phase, 60-cycle line 50 miles long, the wires being No. 0000 A.W.G. (or B. & S.) stranded copper spaced symmetrically with 6 feet between centers, and let the load be 15,000 kilowatts at 60,000 volts between wires and at a power factor of 80 per cent with lagging current. The voltage to neutral is then $60{,}000 \div \sqrt{3} = 34{,}600$ and the current per wire $15{,}000 \div (\sqrt{3} \times 60 \times 0.8) = 180$ amperes. The resistance of each wire per mile is 0.269 ohm at 77° F., and the reactance 0.728 ohm. The equivalent impedance of the load per mile of line is $Z = 34{,}600 \div (50 \times 180) = 3.84$. $\cos\phi = 0.8$ and $\sin\phi = \sqrt{1 - 0.8^2} = 0.6$. Whence

$$\text{Per cent power loss} = Q = \frac{100 \times 0.269}{3.84 \times 0.8} = 8.76 \text{ per cent},$$

$$\text{Per cent voltage loss} = D = 100\left[\sqrt{\left(0.8 + \frac{0.269}{3.84}\right)^2 + \left(0.6 + \frac{0.728}{3.84}\right)^2} - 1\right] = 17.5\%.$$

wer factor at generator end = $\cos\phi_0 = \left(\frac{100 + 8.76}{100 + 17.5}\right) \times 0.80 = 74.1$ per cent,

Per cent impedance drop = $\frac{100\sqrt{0.269^2 + 0.728^2}}{3.84} = 20.2$ per cent.

Graphical Determination of Voltage Loss; Mershon's Chart (Fig. 3). — e voltage loss may also be determined by means of the chart shown in Fig. 3, ich was devised by R. D. Mershon. This chart is nothing more than a ans of solving equation (32) graphically. To use the chart calculate

$$\text{the per cent resistance drop} = r\left(\frac{100\,ll}{V}\right), \tag{37}$$

$$\text{the per cent reactance drop} = x\left(\frac{100\,ll}{V}\right), \tag{38}$$

l from the point on the curve marked "0" where this curve cuts the vertical e corresponding to the load power factor lay off horizontally the per cent istance drop, and from the end of this horizontal line lay off vertically upward per cent reactance drop; the per cent voltage loss is then given by the num- on the circle through the end of this vertical line.

Taking the same example as given in the preceding section, $(100\,ll) \div V = 0 \times 50 \times 180) \div 34{,}600 = 26.0$, whence the per cent resistance drop is $0.269 \times 0 = 7.0$ per cent and the per cent reactance drop is $0.728 \times 26.0 = 18.9$ and refore from the chart the per cent voltage loss is 17.6 per cent.

Calculations in Terms of Voltage at Generator End. — When the volts to neutral at the generator end are given instead of the volts to neutral V at the load end, the ulations for a line of total resistance of R ohms per wire, and total reactance of X as per wire for a load of P kilowatts per wire* at a power factor of $\cos\phi$ at the load l may be made in the same manner as above by first finding V by the formula,

$$V = A\sqrt{1 \pm \sqrt{1 - \frac{(R^2 + X^2)\,P^2 \times 10^6}{A^4\cos^2\phi}}}, \tag{39}$$

ere

$$A = V_0\sqrt{\frac{1}{2} - \frac{1000\,P\,(R\cos\phi + X\sin\phi)}{V_0^2\cos\phi}}. \tag{40}$$

e plus or minus sign in the formula for V arises from the fact that for a given amount delivered power and given voltage at the generator end two different voltages at the d end are possible; for an inductive load the voltage corresponding to the minus sign l in general be less than 50 per cent of the voltage at the generator end, and the "minus n" solution is therefore usually of no practical importance. The maximum power ich can be delivered at the load end for a given voltage at the generator end is

$$P_m = \frac{V_0\cos\phi}{2000\,(\sqrt{R^2 + X^2} + R\cos\phi + X\sin\phi)}. \tag{41}$$

Voltage and Power Loss in Two-phase Three-wire Line. — Take the usual se of the three wires in the same plane, with the common wire midway between the o outers. Let r be the resistance per mile of each outer, and r_1 the resistance per mile the common wire, taken from the tables in the article on *Wires and Cables, Bare*, and and x_1 the corresponding reactances per mile taken from the tables in the article on *ductance and Inductive Reactance*, for a spacing equal to the distance between the middle ire and each outer. Let E be the voltage between each outer and the middle wire, I e amperes in each outer, $\cos\phi$ the power factor of the load, and l the length of the line. ssuming a balanced load, then the voltage between the two outers is $\sqrt{2}\,E$ and the rrent in the middle wire is $\sqrt{2}\,I$, and the total power delivered to the load is $(2\,EI\cos$) ÷ 1000 kilowatts. The per cent power loss is then

$$Q = \frac{100\,(r + r_1)\,ll}{E\cos\phi}.$$

* Calling P_t the total kilowatts delivered to the load, then $P = P_t/2$ for a single hase line. $P = P_t/3$ for a three-phase line and $P = P_t/4$ for a two-phase four-wire line

Google

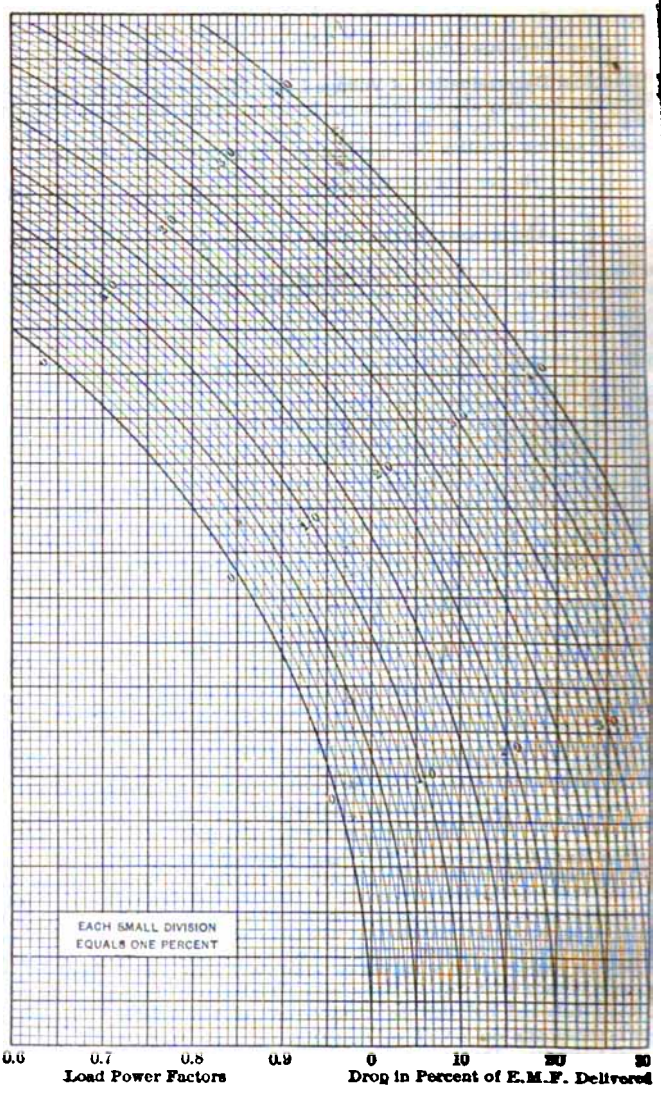

Fig. 3. Mershon's Chart for Calculating Drop in A-C. Line

e equivalent resistances and reactances of the line for the two phases, assuming the rents in the two outer wires to be exactly equal in effective value and to differ in phase exactly 90°, are

$$R_1 = (r + r_1 - x_1 + 0.0014f)\,l, \qquad X_1 = (x + x_1 + r_1)\,l,$$
$$R_2 = (r + r_1 + x_1 - 0.0014f)\,l, \qquad X_2 = (x + x_1 - r_1)\,l,$$

ere f is the frequency in cycles per second. When the wires are transposed only the m $0.0014f$ in the expressions for R_1 and R_2 go out, the other terms in the R's and X's aining unaltered. The voltages at the generator end for the two phases are then

$$E_1 = E\sqrt{\left(\cos\phi + \frac{R_1 I}{E}\right)^2 + \left(\sin\phi + \frac{X_1 I}{E}\right)^2},$$

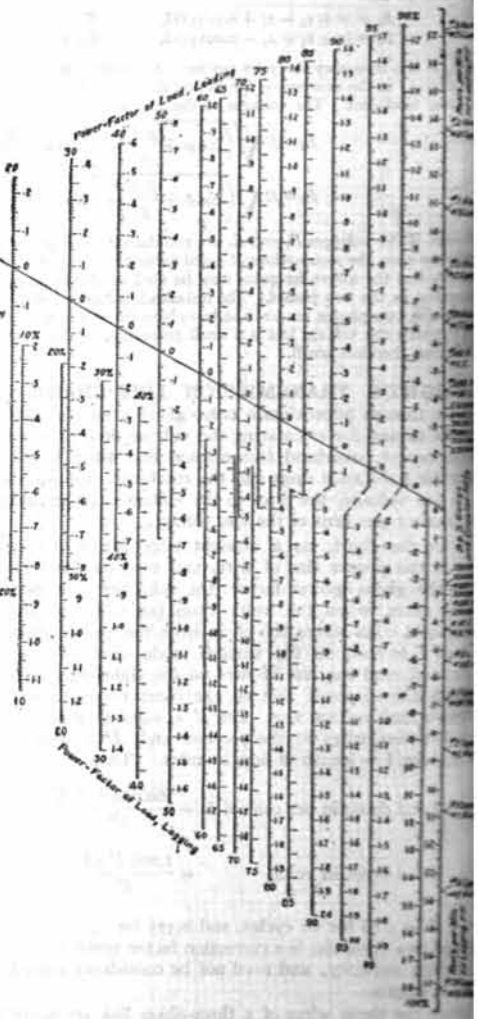
$$E_2 = E\sqrt{\left(\cos\phi + \frac{R_2 I}{E}\right)^2 + \left(\sin\phi + \frac{X_2 I}{E}\right)^2}.$$

course, if the voltages E_1 and E_2 are maintained equal at the generator end, which is ally the case, the assumptions of equal currents and equal voltages at the load end are orrect, but the above formulas may be used to obtain an approximate value of the tage loss in the two phases. The unbalancing due to the unequal equivalent impedes of the two phases renders the two-phase three-wire system undesirable except for s in which the voltage loss is a small percentage of the voltage at the load, and the alancing therefore small.

DWIGHT'S TRANSMISSION LINE CHART.—The chart given in g. 3A, though approximate only, gives a simple and ordinarily sufficiently urate means for calculating the voltage drop or size of wire for any alterting-current, overhead transmission line which is not over 100 miles long. hen the resistance drop and the reactance drop are each under 15 per cent the line voltage, the error in the voltage drop as calculated by this chart is s than 0.5 per cent of the line voltage.

To use the chart, lay a straight edge across it from the proper spacing int to the proper size of wire, and read on the vertical scale corresponding to the given power factor the volts per mile per ampere; call this V. , vice versa, when the volts drop per mile per ampere V is known, lay straight edge across the chart from the proper spacing point to the given lue of V as read on the vertical scale corresponding to the given power tor, and read the size of wire on the right-hand vertical scale. A value of above the diagonal line on the chart corresponds to a "negative drop," ., an actual voltage rise. Let V = volts drop per mile per ampere, E = lts between wires at the receiver end, U = kilovolt-amperes delivered to e receiver, l = length of line, in miles. Then,

$$\text{Total drop, in per cent of } E = \frac{100{,}000\,U\,L\,V}{E^2} - 100\,K\left(\frac{l}{1{,}000}\right)^2$$



$$\text{Total drop, in volts} = \frac{1{,}000\,U\,l\,V}{E} - E\,K\left(\frac{l}{1{,}000}\right)^2$$

here K = 2.16 for 60 cycles, and 0.375 for 25 cycles. The last term in each these two formulas is a correction factor which takes into account the effect the line capacity, and need not be considered when the line is less than 30 iles in length.

When the three wires of a three-phase line are separated by distances a, b nd c, use as the effective spacing $s = \sqrt[3]{a\,b\,c}$. When the three wires are all the same plane, and the middle wire is at the distance a from each of the thers, use as the effective spacing $s = 1.26\,a$.

The above formulas are for two-phase and three-phase lines. For a single-

Example.—Length of line, 100 miles; effective spacing, 8 feet; No. 3 copper, & S. gauge; load, measured at the receiver end, 3,000 kv-a., 66,000 volts, 90 per cent power-factor lagging, 3-phase, 60 cycles.

Lay a straight edge from the 8-ft. spacing point for copper conductor, 60 cycles, to the point for No. 3 copper on the right-hand vertical scale. It crosses the 90 per cent power-factor line at $V = 1.34$.

$$\text{Per cent drop} = \frac{100{,}000 \times 3{,}000 \times 100 \times 1.34}{66{,}000 \times 66{,}000} - \frac{100 \times 2.16}{100} = 7.07\%$$

The voltage rise at no load is 2.16 per cent.

The regulation at the receiver end, or change in voltage from full load to no load, is 9.23 per cent of E. The exact values of the voltage drop and regulation as calculated by the formulas on page 1786 are 7.08 per cent and 9.40 per cent. If the power factor had been leading instead of lagging, V would have been 0.70, and the drop would have been 2.66 per cent, as against the exact value of 2.51 per cent. In the above example, the errors due to the chart are less than 0.2 per cent of line voltage.

SINGLE END-CONDENSER METHOD. — This method assumes that the total current at the load end is equal to the actual load current plus (vectorially) the charging current which would be taken by a single condenser shunted across the line at the load end, the capacity of this condenser being taken equal to the total capacity of the line. This method gives too low a voltage at the generator end by approximately the same amount that the straight impedance

$\overline{CE} = zlI_1,$
$\overline{AE} = V_0,$
$\overline{FE} = \eta,$

method gives it too high, and also gives the power loss too low by approximately the same amount that the straight impedance method gives it too high. By averaging the losses obtained by the two methods a close approximation to their true values is obtained.

Fig. 4 is a diagram of the circuit and Fig. 4a is a complete vector diagram of the voltage and current; voltages are shown by full lines and currents by dotted lines. The diagrams and formulas are for the general case of a line with leakage, but for nearly all practical cases the leakage may be neglected.

Digitized by Google

The effect of the electrostatic capacity of the line is to change both the numerical value and the phase angle of the line current. Or, the condenser and the load may be looked upon as forming together an equivalent load taking a current I_1 at a power factor $\cos\phi_1$ differing from the actual current and power factor of the load. Let

V = volts to neutral at the load end of the line,
I = actual amperes per wire at the load end,
$\cos\phi$ = actual power factor at the load end,
$\sin\phi = \sqrt{1-\cos^2\phi}$ = actual reactive factor at the load end,
l = length of each line wire in miles,
b = capacity susceptance to neutral per mile of line, in micromhos, see tables in the article on *Capacity and Charging Current*,
g = leakage conductance to neutral per mile of line in micromhos, usually taken equal to zero in power lines, as explained above,
$y = \sqrt{g^2+b^2}$ = dielectric admittance to neutral per mile of conductor, in micromhos. Note that for no leakage $y = b$.

The total leakage current, total charging current and total exciting current of the line are then respectively

$$I_g = glV \times 10^{-6}, \qquad I_c = blV \times 10^{-6}, \qquad I_e = \sqrt{I_g^2 + I_c^2}. \tag{42}$$

The total line current, i.e., the resultant of the actual load current and the exciting current, is

$$I_1 = I\sqrt{\left(\cos\phi + \frac{I_g}{I}\right)^2 + \left(\sin\phi - \frac{I_c}{I}\right)^2}. \tag{43}$$

On the assumptions of this method of calculation I_1 is also the current at the generator end.

The power factor of the equivalent load formed by the actual load and the condenser is then

$$\cos\phi_1 = \frac{I\cos\phi + I_g}{I_1}, \tag{44}$$

and the reactance factor of this equivalent load is

$$\sin\phi_1 = \frac{I\sin\phi - I_c}{I_1}. \tag{45}$$

The formulas given above for the straight impedance method are then directly applicable, using for I, $\cos\phi$ and $\sin\phi$ in those formulas the values of I_1, $\cos\phi_1$ and $\sin\phi_1$ just calculated; i.e., the straight impedance method is to be applied not to the actual load but to the equivalent load formed by the actual load and a condenser having an admittance equal to the total admittance of the line.

Example of Calculation by Single End-Condenser Method. — Three-phase line, 50 miles long, No. 0000 A.W.G. stranded copper, 6 feet between centers, frequency 60 cycles, load 15,000 kilowatts, 60,000 volts between wires at load end, 80 per cent power factor at load. This is the same example as used above for the straight impedance method. Then $V = 34{,}600$, $I = 180$, $\cos\phi = 0.8$, $\sin\phi = 0.6$, $l = 50$, $b = 6.03$, $g = 0$, $r = 0.269$, $x = 0.728$. Then,

Charging current $= I_c = 6.03 \times 50 \times 34{,}600 \times 10^{-6} = 10.4$ amperes,

$$\text{Resultant current} = I_1 = 180\sqrt{(0.8)^2 + \left(0.6 - \frac{10.4}{180}\right)^2} = 174 \text{ amperes},$$

$$\text{Power factor of equivalent load} = \cos\phi_1 = \frac{180 \times 0.8}{174} = 0.828.$$

Digitized by Google

e factor of equivalent load $= \sin\phi_1 = \dfrac{180 \times 0.6 - 10.4}{174} = 0.561$,

ıce of equivalent load per mile of line $= Z_1 = \dfrac{34{,}600}{50 \times 174} = 3.98$,

power loss $= Q = \dfrac{100 \times 0.269}{3.98 \times 0.828} = 8.16$ per cent,

voltage loss $= D$

$$\sqrt{\left(0.828 + \frac{0.269}{3.98}\right)^2 + \left(0.561 + \frac{0.728}{3.98}\right)^2} - 1 = 16.30 \text{ per cent},$$

ctor at generator end $= \cos\phi_0 = \left(\dfrac{100 + 8.16}{100 + 16.3}\right) \times 0.822 = 76.4$ per cent.

ent power loss and voltage loss obtained by the straight impedance lecting the line capacity are respectively 8.76 and 17.6 per cent. As e the single end-condenser method gives these losses too low (for ads) by approximately the same amount that the straight imped- d gives them too high, whence closer approximations to the true per cent power loss $= (8.16 + 8.76) \div 2 = 8.46$ and per cent voltage $+ 17.6) \div 2 = 17.0$.

ion of Effect of Synchronous Condenser. — Formulas (43) to lirectly to the calculation of the effect of a synchronous condenser f the line taking a current having an in-phase or energy component nd a quadrature leading component equal to I_c. Hence the voltage, current and power niddle point of the line may be figured by the straight impedance method Then, considering the voltage, current and power factor thus calculated ad at the middle point of the line, the second half of the line may be cal- single end-condenser method just described.

proper values (which are somewhat complicated functions of the actual and the frequency) to the constants of the "T" circuit shown in Fig. 5, y be made *exactly equivalent*, as far as the relations between the voltage, wer at the two ends are concerned, *to a line of any length and for any fre-* orrected" constants are entirely independent of the voltage, current and the load; see p. 1683.

the "T" Circuit in Symbolic Notation. — The solution of the circuit is also given below in terms of complex quantities (*see under Symbolic article on Alternating Currents*). Let

Digitized by Google

V = numerical value of volts to neutral at the load end of the line,
I = amperes per wire at the load end of the line, taken as the vector of reference,
$\cos\phi$ = power factor at the load end of the line,
$\dot{V} = V\cos\phi + jV\sin\phi$ = volts to neutral at the load end of the line, referred to the current at the load end,
$\dot{z} = r + jx$ = conductor impedance in ohms per mile of wire, r being the resistance per mile and x the reactance per mile,
$\dot{y} = g + jb$ = dielectric admittance, one wire to neutral, in micromhos per mile of line, where g is the leakage conductance per mile and b the capacity susceptance per mile,
l = length of each wire in miles.

Put

$$\dot{M} = 10^{-6}\dot{y}\dot{z}l^2 = [(gr - bx) + j(br + gx)]\,10^{-6}l^2. \qquad (a)$$

Then the current at the generator end, in symbolic notation, is

$$\dot{I}_0 = (1 + \tfrac{1}{2}\dot{M})\,I + 10^{-6}\dot{y}\dot{V}, \qquad (c)$$

and the volts to neutral at the generator end, in symbolic notation, are

$$\dot{V}_0 = (1 + \tfrac{1}{2}\dot{M})\,\dot{V} + \dot{z}l\,(1 + \tfrac{1}{4}\dot{M})I. \qquad (d)$$

Calling I_0' and I_0'' the real and "j" components respectively of the current $\dot{I}_0$, and V_0' and V_0'' the real and "j" components of the voltage $\dot{V}_0$, then the numerical values of the current and voltage at the generator end are

$$I_0 = \sqrt{(I_0')^2 + (I_0'')^2}, \quad \text{and} \quad V_0 = \sqrt{(V_0')^2 + (V_0'')^2}, \qquad (e)$$

and the power input per wire at the generator end is

$$P_0 = V_0'I_0' + V_0''I_0''. \qquad (f)$$

In applying this last formula particular attention must be paid to the signs of the quantities involved, e.g., if $\dot{V}_0 = 1000 + j\,300$ and $\dot{I}_0 = 100 - j\,20$, then $V_0' = 1000$, $V_0'' = 300$, $I_0' = 100$ and $I_0'' = -20$, and $P_0 = 1000 \times 100 - 300 \times 20$. The power factor at the generator end is

$$\cos\phi_0 = \frac{P_0}{V_0I_0}. \qquad (g)$$

SPLIT-CONDENSER OR "π" OR "U" METHOD. — This method assumes that the line may be considered equivalent to the circuit shown in Fig. 6, which represents a single impedance in series with the load, the resistance and inductance of this impedance being equal respectively to the total conductor resistance and inductance of the line, and a condenser shunted across the line at each end, each condenser having a capacity and leakage conductance equal respectively to half the total capacity and half the total leakage conductance of the line.

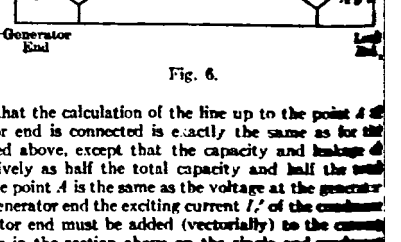

Fig. 6.

An inspection of Fig. 6 will show that the calculation of the line up to the point A at which the condenser at the generator end is connected is exactly the same as for the single end-condenser method described above, except that the capacity and leakage of the end condenser are taken respectively as half the total capacity and half the total leakage of the line. The voltage at the point A is the same as the voltage at the generator end, but to find the current I_0 at the generator end the exciting current I_1' of the condenser shunted across the line at the generator end must be added (vectorially) to the current I_1 at A. Using the same notation as in the section above on the single end-condenser method, the total generator current is then

$$I_0 = I_1\sqrt{\left(\cos\phi_0 + \frac{I_1'}{I_1}\right)^2 + \left(\sin\phi_0 - \frac{I_1''}{I_1}\right)^2},$$

where

$$I_1' = \tfrac{1}{2}gV_0 \times 10^{-6} \quad \text{and} \quad I_1'' = \tfrac{1}{2}bV_0 \times 10^{-6}.$$

e case of the "T" circuit, a "π" circuit, such as shown in Fig. 6, may be given ected" constants as will make it exactly equivalent for any one frequency, as terminal conditions are concerned, to a line of any length whatever no matter his frequency may be; see p. 1787.

of the "π" Circuit in Symbolic Notation. — Using the same notation ction above on the *Solution of the "T" Circuit in Symbolic Notation*, and cal- e quantity M by the same formula, viz., equation (46), the current and voltage rator end in symbolic notation are respectively

$$\dot{I}_0 = (1 + \tfrac{1}{2}\dot{M})\,\dot{I} + 10^{-6}\dot{y}\,(1 + \tfrac{1}{4}\dot{M})\,\dot{V}, \qquad (52)$$

$$\dot{V}_0 = (1 + \tfrac{1}{2}\dot{M})\,\dot{V} + z\dot{I}. \qquad (53)$$

ical values of these quantities, the power and the power factor are then to be n the same manner as for the "T" circuit, viz., by formulas (49) to (51).

CALCULATION OF A-C. LINES OF ANY LENGTH AND NCY.* — The charging current (and also the leakage current) for any a transmission through only on of the line between the ient and the end. Fig. 7.

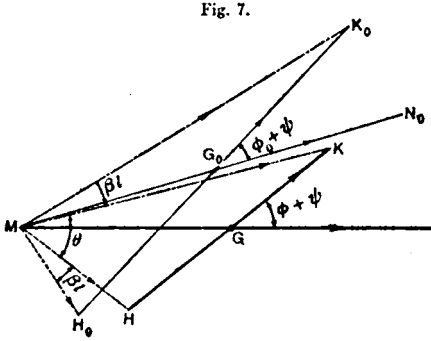

Fig. 7a.

$\overline{MN} = I,$	$\overline{MK}_0 = Ae^{\alpha l},$
$\overline{HK} = YV,$	$\overline{MH}_0 = Be^{-\alpha l},$
$\overline{MK} = A,$	$\overline{MN}_0 = I_0,$
$\overline{MH} = B,$	$\overline{H_0K}_0 = YV_0.$

o make clear the physical meaning of the various terms employed, olution is first given in terms of instantaneous values. Following the working formulas (1) in terms of exponentials, viz., ϵ^x and ϵ^{-x}, of real hyperbolic functions, and (3) in terms of hyperbolic func- lex angles.

uations of Transmission Line. — Let l = the distance in miles of any ransmisaion line, measured from any arbitrarily chosen point (say from let i = the instantaneous current in amperes in the conductor at this sitive in the direction *opposite* to that in which l is measured (i.e., positive load end); let v = the potential drop in volts between this point and the t r = the conductor resistance in ohms per mile, L = the inductance of n henries per mile, C = the capacity to neutral in microfarads per mile

s section is abstracted from the lecture notes of Dr. H. Pender.

Digitized by Google

and g = the leakage conductance to neutral in micromhos per mile. The following relations then hold at any point along the line, t being time in seconds measured from an arbitrarily chosen instant:

$$\frac{dv}{dl} = ri + L\frac{di}{dt}, \tag{5}$$

$$10^6\frac{di}{dl} = gv + C\frac{dv}{dt}. \tag{6}$$

If the circuit is composed of two or more sections of different constants (e.g., an overhead section and an underground section, or a circuit formed by a step-up transformer, transmission line and a step-down transformer) then a similar set of equations holds for each section of the circuit, the constants r, L, g, and C being in general different for the several sections.

The complete solution of any two equations of the form given by (54) and (55) consists of an infinite series of terms for both v and i, corresponding terms in the two series having the following values:

$$i = \sqrt{\frac{2}{}}\, e^{-(\alpha-\epsilon)t}\left[Ae^{\alpha l}\sin(\omega t+\beta l+\theta_1) + Be^{-\alpha l}\sin(\omega t-\beta l+\theta_2)\right], \tag{5'}$$

$$v = \frac{\sqrt{2}}{Y} e^{-(\alpha-\epsilon)t}\left[Ae^{\alpha l}\sin(\omega t+\beta l+\theta_1-\psi) - Be^{-\alpha l}\sin(\omega t-\beta l+\theta_2-\psi)\right]. \tag{6'}$$

Physical Interpretation and Names Given to the Various Constants. — The constant ω in equations (56) and (57) is equal to $2\pi f$, where f is the frequency of the oscillation represented by these equations. In the most general case any change in the circuit conditions, such as closing or opening a switch, or a lightning stroke in the vicinity of the circuit, may set up an infinite number of oscillations of different frequencies, their frequency being determined by the initial conditions at the instant the change is made. The current and voltage set up by each oscillation is represented by a set of terms of the form given by (56) and (57), and the resultant current and voltage will be respectively the sum of all the current terms and the sum of all the voltage terms. The oscillation of any given frequency, however, may be considered separately, as it is uninfluenced by the presence of the other oscillations. Moreover, in the case of a composite circuit, consisting say of a step-up transformer, transmission line and step-down transformer, if an oscillation of frequency f is set up in one part of the circuit it will also appear in all other sections of the circuit, though it may be greatly damped in these sections and therefore produce no appreciable effect.

Attenuation Constant (α), Wave Length Constant (β), Wave Length λ and Velocity of Propagation (U). — Referring to equations (56) and (57) each oscillation sets up in each section of the circuit two waves, each of which has a wave length $\lambda = \frac{2\pi}{\beta}$; the constant β is therefore called the "wave length constant;" it is a function of the frequency and of the constants r, L, g and C of the circuit. The two waves travel along the line in opposite directions each with a velocity $U = \frac{\omega}{\beta}$; in a composite circuit this velocity U is in general different for each section of the circuit. One wave may be looked upon as the "incident" and the other as the "reflected" wave. The amplitude of each wave diminishes by the factor e^{α} as the wave travels unit distance; the factor e^{α} is called the "attenuation factor" and the constant α is called the "attenuation constant." The attenuation constant is a function of the frequency and the constants r, L, g and C of the circuit; see p. 1784.

Surge Admittance (Y) and its Power-factor Angle (ψ). — The constant Y, which is equal to the quotient of the amplitude (or r.m.s. value) of the incident current wave by the incident voltage wave, is called the "surge admittance" and its reciprocal is called the "surge impedance"; it is a function of the frequency and the constants r, L, g and C of the circuit; see p. 1784. The constant ψ, which is equal to the angle by which the incident current wave leads the incident voltage wave, is called the "power-factor angle of the surge admittance"; it is a function of the frequency and the constants r, L, g and C, see p. 1785.

Amplitude Constants (A and B) and Phase-Angle Constants (θ_1 and θ_2). — The constants are equal to the amplitudes of the incident and reflected current waves at the point from which the distance l is measured, and the constants θ_1 and θ_2 give the

ese two waves at this point ($l = 0$) at the instant from which time is measured ote that the incident current wave at $l = 0$ leads the reflected current wave le $\theta = \theta_1 - \theta_2$. The determination of these constants for steady state condi- en on p. 1785.

ural Damping Constant (u), Energy Transfer Constant (s) and Com- nping Constant ($u - s$). — In the general case of a natural oscillation in circuit the amplitude of each wave diminishes in unit time by the factor factor is called the "composite damping factor," and the constant $(u - s)$ e "composite damping constant." The composite damping constant, like cy f, is the same for all sections of a composite circuit. In the case of a line onstants throughout, not connected to any terminal apparatus, it can readily hat $s = 0$, in which case the amplitude of the oscillations diminishes in unit factor ϵ^{u}; this factor is therefore called the "natural damping factor" and u, which for a section having the constants r, L, g and C per unit length,

$$u = \frac{1}{2}\left(\frac{r}{L} + \frac{g}{C}\right), \tag{58}$$

natural damping constant." Any section of a composite circuit for which the ng $\epsilon^{(u-s)}$ is less than the natural damping ϵ^{u} must receive energy from some ; consequently a positive value of s for a given section means that energy into this section from some other section of the circuit. Similarly, a nega- s for a given section means that energy is transferred from this section to ection. The constant s may therefore be called the "energy transfer con- e the voltage and current in the circuit cannot increase indefinitely the er constant s can never have a positive value greater than u.

composite damping constant $(u - s)$ is the same for all sections of a circuit, t the transfer of energy from one section to another by oscillations in a com- will always be into the section in which u is the larger from the section in e smaller. Neglecting the leakage conductance g, this means that energy will into section 1 from section 2, when $\frac{r_1}{L_1}$ is greater than $\frac{r_2}{L_2}$, that is, energy from the section of the larger "time constant" $\left(\frac{L_2}{r_2}\right)$ to that of the smaller nt" $\left(\frac{L_1}{r_1}\right)$. When the resistances are small, this means that in the limiting nergy ($= \frac{1}{2} L_2 I^2$) of the magnetic field of the second section may go into nergy ($= \frac{1}{2} C_1 V^2$) in the first section, producing therefore a very high volt- ction point when the inductance L_1 of the second section is large compared city C_1 of the first section. This accounts for the very high voltages some- luring switching operations at the junction point of an overhead line with d line, or in a transformer connected to a long overhead line.

tate" Conditions in a Transmission Line. — From the above discussion at when a sufficient time (usually a small fraction of a second) has elapsed ge in the circuit conditions, the only terms left in the general equations ion line for a given impressed sine-wave voltage of frequency f are those , viz.,*

$$\sqrt{2}\left[A\epsilon^{\alpha l}\sin(\omega t + \beta l) + B\epsilon^{-\alpha l}\sin(\omega t - \beta l - \theta)\right] \tag{59}$$

$$\frac{\sqrt{2}}{Y}\left[A\epsilon^{\alpha l}\sin(\omega t + \beta l - \psi) - B\epsilon^{-\alpha l}\sin(\omega t - \beta l - \theta - \psi)\right]. \tag{60}$$

alue of the current at any point is then equal to the sum of two vectors ths $A\epsilon^{\alpha l}$ and $B\epsilon^{-\alpha l}$, the former leading the latter by the angle $(\alpha\beta l + \beta)$, e value of the voltage is equal to the difference of these same two vectors The phase angle between the voltage and current is equal to the phase he sum and difference of the A and B vectors less the angle ψ.

state conditions time may be counted from any arbitrarily chosen interval, ons (56) and (57) may be put equal to zero, and for convenience $-\theta$ may

Notation for Steady State Conditions. — These relations are clearly shown in the vector diagram, Fig. 7a, which is a complete vector diagram of a transmission line with distributed capacity and leakage. The four constants α, β, Y and ψ are constants of the line, independent of the load, and are expressed in terms of the ordinary line constants as follows: Let

f = frequency in cycles per second,

r = conductor resistance per mile, in ohms; see tables in article on *Wire and Cables, Bare*,

$x = 2\pi fL$ = conductor reactance per mile, in ohms, corresponding to the impressed frequency f; see tables in article on *Inductance and Inductive Reactance*,

$z = \sqrt{r^2 + x^2}$ = conductor impedance per mile, in ohms,

g = leakage conductance to neutral per mile of line, in micromhos; see above, p. 1667. For power lines g is usually taken equal to zero.

$b = 2\pi fC$ = capacity susceptance to neutral per mile of line, in micromhos, corresponding to the impressed frequency f; see tables in article on *Capacity and Charging Current*,

$y = \sqrt{g^2 + b^2}$ = dielectric admittance per mile, in micromhos; when $g = 0$, then $y = b$,

$\alpha = 10^{-3}\sqrt{\dfrac{yz - bx + gr}{2}}$ = the attenuation constant; for r and g small compared with x and b this reduces to $\dfrac{10^{-3}}{2}\left(r\sqrt{\dfrac{C}{L}} + g\sqrt{\dfrac{L}{C}}\right)$.

$\beta = 10^{-3}\sqrt{\dfrac{yz + bx - gr}{2}}$ = the wave length constant; for r and g small respectively compared with x and b this reduces to $2\pi f \times 10^{-3}\sqrt{LC}$, which for an overhead line equals approximately $\dfrac{2\pi f}{180{,}000}$,

$Y = 10^{-3}\sqrt{\dfrac{y}{z}}$ = surge admittance; for r and g small respectively compared with x and b, this reduces to $10^{-3}\sqrt{\dfrac{C}{L}}$. The reciprocal of the surge admittance is called the "surge impedance,"

$\psi = \tan^{-1}\sqrt{\dfrac{yz - bx - rg}{yz + bx + rg}}$ = the power-factor angle of the surge admittance, taken positive for $gx < br$ and negative for $gx > br$. For r and g small compared with x and b, then $\psi = 28.7\left(\dfrac{r}{x} - \dfrac{g}{b}\right)$ degrees.

$U = \dfrac{2\pi f}{\beta}$ = velocity of propagation in miles per second; for a frequency sufficiently high to make r negligible compared with x, and g negligible compared with b, this reduces to $\dfrac{10^3}{\sqrt{LC}}$, which for an overhead line with wires far apart is equal to the velocity of light in air, viz., 180,000 miles per second, approximately,

$\lambda = \dfrac{2\pi}{\beta} = \dfrac{U}{f}$ = wave length of each wave in miles; for a frequency f sufficiently high to make r negligible compared with x, and g negligible

compared with b, this reduces to $\frac{10^5}{f\sqrt{LC}}$, which for an overhead line is equal approximately to $\frac{180{,}000}{f}$ miles.*

a the vector diagram and in the formulas given below, let

l = length of the line in miles,
I = effective (r.m.s.) value of the amperes per wire at the load end,
V = effective (r.m.s.) value of the volts to neutral at the load end,
ϕ = the power-factor angle at the load end, i.e., $\cos\phi$ is the power factor at the load end. ϕ is taken positive for a lagging and negative for a leading current,
I_0, V_0, ϕ_0 = corresponding quantities at the generator end.

Solution by Vector Diagram (Fig. 7a). — Having calculated the constants α, β, Y and ψ, and knowing the current I, voltage V and power-factor le ϕ of the load,

Lay off $\overline{MN} = I$ as the base line, and bisect it at G,

At the angle $(\phi + \psi)$ ahead of $\overline{MN}$ lay off the line $\overline{HK}$ equal in length to YV, so that it is also bisected by G,

Then measure off $\overline{MK} = A$ and $\overline{MH} = B$,

Lay off at the angle 57.3 βl degrees ahead of A the line $\overline{MK_0}$ equal in length† to $Ae^{\alpha l}$,

Lay off at the angle 57.3 βl degrees behind B the line $\overline{MH_0}$ equal in length to $Be^{-\alpha l}$,

Bisect H_0K_0 at G_0.

Then the line $\overline{MN_0} = 2\,\overline{MG_0}$ is equal to the current at the generator end,

The line $\overline{H_0K_0}$ divided by Y is equal to the voltage at the generator end,

The angle between $\overline{G_0N_0}$ and $\overline{G_0K_0}$ less the angle ψ is the power-factor angle at the generator end.

Note that the voltage at the load end if drawn in the diagram would be at angle ψ behind the vector $\overline{GK}$, and at the generator end would be at the le ψ behind $G_0\overline{K_0}$.

Algebraic Solution for Steady-state Conditions. — The vector diam may be solved algebraically as follows: Calculate first the constants A, nd θ from the formulas:

$$A = \tfrac{1}{2}\sqrt{I^2 + (YV)^2 + 2\,YVI\cos(\phi+\psi)}, \tag{61}$$

$$B = \tfrac{1}{2}\sqrt{I^2 + (YV)^2 - 2\,YVI\cos(\phi+\psi)}, \tag{62}$$

$$\theta = \tan^{-1}\left[\frac{2\,YVI\sin(\phi+\psi)}{I^2 - (YV)^2}\right]. \tag{63}$$

te that $\sin\theta$ has the same algebraic sign as the numerator of this fraction l $\cos\theta$ his the same algebraic sign as the denominator of this fraction; this s the quadrant in which θ lies.

Put $$A_0 = Ae^{\alpha l}, \quad \text{and} \quad B_0 = Be^{-\alpha l}. \tag{64}$$

* The above formulas for s, y, α, β, Y, ψ, U and λ also hold for the transient or free illations in a single circuit, and also for each section of a composite circuit, provided hese formulas $r_1 = r\,(u - s)\,L$ is substituted for r and $g_1 = g + (u - s)\,C$ is substied for g.

† See the table in the article on *Exponential Functions* for values of e^x and e^{-x}, where x any number.

Digitized by Google

The current, voltage and power-factor angle at the generator end are, then, expressing all angles in degrees,

$$I_0 = \sqrt{A^2 + B^2 + 2AB\cos(114.6\beta l + \theta)},$$

$$V_0 = \frac{1}{Y}\sqrt{A^2 + B^2 - 2AB\cos(114.6\beta l + \theta)},$$

$$\phi_0 = \tan^{-1}\left[\frac{2AB\sin(114.6\beta l + \theta)}{A^2 - B^2}\right] - \psi.$$

Note that the quadrant in which $(\phi_0 + \psi)$ lies is determined by the algebraic signs of the numerator and denominator of the fraction in the brackets, just as in the case of the angle θ.

Solution of Steady State Conditions in Terms of Hyperbolic Functions.[1] — The above expressions for the current, voltage and power factor at the generator may also be put in the form,

$$I_0 = I\sqrt{\frac{\cosh(2\alpha l + \gamma) + \cos(114.6\beta l + \theta)}{\cosh\gamma + \cos\theta}},$$

$$V_0 = V\sqrt{\frac{\cosh(2\alpha l + \gamma) - \cos(114.6\beta l + \theta)}{\cosh\gamma - \cos\theta}},$$

$$\phi_0 = \tan^{-1}\left[\frac{\sin(114.6\beta l + \theta)}{\sinh(2\alpha l + \gamma)}\right] - \psi,$$

where θ and γ are given by the formulas

$$\gamma = \tanh^{-1}\left[\frac{2YVI\cos(\phi + \psi)}{I^2 + (YV)^2}\right],$$

$$\theta = \tan^{-1}\left[\frac{2YVI\sin(\phi + \psi)}{I^2 - (YV)^2}\right].$$

The other quantities are as above defined. Note that θ is the same angle as given by equation (63) and the quadrant in which it lies is to be determined as described in the note under (63). Also note that the constant γ given by (71) may be expressed in terms of A and B, given by (61) and (64), by means of the formula

$$\gamma = \log_e\left(\frac{A}{B}\right) = 2.302\log_{10}\left(\frac{A}{B}\right).$$

Formulas for Open Circuit and Short Circuit at Load End. — When the line is open at the load end, $I = 0$, whence from equations (61) to (63), $A = \frac{1}{2}VY$, $B = \frac{1}{2}VY$, and $\theta = 180°$ (since the denominator of the fraction is negative). When the line is short-circuited at the load end, $V = 0$, and $A = \frac{1}{2}I$, $B = \frac{1}{2}I$, and $\theta = 0°$ (since the denominator of the fraction is positive). The current, voltage and power-factor angle at any point along the line may then be found in either case by substituting these values in equations (65) to (67) which reduce to the simple hyperbolic forms:

On open circuit	On short circuit
$I_0 = YV\sqrt{\sinh^2(\alpha l) + \sin^2(57.3\beta l)}$	$I_0 = I\sqrt{1 + \sinh^2(\alpha l) - \sin^2(57.3\beta l)}$
$V_0 = V\sqrt{1 + \sinh^2(\alpha l) - \sin^2(57.3\beta l)}$	$V_0 = \frac{I}{Y}\sqrt{\sinh^2(\alpha l) + \sin^2(57.3\beta l)}$
$\phi_0 = -\tan^{-1}\left[\frac{\sin(114.6\beta l)}{\sinh(2\alpha l)}\right] - \psi$	$\phi_0 = +\tan^{-1}\left[\frac{\sin(114.6\beta l)}{\sinh(2\alpha l)}\right] - \psi$

[1] Tables of hyperbolic functions are given in the article on *Hyperbolic Functions*.

Digitized by Google

lution of Steady-state Equations in Complex Hyperbolic Functions.* — all quantities other than the length l in symbolic notation (*see Alternating* the equations of the transmission line for *steady state conditions only*, may

$$\dot{I}_0 = \dot{I} \frac{\sinh (l\sqrt{\dot{y}\dot{z}} + \dot{B})}{\sinh \dot{B}}, \tag{74}$$

$$\dot{V}_0 = \dot{V} \frac{\cosh (l\sqrt{\dot{y}\dot{z}} + \dot{B})}{\cosh \dot{B}}, \tag{75}$$

ymbols other than $\dot{B}$ have the same meanings as above, except that they are l as complex quantities and

$$\dot{B} = \tanh^{-1} \left(\frac{\dot{I}}{\dot{V}} \sqrt{\frac{\dot{z}}{\dot{y}}} \right) \tag{76}$$

t of $\sqrt{\dot{y}\dot{z}}$ is the attenuation constant and the imaginary or "j" part is the constant.

rously Equivalent "T" and "π" Circuits. — As noted above the middle "T" circuit, Fig. 5, or the split condenser or "π" circuit, Fig. 6, is rigorously the actual transmission line when proper values are assigned to the constants nits. The corrected values z' and y' of the impedance per mile and of the er mile are, in symbolic notation, as follows:

"T" circuit	"π" circuit
$\dot{z}' = \dot{z} \dfrac{\tanh \left(\frac{l\sqrt{\dot{y}\dot{z}}}{2} \right)}{\frac{l\sqrt{\dot{y}\dot{z}}}{2}}$	$\dot{z}' = \dot{z} \dfrac{\sinh (l\sqrt{\dot{y}\dot{z}})}{l\sqrt{\dot{y}\dot{z}}}$
$\dot{y}' = \dot{y} \dfrac{\sinh (l\sqrt{\dot{y}\dot{z}})}{l\sqrt{\dot{y}\dot{z}}}$	$\dot{y}' = \dot{y} \dfrac{\tanh \left(\frac{l\sqrt{\dot{y}\dot{z}}}{2} \right)}{\frac{l\sqrt{\dot{y}\dot{z}}}{2}}$

ly's tables above referred to are given tables of these correction fractions.

S AFFECTING THE MECHANICAL DESIGN. — In design- ssion line the following factors, in addition to the line losses, must l: (1) right-of-way, (2) telephone circuits, (3) ground wires, (4) ;) type of supporting structure, (6) type of insulators, (7) con- emperature range, (9) collection of ice, (10) wind velocity and wind ie requirements imposed by these several conditions are noted be- ler mentioned; this is followed by the formulas and curves neces- the required calculations.

ınd Width of Right-of-way. — The right-of-way should be as straight as practicable. Its width for a single line should be equal of space over which the conductors normally hang, plus twice the conductors under maximum wind, plus twice the safe clearance or to possible buildings adjacent to the right-of-way. In com- e swing allowance must be made for swing of suspension insula- ing of conductor should be based on the longest span ordinarily

bles and charts of such functions have been published by Prof. A. E. Ken- *Complex Hyperbolic and Circular Functions*, Harvard University Press,

Digitized by Google

used, and extra width should be secured wherever extraordinarily long spans are made. For telephone lines on separate poles extra width will be required unless the power wires are high enough to swing safely over them. Where two power lines are on one right-of-way the towers for the two lines should be located directly opposite each other, especially on long spans, since the two lines may then be placed close together with less danger of the wires of the two lines swinging together. However, it is usually desirable to have the lines far enough apart so that the towers of one line may fall without striking those of the other line. The right-of-way should be passable (or at least accessible) for patrolling as well as for construction.

When it is necessary that the right-of-way cross railroads, roads or other lines the length of crossing should be reduced to a minimum by making the crossing at as near right angles as practicable. Rights-of-way through swamps often require expensive road building and expensive tower foundations, though small swamps (up to about 1000 feet across) can often be crossed in a single span. Steep side hills require extra expense for foundations and tower extensions, and introduce a hazard of injury to tower from sliding earth, rocks, trees or snow. A right-of-way through forests requires expensive clearing.

It is usually advantageous to own and fence the right-of-way. However, when the right-of-way passes through farm lands, it is sometimes advantageous not to fence it in, but to have it cultivated and kept free from brush. Instead of purchasing a right-of-way, it is often sufficient to obtain easements covering the location of towers and suspension of wires. Easements should include the right to remove and trim trees under and adjacent to the line.

Telephone Circuits for Power Lines. — When the line voltage does not exceed 66,000 volts, the telephone circuits are usually carried on the same poles or towers as the power circuits, being placed below the power conductors. A separate line of wooden poles on the same right-of-way is usually employed when the voltage is higher than 66,000.

Where the telephone wires are on the same supporting structure as the power wires, sufficient clearance between the power and telephone circuits must be allowed to make the telephone line accessible for repairs and also to prevent the two circuits touching under abnormal conditions. On wood pole lines of short span (100 to 125 feet) the vertical clearance at the poles or towers ranges from 4 feet for 22,000 volts to 6 feet for 66,000 volts. On long span lines greater spacing is necessary to allow for safe clearance in the middle of the longest span due to the change in the sag of the power and telephone wires under all conditions of unequal ice loading and all variations of side deflection due to wind.

Telephone wires are ordinarily of copper, though copper-clad steel is sometimes used for long spans. For spans up to 125 feet No. 10 B. & S. copper may be used (though No. 8 is preferable) while for longer spans larger sizes (usually No. 8 or No. 6 or even No. 4) are necessary to allow for sleet load. A spacing of 12 inches between wires may be used for 125-foot spans, but a wider spacing is necessary for longer spans. Where inadequate spacing is used the telephone lines will frequently become crossed by the wind, unless they are strung with little sag, in which case they are overloaded and broken by sleet. With wide spacing and large sag higher poles must be used.

Ground Wires. — Grounded cables or wires are placed above the transmission line circuits to protect the latter from lightning discharges (*see Lightning Protectors*). They are usually grounded at each supporting structure except where short spans are used. The same care must be exercised to obtain clearances between conductors and ground cables or wires, as outlined above under telephone circuits. For tower lines having flexible towers and single-circuit towers having conductors arranged in a horizontal plane, two ground cables are

Digitized by Google

le, but for double-circuit tower lines either one or two may be used. As l rule a line drawn through the ground cable and any conductor should : an angle of more than 45 degrees with the vertical.

nces. — The following clearances require determination: conductor d; to edge of right-of-way; to tower; to ground wire; to telephone other conductors.

inimum clearance from the high-voltage wires to the surface of the ordinarily 20 feet or more, and from the telephone wires on towers igh-voltage wires is 18 feet to ground. The minimum clearance from to the edge of the right-of-way or to the tower, under maximum swing ors and cables in the wind, should exceed the striking distance corre- to the arc-over voltage of the insulators used. The minimum clear- een conductors, under extreme conditions of unequal ice loading (*see* uld exceed the striking distance of the normal voltage by a factor of at least two. The normal clearance between conductors should be ter than this, and is ordinarily from 10 inches to 1 foot per 10,000 volts ires.

Supporting Structure. — (*See also Poles for Overhead Lines; Cross ms.*) Wood poles are usually the cheapest form of supporting r lines up to about 66,000 volts. Most lines of voltage over 66,000 ines of lower voltage are supported on steel towers.

line of poles or towers may support one, two and occasionally more Where several circuits are required two or more single-circuit tower conductors arranged in a horizontal plane have the advantage that of an accident will usually be confined to one circuit, and that one safely be repaired with another circuit alive, but this arrangement maximum width of right-of-way. Where it is important to use the economically two-circuit towers having the conductors of each cir- d in vertical planes on each side of the tower are used.

es are ordinarily placed from 100 to 200 feet apart and steel towers 800 feet apart. The span for steel tower lines is ordinarily chosen ler the sum of the costs of all of the items a minimum, and is usually within the limits mentioned.

or towers ordinarily used where the line is straight are designed to ight of the conductors with sleet and the side pressure of wind on ot to resist the tension in the conductors which is assumed to be rtially balanced. Such towers are called standard, straight line l towers. Heavier towers designed to resist the unbalanced tension ables (which may occur if the cables are broken on the other side of called anchor or dead-end towers, are used at intervals of from pans where the line is straight. Heavier towers designed to resist ed lateral resultant of the tension in the cables are also used at re known as angle towers. For economy in design and manufac- and angle towers (for any angle up to about 60°) are usually made ble. Where towers are not very high, economy is often secured by towers intermediate between square anchor and angle towers. On nes extra strong poles guyed or braced in all four directions, with arms and double pins and insulators, are used for anchoring the line

nsulators. — (*See also Insulators.*) Pin insulators are usually used p to 50,000 and suspension insulators for higher voltages. Suspen- s are sometimes used for lower voltage where a high factor of safety or the lower voltages the cost of the line is usually less for pin than n insulators. The suspension insulator requires a higher tower

than the pin insulator, for the conductor is below the cross arm, and a longe cross arm is also required to allow for the swing of the insulators in the wind

Conductors for Overhead Lines. — (*See also Wires and Cables.*) Copper, aluminum or steel, or combinations of the two former with steel, are used for line conductors. The use of an all-steel conductor is limited to those cases where great mechanical strength is required, although some economy is claimed for it when high voltages are used and a conductor of large diameter is required on account of corona (*see Corona*). Conductors consisting of a steel center with copper or aluminum outside are used where long spans are desirable and mechanical strength of conductor is required, and may also be used where large diameter is required to prevent corona formation. The maximum stress in wires and cables should not exceed the elastic limit. This condition is ordinarily met if a factor of safety of two, based on the ultimate strength, is used.

Distribution of Stress in Stranded Conductors. — Conductors for long spans are usually stranded when larger than No. 6 B. & S. gage, on account of the tendency to crystallize at the points of support, due to swinging in the wind. However, the maximum size of solid conductor which may be used is dependent largely upon the kind of support; if these are designed to prevent sharp bending, solid conductors, larger than No. 6, may be used. One difficulty in the use of a stranded cable is that for a given total tension in the cable the wires in the various layers are not all stressed equally. In particular, the center wire or core, if of metal, takes more than its share of the tension. On this account the actual sag in the cable when suspended may differ from that calculated, unless an allowance is made for the unequal tension in the various wires composing the cable. One method of avoiding this difficulty is to stress the cable, before stringing it, to a tension per square inch corresponding to the elastic limit of the component wires; the center wire will then be given a permanent set and when the cable is again stressed each of the component wires will tend to take the same proportion of the total tension.

Cables having centers or cores of a different material than the outside strands should be so designed that both materials share the stress over the operating range of temperatures, to such extent as is possible. The properties of steel-core aluminum cables and the method of considering stresses therein are given in the article on Wires and Cables, Bare.

The distribution of stress among the wires of which conductors may be composed applies more particularly to long spans where clearances are important and it is necessary to use small deflections compared to lengths of spans. For all ordinary construction, having spans of 500 to 600 feet or less, a very slight change in either thickness of ice or amount of wind pressure on the conductor will affect results as much as the error resulting from not taking into consideration the distribution of stresses in conductors.

Mechanical Characteristics of Conductor Materials. — For purposes of design both elastic limit and modulus of elasticity of cables should be obtained from tests on samples of the cables actually to be used, since errors in these materially affect the accuracy of the calculations of deflections in spans. The modulus of elasticity of cables varies widely with the number of wires and their pitch or lay in the different layers. Table I shows the values of these quantities and also of the other mechanical properties of conductors commonly used in design, when specific test results are not available. See also the articles on *Aluminum; Copper; Strength and Elasticity; Wires and Cables, Bare.*

Temperature Range. — The maximum and minimum air temperatures which have occurred in any locality for a period of years can be obtained from the records of the United States Weather Bureau, or from similar records for other countries. The minimum air temperature recorded (which may be as

me of the northern states) will be the minimum temperature ctor may be expected to reach. However, since the conduc- d to the direct rays of the sun, they will reach a maximum temper- e summer considerably in excess of the Weather Bureau records, ve the temperatures in the shade.

ther important temperature which should be determined is that of the when coated with ice. As noted below, a sleet storm is usually followed by ll in temperature, and although the ice forms at 32° F., the wire may reach uch lower temperature while the ice is on it.

The following temperature ranges have been used in the design of certain es:

	Maximum	Minimum
Eastern Canada	+ 120° F.	− 40° F.
Mississippi Valley	+ 120° F.	− 20° F.
Southern California	+ 140° F.	+ 10° F.

Collection of Ice on Wires. — Investigation of the records of the Weather ureau leads to the conclusion that sleet and ice storms are generally followed by lling temperatures and high winds, and transmission lines should be designed meet these conditions. Records indicate that under favorable conditions ice d sleet will collect on wires and cables to the same amount in any climate where ezing temperatures are obtained. Mild, moderate and cold climates differ the frequency with which conditions are favorable. In general, sleet storms e most frequent in the moderate climates, since precipitation takes place more ten at freezing temperatures. Destructive sleet storms occur in the eastern art of the United States at least as far south as Atlanta. One-half inch ickness of solid ice on wires and cables is generally assumed in designing ansmission lines, but thicknesses of one-quarter and three-quarter inch are lso assumed in the more favorable and unfavorable localities.

Ice and sleet generally collect quite uniformly on wires throughout their ngth. The collection is sometimes in the form of icicles but more often is g-shaped in cross section, with the wire in the small end of the section. It equently falls off non-uniformly in sections.

Clear solid ice weighs 57 pounds per cubic foot or 0.033 pound per cubic inch, ut sleet or frozen snow such as often collects on wires weighs much less, some- imes as little as 8 pounds per cubic foot.

Digitized by Google

Effect of Surface and Electric Potential on Collection of Ice. — Local observations of single ice or sleet storms have shown that ice will sometimes collect on one wire or cable and not on an adjoining one. This has led to the conclusion that ice will not collect on certain kinds of wires, but more extensive observations indicate that ice will collect on any kind of wire under favorable conditions. Observations on wires carrying sufficient current to heat them and wires having potential near the critical corona voltage are not sufficiently extensive to warrant the conclusion that they will not collect ice and sleet.

Wind Velocity and Wind Pressure on Wires. — As noted in the article on *Wind Pressure*, the records of the United States Weather Bureau give nominal average velocities for five minute intervals, the true average velocities differing from the recorded velocities as follows:

Recorded velocity in miles per hour	10	20	30	40	50	60	70	80	90	100
Actual velocity in miles per hour	9.6	17.8	25.7	33.3	40.8	48.0	55.2	62.2	69.2	76.1

The Weather Bureau records give no indication of the "gust" velocities which may occur during the five minute periods, and which may greatly exceed the average velocity. Tests with a Dines pressure tube anemometer have shown that the extreme maximum is about 50 per cent greater than the average for short periods.

The extreme maximum wind velocity observed in Chicago in the whole thirty-six year period from 1873 to 1910 was 84 miles per hour (uncorrected) in February, 1894. A velocity of 76 miles per hour (uncorrected) was observed once in November, 1898, and a velocity of 72 miles per hour (uncorrected) was observed seven times. During the ten year period from 1894 to 1903 the maximum wind velocity in a few other representative localities was as follows, all velocities being the observed or uncorrected velocities: Bismark, N. D., 72; Eastport, Me., 78; Buffalo, N. Y., 90; New York City, N. Y., 78; Galveston, Tex., 84; Savannah, Ga., 76; Salt Lake City, Utah, 60. All the maxima range between 60 miles and 90 miles per hour.

The wind pressure on a cable is usually calculated from the formula

$$p = KV^2, \qquad (1)$$

where p is the pressure in pounds per square foot of the projected area of the cable (including sleet and insulation, if any), and V is the actual velocity of the wind in miles per hour blowing perpendicularly across the span. The projected area, in square feet, of a one-foot length of cable is equal to the over-all diameter in inches divided by 12, where by over-all diameter is meant the diameter over the ice and insulation, if any. Buck's formula (*see article on Wind Pressure*) gives a value of 0.0025 for the constant K, whereas a value of 0.002 derived from the work of the Weather Bureau and experiments of Borda is also used.

Maximum Loading. — There is considerable difference of opinion as to what should be taken as the maximum loading in designing a transmission line. The Committee on Overhead Line Construction of the N.E.L.A. have proposed three different loadings, viz.: (A) No ice and a wind pressure of 15 pounds per square foot; (B) ice ½-inch thick and a wind pressure of 8 pounds per square foot; and (C) ice ¾-inch thick and a wind pressure of 11 pounds per square foot. Class B loading gives greater stress than Class A loading for all sizes of wire in use. The difference is greatest for small sizes.

Several important lines have been designed on the assumption of a maximum loading of ½ inch of ice and wind pressure at 6 pounds per square foot, the temperature corresponding to this loading being taken as 0° F. In these same lines the clearance under unequal loadings was calculated on the assumption of five

Digitized by Google

s between anchor towers, with no ice on the third span of the lower con-
or, and no ice on the first, second, fourth and fifth spans of the upper
uctor, but with a loading of ¼ inch of ice on all other spans the tempera-
being taken as 32° F. and no wind assumed.

ERTICAL AND TRANSVERSE FORCES ON A SUSPENDED LE. — The resultant force acting on one foot of a suspended wire is in gen-
made up of three components, viz.:

= weight of the conductor (including insulation, if any) per foot length, in pounds;
= weight of the ice coating per foot length of the conductor, in pounds;
= wind pressure per foot length of the conductor, in pounds.

weight of the conductor per foot length may be taken directly from the es in the articles on *Wires and Cables, Bare*, as can also the diameter of the luctor (over the insulation, if any). Let d be this diameter in inches and let the thickness of the ice coating, then the weight of the ice coating per foot th of the conductor is

$$i = 1.24\, t\,(d + t). \tag{2}$$

p be the wind pressure per square foot of projected area, assumed or calcu-d from equation (1); then the wind pressure per foot length of the conductor, the horizontal component of the resultant force, is

$$h = \frac{p\,(d + 2t)}{12}. \tag{3}$$

vertical component of the resultant force per foot length of conductor, which qual to the resultant force for no wind, is

$$v = c + i. \tag{4}$$

lues of v and h for various ice thicknesses and various sizes of wires are given Table II. The values of h are given in the table for a wind pressure of 10 unds per square foot; these values of h are designated h_0; for any other wind ssure of say p pounds multiply these values by $\frac{p}{10}$. Knowing v and h the ultant force w for any combination of wind and ice loads is readily determined the formula

$$w = \sqrt{v^2 + h^2}. \tag{5}$$

Digitized by Google

TABLE II. VERTICAL AND HORIZONTAL LOADING FORCES*

Pounds per Foot of Conductor

The horizontal component h_0 is given for a wind pressure of 10 lb. per s., for any other wind pressure of p lb. per sq. ft., $h = \frac{ph_0}{10}$.

The resultant force for any ice thickness and wind pressure is $w = \sqrt{v^2 + h^2}$

CALCULATION OF SAG AND TENSION. — A wire or cable suspend between towers takes the form of a catenary curve. In transmission line pr tice the maximum deflection or sag is always small compared to the span, th is, the curve is very flat. The shape of such a flat catenary curve does not di appreciably from a parabola and, as the approximate parabolic formulas much simpler than the more exact catenary formulas, they are used inste The flatness of the curve allows of some further simplifications even in the p bolic formulas, viz., (1) the tension is considered uniform throughout the the slight excess of tension at the ends over that at middle being neglected, the change of length of the wire due to elastic stretch or temperature expan is taken as equal to the change of length of a wire equal in length to the h zontal distance between the points of support.

Notation Used in Sag-tension Formulas. — The following notation, alphabetically, will be used throughout the discussion of sag and tension

A = cross section of the conductor (actual metal cross section) in circ inches = square of diameter in inches; 1 circular inch = 1,000 circular mils.

a = coefficient of linear expansion of the conductor per ° F.; see Table above.

D = deflection, in feet, of the lowest point of the conductor when suspend from two points of support at the same elevation and at a distance apart. (D is measured in the direction of the resultant transv force.)

e = difference in elevation of the two points of support, in feet.

F = longitudinal horizontal component of the stress in the conductor, pounds. (The resultant stress in the wire at the insulator is equal $\sqrt{F^2 + H^2 + V^2}$, where V is the weight of the conductor and ice fr the insulator to the lowest point of the span, and H is the total w pressure on half the length of span; H and V in this expression usually negligible compared with F.)

h = wind pressure in pounds per foot length of conductor assumed perpe dicular to the vertical plane through the two points of support. s equation (3) and Table II above.

L = length of span in feet, i.e., the horizontal distance between the two post of support in feet.

l = length in feet of the arc of the curve in which the conductor hangs, i the length of stretched conductor between the two points of suppor

M = modulus of elasticity of the conductor in pound-inch units; see Table above.

$S = \frac{vD}{w}$ = sag of the lowest point of the conductor below the horizontal lin through the lower point of support; for no wind $S = D$.

T_0 = maximum allowable tension in the conductor in pounds per square inch of its cross section; T_0 is usually taken as one-half the ultimate strength of the conductor; see Table I.

v = vertical force in pounds on a one-foot length of the conductor, including the weight of conductor and the weight of the ice, if any, on it; s equation (4) and Table II above.

$w = \sqrt{v^2 + h^2}$ = resultant load in pounds on a one-foot length of the con ductor.

$Z = \frac{hD}{w}$ = side swing, in feet, of the middle point of the conductor, measured perpendicularly to the vertical plane through the two points of support.

mental Equations of a Wire Span. — As noted above, a perfectly
ire suspended between two points of support hangs in a catenary.
mption that the wire hangs in a parabola instead of in a catenary is
y accurate for all practical calculations of wire spans, the error in the
ated on this assumption being less than 2 per cent of its true value
sag is less than 0.06 times the length of the span (e.g., less than 60 feet
-foot span), and the error in the length of the wire calculated on this
n being less than 0.002 per cent of its true value for the same limiting
. The formulas given below are all based on the assumption of a

flection, Sag and Side Swing. — For a given length of span L,
and stress F, the deflection D for the points of support at the same
s given by the relation

$$D = \frac{wL^2}{8F}. \tag{6}$$

e is no wind this is also equal to the vertical sag, that is $S = D$. When
nd, w is greater than the vertical loading v, and the vertical sag for the
upport at the same elevation is

$$S = \frac{vD}{w} = \frac{vL^2}{8F}. \tag{7}$$

ion (7) has the value given by equation (6). When one point of
at an elevation e above the other, then the vertical sag of the lowest
e conductor below the lower point of support is

$$S' = S\left(1 - \frac{e}{4S}\right)^2, \tag{8}$$

given by equation (7). The horizontal distance of the lowest point
luctor from the lower point of support is

$$L' = \frac{L}{2}\left(1 - \frac{e}{4S}\right). \tag{9}$$

swing Z of the middle point of the conductor, which is the point
flected the maximum distance from the vertical plane through the
of support, is

$$Z = \frac{hD}{w} = \frac{hL^2}{8F}. \tag{10}$$

on (10) has the value given by equation (6).

th of Stretched Conductor. — The length of conductor between
nts of support for a given length of span L, loading w, stress F and
elevation e, is

$$l = L + \frac{8}{3}\frac{D^2}{L} + \frac{e^2}{2L}, \tag{11}$$

the value given by equation (6), that is, D is the deflection for the
of span, loading and tension, but for the points of support at the
on.

Digitized by Google

Effect of Changes in Loading and Temperature. — When the loading or the temperature changes, the stress in the conductor will change to some new value, F_0 say, and the deflection will change to some new value, say D. Let the new loading be w_0 and the new temperature be t_0, the initial temperature being t; also let a be the coefficient of linear expansion, M the modulus of elasticity, and A the cross section of the conductor in millions of circular mils. Then, when the points of support remain fixed, the following relation must hold

$$\frac{8}{3L^2}(D^2 - D_0^2) = a(t - t_0) + \frac{1.273}{MA}(F - F_0).$$

The D's in this equation are the same as given by equation (6) for a loading w and w_0 respectively and stresses of F and F_0 respectively. Note that equation (12) is independent of the difference in elevation of the two points of support; also that the two sets of symbols, with and without the subscripts, refer to *any* two sets of conditions.

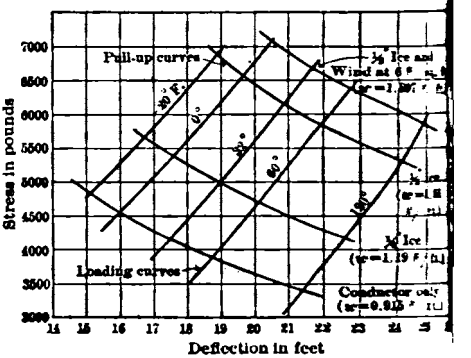

Fig. 8. Stress-Deflection Chart for a 300,000-Circular-Mil 19-Strand Copper Conductor on an 800-ft. Span

Stress - Deflection Charts (Fig. 8). — In order to apply the above equations to the calculation of clearances under various conditions equation (6), namely

$$D = \frac{wL^2}{8F}, \qquad (13)$$

and equation (12), which may be written

$$F = F_0 - \frac{2.10\,MA}{L^2}D_0^2 - \frac{MAa}{1.273}(t - t_0) + \frac{2.10\,MA}{L^2}D^2, \qquad (14)$$

may be plotted for any given length of span as shown in Fig. 8, with deflection D as abscissas and the stress F as ordinates.

Pull-up Curves. — The curves representing the relation between D and F in equation (13) are equilateral hyperbolas, as many of these curves being drawn as there are loadings to be considered. These hyperbolas may be called "pull-up" curves, since they give the stress to which the wire must be pulled up for any given deflection. In Fig. 8 four pull-up curves are shown, one for the conductor only ($w = 0.915$), conductor coated with ¼ inch of ice but no wind ($w = 1.19$), conductor coated with ½ inch of ice but no wind ($w = 1.61$), and conductor coated with ½ inch of ice and a wind pressure of 6 pounds per foot of projected area of wire ($w = 1.807$), this last being taken as the maximum loading.

Loading Curves. — The curves representing the relation between D and F in equation (14) are parabolas with vertical axes, as many of these curves being drawn as there are temperatures to be considered. These parabolas may be called "loading curves," since for a change in loading (at constant temperature) they give the relation which must exist between the new stress and new deflection produced. In order to plot these curves it is necessary to assume a maximum allowable tension, say T_0 pounds per square inch, a maximum load-

Digitized by Google

d the minimum temperature t_0 at which this loading is assumed to ten

$$F_0 = \frac{AT_0}{1.273} \qquad \text{and} \qquad D_0 = \frac{w_0 L^2}{8 F_0},$$

r given temperature t all the terms in the right-hand member of (14) its except the last term, which varies as D^2. In Fig. 8 the maximum ension T_0 is taken as 30,000 pounds per square inch, the maximum is 1.807 pounds per foot length, and the minimum temperature under oading as 0° F. Then $F_0 = 7065$ pounds and $D_0 = 20.5$, which fixes n the 0° loading curve, and the other points on this curve are calcu- ly from (14) by putting $t = 0$. For any other temperature, equation he same shaped parabola as for 0°, but each point of the curve is ically downward a distance $\frac{MAa}{1.273}$ for each degree increase of tempera- e it is only necessary to calculate the 0° loading curve, and the load- r any other temperature can be readily plotted by the use of a pair

Stresses and Deflections. — In stringing cable it is essential that deflection be correct for the stringing temperature, otherwise the tress will be safe or the ground less ue to maxi- tion exceed- ned amount. oper string- of tempera- d tempera- are plotted ss-deflection se curves are and no ice. such curves -foot span Fig. 8. from equation (13) there results a cubic equation in D. This cubic equation can be solved directly by means of Tables III and IV given herewith. (Pender, *Electrical World, Vol. 66, p. 344, 1015.*) The procedure is as follows: using the same notation as above, calculate,

$$b_1 = \frac{1273\,F_0}{MA},$$

$$b_3 = \left(\frac{w_0 L}{0.155\,F_0}\right)^2,$$

$$b_2 = 1000\,a(t - t_0),$$

$$b = \frac{1273\,wL}{MA},$$

B = numerical value of $[b_1 - (b_2 + b_3)]$,

$$x = \frac{b}{B\sqrt{B}}$$

ke y from table.

en the deflection is

$$D = yL\sqrt{B},$$

the stress is,

$$F = \frac{wL^2}{8D}.$$

ote that b_1 may be greater or less than (b_2+b_3); in either case B is to be n *positive* and equal to the numerical value of $b_1-(b_2+b_3)$. Also note that is the elongation, in feet per 1000 feet, of a straight wire when subjected stress of F_0 pounds.

is the number of feet per 1000 feet of wire, by which the length of the wire degrees and loading w_0 exceeds the horizontal distance between the points ipport (when these are at the same elevation).

is the elongation, in feet per 1000 feet of wire, due solely to a change in perature from t_0 to t degrees.

Digitized by Google

b is the elongation, in feet per 1000 feet of wire, due to a stress equal wL (= its own weight plus the total ice and wind, if any, at the temperature

Example. — To find the sag at which a No. 0 B. & S. stranded copp wire must be strung at 60° F. on a 400-ft. span so that the wire will have a fac of safety of two at 0° F. when loaded with ice 0.5 in. thick all around the w and with a wind pressure of 8 lb. per square foot of projected area. The brea ing strength of the wire is 4980 lb., cross-section 105,500 circ. mils, modulus elasticity 16×10^6, and coefficient of expansion 9.6×10^{-6}.

The data and calculations are then as follows:

$$F_0 = 2490 \qquad M = 16\times10^6,$$

$$w = 0.323, \qquad L = 400.$$

$$w_0 = 1.26, \qquad t - t_0 = 60$$

$$A = 0.1055, \qquad a = 9.6\times10^{-6}.$$

Then

$$b_1 = \frac{1273\times2490}{16\times10^6\times0.1055} = 1.878,$$

$$b_2 = \left(\frac{1.26\times400}{0.0155\times2490}\right)^2 = 1.705,$$

$$b_3 = 1000\times9.6\times10^{-6}60 = 0.576,$$

$$b = \frac{1273\times0.323\times400}{16\times10^6\times0.1055} = 0.0975.$$

Noting that b_1 is less than (b_2+b_3),

$$B = 1.705+0.576-1.878 = 0.403,$$

$$x = \frac{0.0975}{0.403\sqrt{0.403}} = 0.382,$$

and, from Table IV, $y = 0.0308$. Whence

$$D = 0.0308\times400\sqrt{0.403} = 7.82 \text{ ft.}$$

This is the sag at 60° F. with no ice or wind.

The sag at 0° F. with no ice or wind is found in exactly the same way, not that for these conditions $b_3 = 0$, and b_1 is greater than (b_2+b_3), giving for B value

$$1.878-1.705 = 0.173,$$

and for x the value

$$\frac{0.0975}{0.173\sqrt{0.173}} = 1.355,$$

and y from Table III is then 0.0367, and

$$D = 0.0367\times400\sqrt{0.173} = 6.10 \text{ ft.}$$

Stress and Deflection in Spans of Unequal Length. — By stringing cab according to the stress determined for each particular length of span, the main

owable tension will be reached in all spans under maximum loading s. Under other loading conditions the tension will be unequal where ths are not the same. This is shown in Fig. 10 which is plotted for the ditions as stated in the title of Fig 8, but for spans of from 600 to n length. Fig. 11 shows the corresponding deflections.

equal stresses on the two sides of the insulator will tend to bend the nsulator pin, but any motion of the point of support will tend to equalize es. When suspension insulators are used, the stresses are practically since the is free to should be t the motion ulator neces- equalize the small. When insulators the cable is strung at a orresponding erage length When the thus strung under min- perature and loading will ceed the as- sion in the ins and be be assumed the longer larly, under emperature the longer have a sag f the value on the as- f the maxi- ble tension

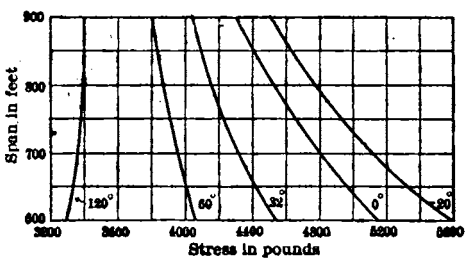

Fig. 10.

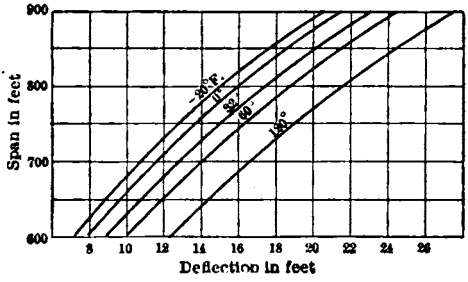

Fig. 11.

ed with maximum loading, and the shorter spans will have a sag ie calculated value. The actual stresses and deflections can be y the method given in the following section.

on of Stresses in Unequally Loaded Spans.* — When suspen- ors are used, any tendency of the stresses in two adjacent spans to qual will produce such a deflection of the insulator, in the direction with greater stress, as will establish equilibrium in the line. This irs will occur (1) when adjacent spans carry unequal ice loads, (2) re on one side of the insulator breaks, and (3) to a slight extent with mperature when the adjacent spans are unequal in length, as noted following method of calculating the "equilibrium" stresses in the orresponding sags is applicable to all cases of initially unbalanced spective of their cause. The method may also be used to calcu- ss and sag in spans supported on pin insulators, provided the mo- ling of the pin and of the pole or tower is known or can be calculated.

* From lecture notes by Dr. H. Pender.

Digitized by Google

Change of Stress Due to Change in Length of Span. — When the length L of the span (i.e., distance between points of support) increases by λ inches, due to a horizontal displacement of the insulators (without slipping of the wire), the stress in the wire is increased by the same amount as would be produced by a fall in temperature of

$$t - t' = \frac{\lambda}{12\,aL} \qquad \text{or} \qquad t' = t - \frac{\lambda}{12\,aL}, \tag{15}$$

degrees Fahrenheit, where t is the actual temperature and t' may be called the "equivalent" temperature corresponding to the change in length λ. In the equation λ is the actual increase in the distance between the points of support in inches, a the temperature coefficient of linear expansion per ° F., and L the original length of the span in feet. For example, in an 800-foot span of copper wire an increase of 1 inch in L corresponds to a drop of temperature of $1 \div (12 \times 9.6 \times 10^{-6} \times 800) = 10.85$ degrees, and an increase in length of λ inches corresponds to a drop of temperature of $t - t' = 10.85\,\lambda$ degrees.

Hence the stress-deflection chart for any given length of span, see Fig. 8, may be used directly to determine the stress in the wire after any change in the length of the span, due to the deflection of the insulator. For example, consider an 800-foot span of 300,000-circular-mil, bare, copper conductor, at 32° F., without ice or wind, initially stressed to 4170 pounds, and let the length of the span be increased 4 inches as the result of the deflection of the insulators by this amount. This increase in length of span will then give the same stress in the wire as would be produced if the temperature fell from 32° to $t' = 32 - 4 \times 10.85 = -11.4$°. The point at which the loading curve (Fig. 8) corresponding to a temperature of -11.4° crosses the pull-up curve for conductor only gives the new stress, viz., 4700 pounds.

Horizontal Pull of Insulator. — Referring to Fig. 12, let m = the horizontal distance in inches (measured along the span) which any insulator is deflected from the vertical, taken positive when to the right, say, and negative when to the left. Let x = the length of the insulator string in inches, i.e., distance from point of attachment to tower to point of attachment to wire. V = total weight of wire and ice between the lowest point of the wire in the span to the left of the insulator and the lowest point of the wire in the span to the right of the insulator plus one-half the weight of the insulator; H = total wind pressure on the length of wire between the middle points of the two adjacent spans, plus half the wind pressure on the insulator; and put $W = \sqrt{V^2 + H^2}$. Then the horizontal component of the pull of the insulator toward the left along the line of the span is *

$$P = \frac{m}{\sqrt{x^2 - m^2}} \cdot W. \tag{16}$$

For example, consider two adjacent spans of 300,000-circular-mil copper, each 800 feet long and with points of support at the same elevation. Let the span to the left be free of ice and let the one to the right have a ½-inch ice coating; assume the insulator to be 60 inches long and to weigh 100 pounds. Then for no wind $H = 0$, $V = 1.19 \times 400 + 0.915 \times 400 + 100/2 = 892$ pounds. Whence for deflections of the insulator of less than 12 inches the horizontal pull of the insulator is $P = (892 \times m) \div 60 = 14.9\,m$, or 14.9 pounds per inch deflection.

* When m is less than 10 per cent of x this may be written, with an error of less than 2 per cent,

$$P = \frac{m}{x} W. \tag{16a}$$

Digitized by Google

Stresses in a Series of Spans When Points of Support are not ed. — Referring to Fig. 12, let the left-hand end of span No. 1 be anchored, assume the insulator at the right-hand end to be deflected a horizontal dis-ce of m_1 inches, due, for example, to a change in the loading on the succeeding

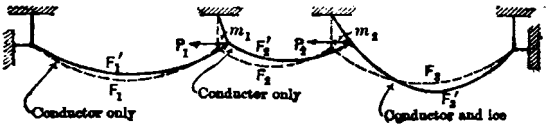

Fig. 12.

ns (or to a change in temperature when the spans are of unequal length). m equation (15) calculate the "equivalent" temperature t_1' corresponding this change in length, and from the pull-up curve in Fig. 8 corresponding assumed loading w_1 of this span find the stress on this curve corresponding a temperature of t_1' degrees; call this stress F_1'.

Next calculate the transverse and vertical loads on the insulator, viz., H_1 and and the resultant load $W_1 = \sqrt{V_1^2 + H_1^2}$, as explained in the preceding sec-n. Then from equation (16) or (16a) calculate the horizontal pull P_1 of the ulator. The stress in the second span, assuming the value of m_1 chosen at start is correct, must then be

$$F_2' = F_1' + P_1. \tag{17}$$

is then determined from F_2' on the pull-up curve. From equation (15) the responding increase in the length of span No. 2 must then be

$$\lambda_2 = 12\,aL_2\,(t - t_2'), \tag{18}$$

ere L_2 is the length of the second span. The corresponding deflection of the ulator at the right-hand end of span No. 2 must then be

$$m_2 = m_1 + \lambda_2, \tag{19}$$

rays taking the insulator deflection positive when to the right, say.

Using the values of λ_2 and m_2 thus found, calculate the λ_3 and m_3 in exactly e same manner as λ_2 and m_2 were calculated, and similarly for the succeeding ans until the next anchor tower is reached. For the anchor tower at the right-nd end of the n-th span, say, the deflection of the insulator must be zero, viz.,

$$m_n = 0. \tag{20}$$

m_n as calculated comes out greater than zero, then the assumed value of m_1 is o great; if m_n comes out less than zero the assumed value of m_1 is too small. y calculating m_n for two or three assumed values of m_1, and plotting m_n as dinates against m_1 as abscissas, the correct value of m_1 will be where this rve crosses the axis of abscissas. Using this correct value of m_1, the stresses d deflections in each span may then be accurately calculated by the process st given, using the Stress-Deflection Chart, Fig. 8. The complete process is st shown by an example.

Example. — Consider the case of three spans between anchor towers, ig. 12) all of the same length, 800 feet, and all supports at the same elevation, 0,000-circular-mil copper being used for the conductor. Let the temperature e 32° F., and let the middle span have a ¼-inch ice coating but the other two pans have no ice on them; also assume no wind. The Stress-Deflection Chart iven in Fig. 8 then applies directly, provided the wires are strung in accordance herewith. Assume that each insulator weighs 100 pounds and has a length of

Digitized by Google

60 inches. Then for an increase of λ inches in the length of any span, the "equivalent" temperature is, from equation (15),

$$t' = 32 - 10.85\lambda$$

or if the equivalent temperature rise t' is known

$$\lambda = 0.092\,(32 - t').$$

The horizontal pull of any insulator for a deflection of m inches (small compared with the length of the insulator) is, from equation (16a),

$$P = 14.9\,m.$$

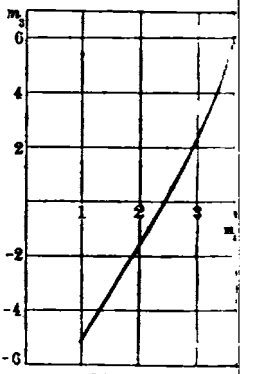

Fig. 13.

In the following table are given the calculations for assumed values of m_1 of 1, 2, 3 and 4 inches, and in Fig. 13 are plotted the corresponding calculated values of m_2 against m_1. It is seen that the relation between m_2 and m_1 is practically a straight line cutting the horizontal axis at $m_1 = 2.4$, which is therefore the correct value of m_1. The calculations for $m_1 = 2.4$ inches are given in the last column of the table. Hence the stresses and deflections in the two end spans (without ice) are $F_1' = F_3' = 4460$ pounds and $D_1' = D_3' = 16.3$ feet respectively, and the stress and deflection in the middle span loaded with ½-inch of ice are $F_2' = 4496$ pounds and $D_2' = 21.1$ feet respectively, the deflections being read directly from Fig. 8 corresponding to the proper stresses and loadings (w).

m_1	= assumed	1	2	3	4	2.4

LOCATION OF TOWERS AND DETERMINATION OF CLEARANCES.—The height of towers is determined so as to give some specified minimum clearance from conductor to ground for some length of span chosen as a nominal standard on the basis of level ground. In practice the ground is rarely level and the towers are actually located to conform to the irregularities of the ground. In locating towers of a given height the spans are made as long as possible consistent with maintaining the ground clearance. The irregularities of the ground are ordinarily advantageous and permit of slightly longer spans on the average than could be obtained with the same height of towers on level ground.

Digitized by Google

and Plan of Right-of-Way. — In order to locate towers properly sary to have a profile of the right-of-way. Profiles are conveniently standard ruled profile section paper to a vertical scale of 20 feet to the . horizontal scale of 200 feet to the inch. Three profiles are desirable, the center of the tower line and one on each side, say at each edge of ıy, as shown on Fig. 14 at *A*, *B* and *C*. The two side profiles indicate t and direction of the slope of the ground across the line, which must l for in determining ground clearance and foundation or tower

f the right-of-way is of course also necessary for determining the con- t angles in the line, and the clearances from the conductor to the edge ıt-of-way when the conductor is deflected horizontally by the wind. n is shown at the bottom of Fig. 14.

tes for Locating Towers. — Three templates are required, one for ırance with maximum sag, marked *M* in Fig. 14, one for uplift at inimum sag, marked *N*, and one for maximum side swing, marked *Z*. ut from thin celluloid and are to the same horizontal and vertical ed for the profile and plan of the right-of-way.

curvature of the catenary or parabola in which the wire hangs de- on the tension and loading and not on the length of the span or on ce in elevation of the points of support, all spans having the same l loading can be drawn (for any one predetermined scale) from a late, irrespective of their lengths or of the differences in elevation of of support. However, when the elevations of the points of support same, the lowest point of the curve is shifted from the middle of the l the lower support, but the axis of the curve remains vertical.

struction of Maximum Sag Template *M*. — The maximum sag ım the Stress-Deflection Chart, Fig. 8, and may be the deflection ıg to the maximum temperature, and conductor only, e.g., 21.4 feet may be the deflection corresponding to 32° F. and the maximum Wind will increase this deflection but will not increase the *vertical* S_m this maximum sag. Then the equation of the maximum sag template *M*, is

$$y = \left(\frac{4\,S_m}{L^2}\right) x^2, \qquad (21)$$

he length of the particular span for which the maximum sag is S_m, in of the curve is its lowest point and the axis of y is vertical; all ıre in feet. Three parabolic curves are given by this template; the presents the position of the cable and is drawn on the basis of the ı under the maximum load; the middle curve is a similar parabola pper curve a distance equal to the minimum allowable clearance to bottom curve is another similar parabola below the upper curve e equal to the height of cable above ground at the support.

truction of Minimum Sag Template *N*. — The minimum sag is rom the Stress-Deflection Chart, and is usually the deflection cor- o the minimum temperature and conductor only, e.g., 15.1 feet in l this sag S_n; then the equation of the minimum sag template, or is

$$y = \left(\frac{4\,S_n}{L^2}\right) x^2. \qquad (22)$$

truction of Maximum Side-swing Template *Z*. — The maxi- wing occurs at time of maximum wind pressure and may be at

Digitized by Google

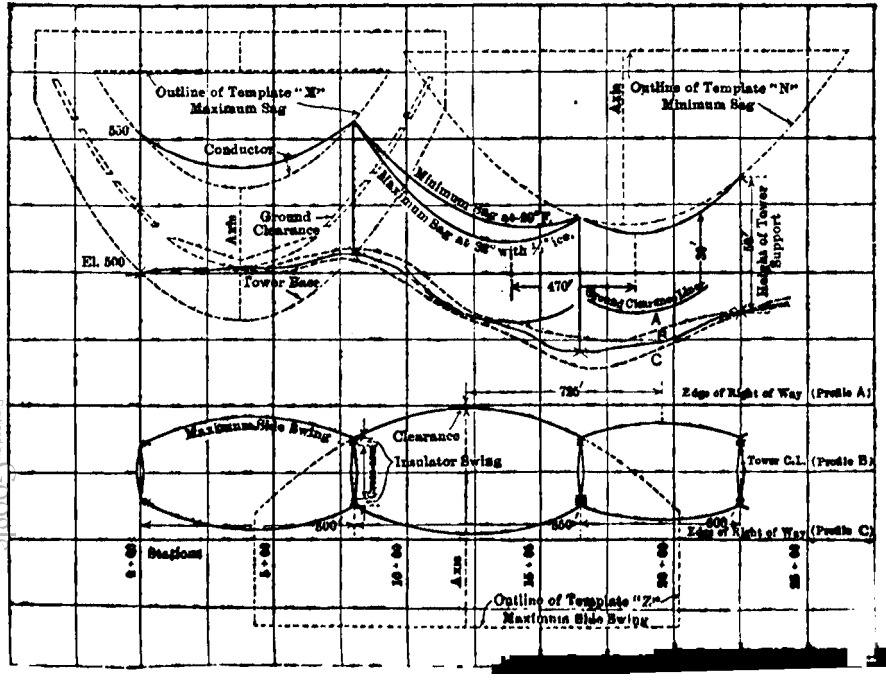

Fig. 14. Chart Showing Use of Templates in Locating Towers and Determining Clearances

imum temperature or may be at 32° F. when covered with ice. In the ter case the side swing depends on the shape (circular or elliptical) of the covering and its specific gravity. For a circular covering of solid ice one ·ular thickness (usually but not necessarily the maximum thickness) gives greatest side swing. For example, in Fig. 8, the maximum side swing occurs $D = 21.7$ and $w = 1.807$, and its value is, see equation (16), $Z = (0.815 \times 21.7)$ $1.807 = 9.8$ feet, 0.815 being the wind pressure per foot of wire. Calling the aximum side swing Z_m, then the equation of the side swing template, or tem- ate Z, is

$$y = \left(\frac{4\,Z_m}{L^2}\right)x^2. \qquad (23)$$

Locating Towers by Means of Template M. — Choose a starting point, as own for example in Fig. 14, at station 0 + 00, elevation 500.0 feet for the first wer location. The template M is then placed over the profile and shifted until axis is vertical and the lower curve is at station 0 + 00, elevation 500.0 feet, and e middle curve is tangent to the ground profile as shown. The proper loca- on for the second tower is at the point where the lower curve again intersects e ground profile, or at station 8 + 00, elevation 506.0 feet, in the example. ie operation is then repeated for the next tower. Adjustments in length of an are usually necessary to meet local conditions, in order to avoid locating wers in roads or swamps and to bring towers at angle points. Adjustments ich increase the ground clearance are of course allowable.

The position of the conductors with maximum sag may be drawn on the profile om the top curve of the template.

Uplift on Insulator; Use of Template N. — An insulator sustains the ight of the lengths of conductor from the insulator to the lowest point of the an on each side. If the conductor leaves the insulator horizontally on one le, the lowest point of that span is at the insulator, which then sustains no ight due to that span. If the conductor has an upward inclination where it ives an insulator, it is exerting an uplift equal to the weight of a length of nductor extending from the insulator along the span produced in the reverse rection to the lowest point of the parabola. Where the conductor has a down- ard inclination on one side and upward on the other side of the insulator, there ll be a weight or uplift on the insulator equal to the difference between the ight of conductor on one side and uplift on the other.

Suspension insulators when used hanging downward to sustain weight are capable of resisting uplift. Where uplift occurs the conductor may be dead ded or may be tied down or weighted down.

The method used for locating towers ordinarily precludes uplift under the ading which gives maximum sag, but uplift may occur when the loading is less.) determine this the minimum sag is drawn on the profile with template N. ie minimum sag curve is drawn between points of support, keeping the axis the parabola vertical as before.

Side Swing of Suspension Insulators. — Let l_1 = the length of conductor tween the lowest point in the span to the left of the insulator and the lowest int in the span to the right of the insulator, and let l_2 = the distance between e middle points of these two spans, both in feet. Also let v = the weight of e conductor and ice per foot length, and h = the wind pressure per foot length ee Table II). Then the vertical pull on the insulator is vl_1 and the transverse rizontal force is hl_2. Also let v_1 = the weight of the insulator and h_1 = the tal wind pressure on it. Then the insulator is deflected sidewise from the rtical by approximately the angle

$$\theta = \tan^{-1}\left[\frac{hl_2 + 0.5\,h_1}{vl_1 + 0.5\,v_1}\right]. \qquad (24)$$

Digitized by Google

Usually the weight of the insulator and the wind pressure on it are negligible compared with the weight and wind pressure on the conductor, in which case

$$\theta = \tan^{-1}\left(\frac{hl_2}{wl_1}\right). \tag{12a}$$

When the points of support are at the same elevation $l_1 = l_2$ and

$$\theta = \tan^{-1}\frac{h}{w}. \tag{12b}$$

Calling X the length of the insulator in feet then the transverse horizontal deflection of the insulator is $X \sin \theta$ feet.

For example, consider the side swing of the third insulator (from the left) in Fig. 14. Then $l_1 = 470$, $l_2 = 850/2 + 600/2 = 725$, $w = 1.61$ (for 300,000-circular-mil conductor with ½ inch of ice), and $h = 0.82$ (for wind pressure of 8 pounds per square foot). Whence, neglecting the weight of the insulator and the wind pressure on it,

$$\theta = \tan^{-1}\frac{0.82 \times 725}{1.61 \times 470} = 38°.$$

If the insulator is 5 feet long, the transverse horizontal deflection is then $5 \sin 38° = 3.1$ feet.

If the angle of swing as thus determined is excessive the cables and insulators will be lifted up into the cross arms at times of low temperatures and high winds. The remedy is the same as in case of direct uplift.

Side Clearance; Use of Template Z. — Where a right-of-way of definite width is obtained it is necessary to determine whether the conductor will swing beyond the edge of the right-of-way. Therefore after the towers have been located by the use of the profile they should be marked on the plan and the side swing marked in from template Z, as shown in Fig. 14. In determining side swing, the swing of the insulator (if suspension type) must be allowed for, as well as the side swing of the conductor. Adequate margin should be allowed between the extreme position of conductor and the edge of the right-of-way, so that a safe clearance will be preserved from any structures erected adjacent thereto. Where extraordinarily long spans must be used, an adequate extra width of right-of-way should be obtained in the first place.

Loss of Clearance Between Conductors Due to Unequal Ice Loading. — Where one span is loaded with ice and the one immediately below it is not, the clearance is reduced. This condition may sometimes arise due to the ice falling off the lower wire before it falls off the upper wire. Where the wires are directly over each other the normal clearance must be great enough to prevent the crossing of wires under these conditions. For ice loading without wind, clearance under unequal loading is most easily obtained by offsetting the wires horizontally for the required clearance instead of increasing the vertical clearance. However, to prevent crossing of the unequally loaded wires when deflected by wind pressure, this horizontal offset must be considerable, as the clearance must then be obtained between the wires in their inclined positions.

If the conductors to which Fig. 8 refer are normally 10 feet apart vertically on an 800-foot span, the sag would be 17.5 feet without ice at 32° F., 19.0 feet with ¼-inch ice, and 20.9 feet with ½-inch ice at 32° F. Consequently, if two cables are used one above the other, and ice should form on the upper but not on the lower, then, assuming fixed points of support (pin insulators), the clearance would be reduced by 3.4 feet for ½-inch ice, and 1.5 feet for ¼-inch ice, making the clearances 6.6 feet and 8.5 feet respectively, instead of 10 feet.

Where suspension insulators are used the reduction of clearance fro
loading is greater. If one span is loaded with ice and the adjacen
same wire are not loaded, the sag of the loaded span will be increas
insulators will swing toward that span. Similarly if one span is
d adjacent spans are loaded,
sag will be decreased. The
nimum clearance occurs where
ly one span of the upper wire
loaded and is immediately
er the only unloaded span of
lower wire. The actual re-
ction is readily calculated by
method given above in the
tion on *Calculation of Stresses Unequally Loaded Spans*, p.
3. The amount of reduction
ends on the number of spans
ween anchor towers, and the
tance from the anchor towers
which the unbalanced loading
urs. For a 300,000-circular-mil copper cable on 800-foot spans

Stresses and Deflections Due to Broken Conductors. — Wl
ctor breaks in a span supported by suspension insulators, the insu
ent to the broken span swing up into line with the cable, throwing
ck into the unbroken part of the cable equal to the length of the
is slack divides between the unbroken spans, increasing the de
h. The stresses and deflections of the unbroken spans may be d
the method given above in the section on *Calculation of Stresses in
ded Spans*, p. 1803, calling the span in which the break occurs sp

ERECTION OF TRANSMISSION LINES. — The preliminar
nstructing a transmission line includes the clearing of the right-of-
of buildings (if necessary), building roads, bridges, fences, gate
ke the right-of-way passable. If the telephone line is to be sup
arate structures, this is generally built in advance of the main line
ring the rest of the construction.

After the towers are in place and the insulators placed, the wires
-strung. The reels are distributed and spaced according to the
le on each. The reels of heavy cable are supported on reel ja
ter wire and cable is usually drawn out on the ground and carried
on the supporting structures. Heavy cables are drawn over rollers
ached to the towers at approximately the final point of support. T

out of wires and cables is usually done with horses, but under favorable conditions a traction engine or hoisting engine can be used. Where lines parallel railroads they have been pulled out successfully with locomotives. Care should be taken in drawing out the cable so as not to scratch or injure it by sharp bends or faulty cable grips, or by dragging it over sharp stones. See also the article on *Wires and Cables, Bare.*

After the cable is drawn out and is in place on the sheaves on the towers, it should be adjusted to the proper sag by using dynamometers for measuring the tension. In order to have uniform tension in all spans when pulling several at one time, the cable should be free to move at all points of support. Wires and cables should be clamped or tied in place while under the proper tension corresponding to the temperature at time of stringing. Wind loads on cables or wires are generally not of an amount during wire stringing to require allowance for additional tension. Splicing sleeves are twisted by hand wrenches in the smaller sizes and by splicing machines for the larger sizes.

At anchor towers loose jumpers must be bent to shape and not left so that they may ground on the tower due to twist of cable, pressure of wind or weight of sleet.

Where ground wires or telephone wires are also on the tower, it is equally important that they be strung at the proper tension; otherwise they may cross and ground the conductors.

Suspension towers (i.e., those intermediate between the dead-end towers) are ordinarily not strong enough to stand the strain of dead-ended cables during high winds and heavy sleet storms; consequently care must be used if cables are temporarily dead ended on them during construction.

Transposition of Transmission Lines. — (*See also Telephone Lines.*) Transpositions are not necessary for the proper operation of an isolated transmission line, but are used to diminish the inductive effects of the transmission line on neighboring circuits. The number of transpositions required depends principally on the sensitiveness and proximity of other circuits, especially telephone lines and on the distance that such lines parallel the transmission line, and also to a lesser degree on the current and voltage of the transmission line.

Where the voltage of transmission is 2200 or less the length of exposure (i.e., distance between two successive transposition points) is usually insufficient to require transpositions and, when the voltage is over 60,000, the lines are often at sufficient distance from nearest telephone line to make transpositions unnecessary. For voltages above 2200 and not over 60,000 a telephone line is ordinarily run the whole distance on the same poles or towers with a transmission line, thereby making transpositions necessary. Transpositions on such transmission lines are ordinarily located three miles or more apart, the telephone line also being transposed every 500 or 600 feet.

Each transposition of a three-phase line ordinarily consists of a spiral of one-third of a turn. Three transpositions give a complete spiral and bring the phases back to their original position. A line is ordinarily transposed by giving it one or more complete spirals, the transpositions being located so as to divide the line into approximately equal sections. For one complete spiral two transpositions dividing the line into thirds are sufficient, though the equivalent of a third transposition is necessary at one end if the phases are to have the same relative position in the station wiring at each end.

Special poles or towers are usually necessary at transposition points.

TESTS AND INSPECTION OF TRANSMISSION LINES. — Tests on transmission lines include testing of the several parts; conductors, insulators, pins, clamps, ties, towers, etc., and are described in the articles on *Wire and*

ulators for Overhead Lines; Poles for Overhead Lines, Cross Arms;
he efficiency and other electrical characteristics of transmission lines
puted with such certainty that tests are not necessary to determine
es, though the calculations are occasionally checked by observations
g actual operation.
ne is completed it should be carefully inspected to see that all joints
nade, all insulators put on, etc. Moreover, before starting continu-
n, it is advisable to apply voltage in order to make sure that the
pen circuited, short-circuited or grounded.
) or more transmission lines are to be in parallel, or where a new line
) points already connected by other lines, it is necessary to test out
sponding phases before connecting in multiple, especially if any of
'e transpositions.

ION. — Patrolmen are usually located between ten and twenty
depending on the character of the country. The coöperation of
along the line must be obtained in order to prevent damage by
insulators, throwing wires over the conductors, blasting rocks or
the line, etc. Patrolmen should inspect the line regularly and keep
and inflammable material away from the poles and towers. They
he condition of the foundations, towers, poles, insulators and con-
addition they should make minor and emergency repairs on the

tches are often installed at each patrolman's house. By manipu-
witches any section of line may then be tested for faults.
maintenance of a line includes resetting foundations that have
ing of foundations with earth to proper depth after heavy rains;
towers before they are affected by rust; renewal of rusted ground
ement of cracked or partially defective insulators that have not
ing sag of any cable where sag has changed due to stretch of cable,
gth during emergency repairs, etc.

Connections. — A good telephone line is essential and the patrol-
:port by telephone at regular intervals. As a convenience in
phones are installed or connections are provided for a portable
it intervals of three or four miles along the line. For the higher
protection must be provided for the person using telephone.
:tion includes insulated stools, telephone insulating transformers,
telephone lightning arresters and fuses.

TRANSMISSION LINES. — To obtain an accurate estimate
transmission line the cost of the various elements should be sepa-
ned. The following over-all costs based on before-the-war
1 as a rough guide in preliminary estimating.

ht-of-Way. — The cost of the right-of-way for a low-voltage line
ominal amount for a line on public roads, to $10,000 per mile or
ate right-of-way in thickly settled districts. A right-of-way 100
res approximately 12 acres per mile, which for farming land at
amounts to $2400 per mile. Land values may be expected to
rably higher for right-of-way than for farming, especially if a
desired crossing a farm diagonally.
way for high-voltage tower lines should be estimated liberally as
l have long spans and few angles, and cannot be diverted around
rty and obstructions as readily as short-span wooden-pole lines.

ize and Cost of Conductor on Total Cost. — The size and
of conductors greatly affect the cost of a line. A circuit of 3

No. 0000 cables costs about $1500 per mile with copper at 14.4 cents per p and $2000 per mile at 19.2 cents per pound. The cost of smaller cables i portionally less; No. 0 being about one-half, No. 3 about one-fourth and about one-eighth the cost of No. 0000. Thus the copper cost of a thre line will range from about $205 per mile for No. 6 at 15.6 cents per pou $2000 per mile for No. 0000 at 19.2 cents per pound.

For the same power loss in the line aluminum conductors usually cost 10 per cent less than copper.

Total Structural Cost of Wooden Pole Lines. — The structural co wooden-pole transmission line ordinarily ranges from about $1500 per mi 11,000-volt line with 3 No. 6 wires to about $4000 per mile for a 55,000-v with 3 No. 0000 wires, excluding the cost of right-of-way. To the stru cost and cost of right-of-way should be added the charges for engine contractor's services, superintendence, tools and equipment, etc., which amount to from 20 to 40 per cent of the structural cost.

Total Structural Cost of Tower Lines. — The cost of light tower lin 55,000 volts with 3 No. 0000 wires may be as low as for a wooden pole lin about $4000 per mile. For 110,000 volts with three 300,000-circular-m the cost may be about $8000 per mile or more. The cost of towers proper greatly according to the views of the designers as to what risks are pro design, that is, the severity of assumed wind and ice loadings, and the f of safety. The cost of foundations is very small when simple steel stat used in very firm ground, but foundations add greatly to the cost of a line concrete or steel structures are used, so designed as to make the strength ity and holding power of the foundations actually equal to the strength tower under reasonably unfavorable conditions of ground. See artic *Towers for Transmission Lines*.

Period. — From the above definitions it is evident that adding 2π radians, 360° to an angle does not change the value of any of its functions, that is, the functions repeat themselves every time the angle increases by the 2π radians or 360°. They are therefore said to have a period equal to 2π radians or 36

Functions of Angles in Any Quadrant in Terms of Angles in First Quadrant.—

$$\sin(-x) = -\sin x, \qquad \sin(90+x) = \cos x,$$
$$\cos(-x) = \cos x, \qquad \cos(90+x) = -\sin x,$$
$$\tan(-x) = -\tan x, \qquad \tan(90+x) = -\cot x,$$

$$\sin(180-x) = \sin x, \qquad \sin(180+x) = -\sin x,$$
$$\cos(180-x) = -\cos x, \qquad \cos(180+x) = -\cos x,$$
$$\tan(180-x) = -\tan x, \qquad \tan(180+x) = \tan x,$$

$$\sin(270-x) = -\cos x, \qquad \sin(270+x) = -\cos x,$$
$$\cos(270-x) = -\sin x, \qquad \cos(270+x) = \sin x,$$
$$\tan(270-x) = \cot x, \qquad \tan(270+x) = -\cot x.$$

Table of Trigonometric Functions. — By making use of the above relati the functions of any angle may be obtained from a table giving the values of t functions for angles between 0 and 90°. Such a table is given below. For t cot, sec and csc take the reciprocals of the tan, cos and sin respectively.

Example of Use of Table. — $\sin 21.6° = 0.3681$, $\cos 21.6° = 0.$ $\tan 21.6° = 0.3959$; $\sin 107° = \sin(180° - 107°) = \sin 73° = 0.9563$, $\cos 107° =$ $\cos 73° = -0.2924$, $\tan 107° = -\tan 73° = -3.2709$.

nctions. — If $a = \sin x$, then x is the angle whose sine is a; this may sed symbolically $x = \sin^{-1}a$, which is read "x equals the angle whose The angle x is also called the "anti-sine" or the "inverse sine" of r notation is used for the other functions; for example, $x = \cos^{-1}b$ express the relation that x is the angle whose cosine is b. At least functions" must be known to completely determine the quadrant in ngle lies; for example, if $x = \sin^{-1} 0.5$ then x may be either 30° or if we also have $x = \cos^{-1} 0.866$, then x must equal 30°, while if $x =$ .866), then x must equal 150°.

ctions may be taken from the table given above by finding the angle in corresponding to the function in the table. *Example:* $\sin^{-1} 0.319$ $180° - 18.6° = 161.4°$.

— The expression $(1 - \cos x)$ is called the "versine" of x.

s Among Functions of the Same Angle. —

$$x = \frac{\sin x}{\cos x} = \frac{1}{\cot x}, \qquad \sin^2 x + \cos^2 x = 1,$$

$$x = \frac{1}{\cos x}, \qquad 1 + \tan^2 x = \frac{1}{\cos^2 x},$$

$$x = \frac{1}{\sin x}, \qquad 1 + \cot^2 x = \frac{1}{\sin^2 x},$$

$$)-x) = \cos x, \qquad \sin(-x) = -\sin x,$$

$$)-x) = \sin x, \qquad \cos(-x) = \cos x,$$

$$)-x) = \cot x, \qquad \tan(-x) = -\tan x.$$

Difference of Two Angles. —

$$\sin(x+y) = \sin x \cos y + \cos x \sin y,$$
$$\cos(x+y) = \cos x \cos y - \sin x \sin y,$$
$$\tan(x+y) = \frac{\tan x + \tan y}{1 - \tan x \tan y},$$
$$\sin(x-y) = \sin x \cos y - \cos x \sin y,$$
$$\cos(x-y) = \cos x \cos y + \sin x \sin y,$$
$$\tan(x-y) = \frac{\tan x - \tan y}{1 + \tan x \tan y}.$$

the Functions of Two Angles. —

$$\sin x \sin y = \tfrac{1}{2}[\cos(x-y) - \cos(x+y)],$$
$$\sin x \cos y = \tfrac{1}{2}[\sin(x+y) + \sin(x-y)],$$
$$\cos x \sin y = \tfrac{1}{2}[\sin(x+y) - \sin(x-y)],$$
$$\cos x \cos y = \tfrac{1}{2}[\cos(x+y) + \cos(x-y)].$$

f Twice an Angle. —

$$\text{in } 2x = 2 \sin x \cos x, \qquad \cos 2x = \cos^2 x - \sin^2 x,$$

$$\tan 2x = \frac{2 \tan x}{1 - \tan^2 x}.$$

f Half an Angle. —

$$\frac{-\cos x}{2}, \qquad \cos\frac{x}{2} = \sqrt{\frac{1+\cos x}{2}}, \qquad \tan\frac{x}{2} = \sqrt{\frac{1-\cos x}{1+\cos x}}$$

Three Times an Angle. —

$$x = 3 \sin x - 4 \sin^3 x, \qquad \cos 3x = 4 \cos^3 x - 3 \cos x,$$

$$\tan 3x = \frac{3 \tan x - \tan^3 x}{1 - 3 \tan^2 x}.$$

TRIGONOMETRY. — (*See also Trigonometric Functions.*) Any triangle completely defined when, (1) two sides and the included angle are kno (2) one side and two angles are known, (3) three sides are known. Let t sides and angles of a triangle be designated as in Fig. 1.

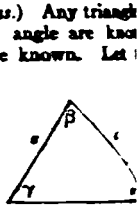

Fig. 1.

1. **Given two sides a and b, and the included angle γ.** Then

$$c = \sqrt{a^2 + b^2 - 2ab\cos\gamma}$$

$$\sin\alpha = \frac{a}{c}\sin\gamma$$

$$\beta = 180 - \alpha - \gamma.$$

2. **Given the side a and the two angles β and γ. Then**

$$\alpha = 180 - \beta - \gamma$$

$$b = a\frac{\sin\beta}{\sin\alpha}$$

$$c = a\frac{\sin\gamma}{\sin\alpha}.$$

3. **Given the three sides a, b and c.** Put

$$s = \tfrac{1}{2}(a + b + c)$$

Then

$$\sin\alpha = \frac{2}{bc}\sqrt{s(s-a)(s-b)(s-c)}$$

$$\sin\beta = \frac{b}{a}\sin\alpha$$

$$\gamma = 180 - \alpha - \beta.$$

Relations Between Sides and Angles. — The following relations bet the sides and angles of a triangle are sometimes useful:

$$\frac{a}{\sin\alpha} = \frac{b}{\sin\beta} = \frac{c}{\sin\gamma}$$

$$\cos\alpha = \frac{b^2 + c^2 - a^2}{2bc}$$

$$\sin\frac{\alpha}{2} = \sqrt{\frac{(s-b)(s-c)}{bc}}$$

$$\cos\frac{\alpha}{2} = \sqrt{\frac{s(s-a)}{bc}}$$

and similar relations for the other two angles.

Y SYSTEMS, OVERHEAD. — (*See also Cars, Electric; Cross motives, Electric; Poles for Overhead Lines; Rails, Track and Third; lectric, Traction Systems for; Railways, Location and Permanent Way ail Systems; Transmission Lines; Trolley Systems, Underground; Cables, Bare.*) The following is a brief table of contents of this

ns	p. 1825
ions of Various Types	1825
l Design	1826
cal Design	1834
Examples of Construction	1843
tions	1846
n	1846
	1847
	1849
phy	1850

y wire is usually of hard-drawn copper but sometimes of steel, ɔended from insulators some 16 to 30 feet above the ground, and ɔntinuous contact surface to a trolley wheel or bow attached to ock. There are two classes of trolley construction, the span wire bracket; each may have either simple or catenary suspension.

e and Side-bracket Construction. — In the simple span wire the trolley wire is supported by wires stretched across the tracks s or building walls. The side-bracket construction resembles the :ept that instead of the supporting wire being stretched between is stretched between two supports on the same pole. In both of : construction, the trolley wire is supported at intervals of 100 feet sags considerably between supports, making it necessary for the n constant vertical vibration as the cars move.

Construction. — The speed attained upon modern electric roads cult to obtain satisfactory service with a trolley wire which dips support and sags and sways with every impulse. The catenary was devised to meet this condition. In general, it consists of a er trolley wire suspended horizontally from a sagging messenger is suitably insulated and firmly held in place. The supporting erably employed for interurban single- or double-track roads is of et type, but for some conditions cross-span construction becomes he latter method of support differs only in the substitution of a s span for the bracket arm and doubling the number of poles ngle track.

'IONS OF VARIOUS TYPES OF CONSTRUCTION. — The :y system is used on urban railways, wherever the unsightliness or :xposed construction is not considered objectionable. It is used and suburban lines wherever the current taken by the trains is not economically carried on copper wires. In recent years it has been ction with the alternating-current systems of electric traction on lines.

construction is the most sightly for double-track city railways, namental brackets are used, side-pole construction being gener- ngle-track lines. Span-wire construction is used where, for any practicable to have the poles near the tracks or where, as is com- in Europe, the span wires are supported from the walls of build- e against overhead lines is often due to the excessive loading of both unsightly and dangerous.

ELECTRICAL DESIGN OF CONDUCTORS. — In designing the tr system careful attention must be given to both the electrical and mechan features. In this section will be treated the electrical features, and in the lowing section the mechanical features. The electrical design of railway tribution systems involves the consideration of potential drop, heatin conductors and feeder economy. The heating of conductors is seldom important factor in railway feeder design, as it is usually necessary to u low current density to keep down the drop of potential. A discussion o heating of conductors will be found under *Wires and Cables, Bare*. The fe system being sufficient to meet the conditions imposed by the all potential drop (*see below*), it will be economical to make it greater i saving in the cost of energy which will result, is greater than the increa interest and other charges on the additional investment.

Allowable Potential Drop. — The total potential drop is limited by necessity of running the cars at a certain speed and by the need of keepin car lights brilliant. The potential drop in the ground conductors, i.e., the tr rails and bare negative feeders, is further limited by the danger of electro by current leaking into the earth (*see article on Electrolysis*).

The drop in the grounded conductors under maximum-load condition limited by law in Great Britain to 7 volts between any two points of the sy In Germany the maximum drop in the grounded conductors is limited to 1 per kilometer (1.61 volts per mile). In the United States the legal limit i matter of local option and is, in general, less severe than in Europe.

Calculation of Potential Drop. — The method of calculation of pote drop depends upon the following conditions: (1) whether the current is dir alternating; (2) whether the load is concentrated at one point, sparsely dis uted or evenly distributed; (3) the distribution of metal in the feeder cir and (4) whether the section is being fed by one or by two or more substat Calculations for alternating-current lines differ from those for direct-cur lines only in taking into account the inductance, as described below. On railways it is usual to assume the load to be evenly distributed, it being st as a given number of amperes per foot (*see article on Railways, Energy Re ments and Motor Capacity for*). If the load is actually concentrated a equidistant points, the drop will exceed that calculated on the assumption uniform distribution by about $\frac{100}{\pi}$ per cent. On interurban and trunk li the cars are usually concentrated at one or two points between substati making the assumption of uniform distribution impracticable. In such c the loads should be located so as to give the worst conditions, and calculati made as for any network.

Where electrolytic damage is to be guarded against, the drop of potenti the track rails themselves has to be calculated, as well as the total drop i rails and feeders.

Resistance of Trolley and Track. — Values of the resistance of tr wires to direct current will be found in the article on *Wires and Cables, B* and values of the resistance of rails to direct current will be found in the ar on *Rails, Steel*. It should be noted that the resistances of the trolley and p tive feeders are in parallel and that the track rails and negative feeders ar parallel. Also note that in the case of high-voltage systems a considera portion of the current returns through the earth and not through the rails a consequently the drop in the rails is due only to that part of the current wh returns through them. For preliminary calculations, however, the full curre may be assumed as returning through the rails.

mulas for Direct-current Trolley Circuits. — The following formulas to certain typical circuits which frequently occur in practice. Let

I = total current in amperes taken by all cars on section considered,
L = total length of section in 1000 feet,
$_p$ = total drop in volts, in positive conductors between substation bus and far end of line,
$_n$ = total drop in volts in negative conductors between substation bus and far end of line,
$V = V_p + V_n$ = total drop in volts in both positive and negative conductors,
$_p$ = resistance in ohms of all the positive conductors in multiple per 1000 feet of line,
$_n$ = resistance in ohms of all the negative conductors in multiple per 1000 feet of line,
$r = r_p + r_n$ = total resistance in ohms per 1000 feet of line,
l = distance in 1000 feet, from far end of line to any point P,
v = drop to the point P, subscripts used as for V.

Uniformly Distributed Load, Uniform Conductor, Fed from One tation. — Then

$$v = \frac{rIl^2}{2L},$$

$$V = \frac{rIL}{2}.$$

e formulas are applicable to either the positive or negative conductors idered separately or to both in series.

Uniformly Distributed Load, Conductor Tapered to give Mini- Weight of Metal, Fed from One Substation. — For minimum ht the tapering must be such that at any point P

$$r = \frac{3V}{2I\sqrt{L}\sqrt{l}},$$

the cross-section, if all the conductors are of the same metal, must increase tly as the square root of l. drop to the point P is

$$v = \frac{V\sqrt{l^3}}{L^3}.$$

e formulas also apply to r the positive or negative luctors separately or to both ries.

Uniformly Distributed d, Conductor Divided into tions (Fig. 1); Each Sec- of Constant Resistance, from One Substation. he drop from P_n to the far of line is

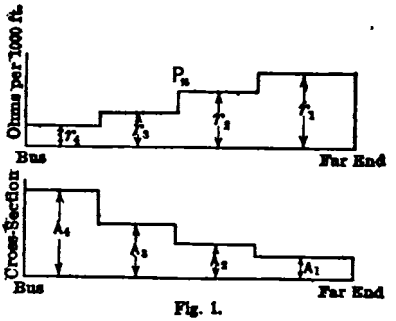

Fig. 1.

$$\frac{I}{2L}\sum_{s=1}^{s=n} r_s[l^2_s - l^2_{(s-1)}].$$

s formula is applicable to either the positive or negative conductors. The script s is here the general form of the subscript corresponding to each ion represented by 1, 2, 3 and 4 in Fig. 1.

Concentrated Load, Section Fed from One End.—Fig. 2 shows 4-track road with 4 trolley wires and 3 feeders with the tracks cross-bonded intervals. The solution given below is a general one, and may be applied any case from 1 track and 1 trolley wire up. Let all distances be expressed in 1000 feet and let

N_f = number of feeders in section considered, e.g., for the section AB, $N_f = 3$, and for the section BD, $N_f = 2$,

N_c = number of contact conductors, trolley wires or third rails in section considered, e.g., four are shown in Fig. 2,

N_t = number of tracks in section considered,

R_f = resistance of each feeder per 1000 feet,

R_c = resistance of each contact conductor per 1000 feet,

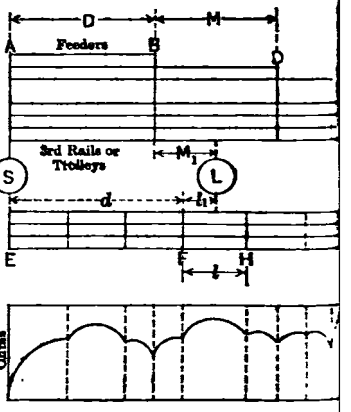

Fig. 2.

R_t = resistance of each track per 1000 feet (1 rail or 2 rails in multiple depending upon whether 1 or 2 rails are used for return conductor),

$$n = N_c + \frac{R_c}{R_f} N_f \qquad \text{for the section considered.}$$

Then for the section in which the load may be, the resistance of the positive conductors from the load to the end of that section in the direction of the substation, e.g., the resistance from L to B, is

$$R_c M_1 \left[1 - \frac{(n-1) M_1}{nM} \right].$$

The resistance of the positive conductors in any section such as BA is

$$\frac{R_c D}{n}.$$

(Note that the value of n for this section is not the same as for the section BD.)

The resistance of the negative conductors from the load to the first cross bond in the direction of the substation, e.g., the resistance from L to F, is

$$R_t l_1 \left[1 - \frac{(N_t - 1) l_1}{N_t l} \right].$$

The resistance of the remaining portion of the negative conductors, e.g., from F to E, is

$$\frac{R_t d}{N_t}.$$

(Note that if negative feeders are used, each negative feeder having a resistance of R_f' per 1000 feet, then for N_t in the last two formulas substitute $n' = N_t + \frac{R_t}{R_f'} N_f'$, where N_f' is the number of negative feeders for that section.)

The total resistance from the load to the substation is the sum of the resistances as above calculated.

Concentrated Load, Section Fed from Both Ends, Substation tage at the Two Ends the Same. — The most convenient method of ıting such problems is to plot an "equivalent-resistance-distance" curve h as shown in Figs. 2 to 5. By "equivalent resistance" is here meant that stance by which the total current taken by the load must be multiplied give the total drop in voltage between the load and either substation. For mple, if the substation voltage is 600 at each end, the voltage across the l is 550 and the current taken by the load is 200 amperes, then the equivalent stance is $R = \frac{600 - 550}{200} = 0.25$. This method avoids the determination of distribution of the current in the various parts of the network, and the stance when once determined can be applied to any load.

. In Fig. 3 is shown a single track and single trolley. S_1 and S_2 are sub-tions; L is a load placed itrarily between correspond-points P_1 and P_2 on the pos-e and negative conductors pectively. Let

a = resistance of the conductors between the points $S_1P_1P_2S_1$;

b = resistance of the conductors between the points $S_2P_1P_2S_2$.

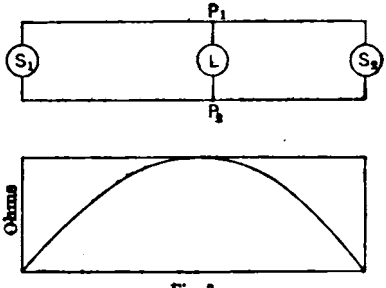

Fig. 3.

ese resistances are the resist-es of the transmitting con-tors and do not include the rnal resistances of the substations and load. Then the equivalent resist-e is

$$R = \frac{ab}{a+b}.$$

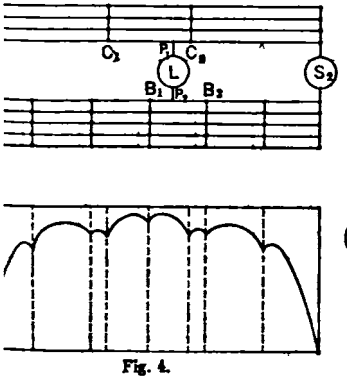

Fig. 4.

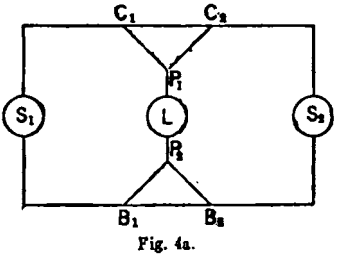

Fig. 4a.

2. In Fig. 4 is shown a 4-track road with 4 trolleys, both track and trolley oss-bonded. Fig. 4a is a simplified diagram of Fig. 4, corresponding points ing designated by identical letters.

Digitized by Google

S_1 and S_2 are substations; L is a load placed arbitrarily between points P_1 on the positive system and P_2 on the negative system; C_1 and C_2 are ties between positive conductors and B_1 and B_2 ties between negative conductors.

Let

a = resistance of loop $S_1C_1P_1LP_2B_1S_1$,
b = resistance of loop $C_1P_1C_2C_1$,
c = resistance of contact conductor C_1P_1,
d = resistance of contact conductor C_2P_1,
e = resistance of loop $B_1P_1B_2B_1$,
f = resistance of track B_1P_1,
g = resistance of track B_2P_1,
h = resistance $\frac{d^2}{b} + \frac{g^2}{e}$,
i = resistance $\frac{c^2}{b} + \frac{f^2}{e}$,
j = resistance $S_2C_1P_1LP_2B_2S_2$.

These resistances are the resistances of the transmitting conductors and do not include the internal resistances of the substations and load. The equivalent resistance is

$$R = \frac{aj - ah - ji - 2\left(\frac{fg}{e} \times \frac{cd}{b}\right) + \frac{f^2d^2 + c^2g^2}{eb}}{a + j - h - i - 2\left(\frac{fg}{e} + \frac{cd}{b}\right)}.$$

Concentrated Load, Section Fed by Feeders from Both Ends. — Fig. 5 shows a simple case with feeders for the positive conductors only. The general formula is available for such a circuit. Any such network can, however, be calculated by Kirchhoff's Laws (q.v.), using the numerical values of the resistances for the various resistances. The equivalent resistance from the substations to the load is then the drop in voltage for a load of one ampere.

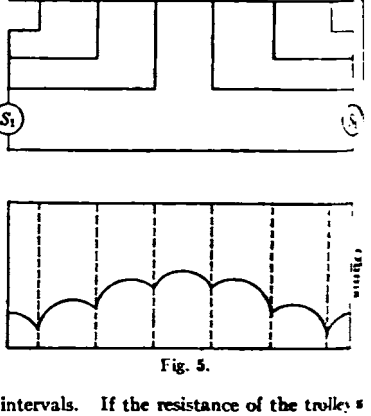

Fig. 5.

Ways of Reducing Total Drop. — Three methods are employed for reducing the total drop in the trolley and rails, viz:

1. **Plain or "Non-boosted" Feeders.** — Copper feeders, usually bare, may be connected to the trolley wire, third rail or track rails at frequent intervals. If the resistance of the trolley is high compared with that of the rails, which is usually the case, the feeders should be used to reënforce the trolley wire and not the track. In general, the most economical use of additional copper is to connect it in parallel with that side of the circuit having initially the higher resistance.

2. **Boosted Feeders.** — An insulated feeder may be tapped into the trolley wire or third rail at one point, and connected to a booster at the substa-

The principle of this method is to increase the activity of the feeder, i.e., ke it carry more current and thereby reduce the current in the trolley wire. is necessary only where the resistance of the line is so low that a moderate- feeder does not take its full share of current. It is not much used because line resistance is already low and the load is small, the drop will usually be enough naturally, and if the load is great, the booster and feeder will ly have to be so large in order to produce any effect, as to be prohibitive it cost and cost of operation.

3. **Floating Battery**, i.e., a battery connected across the line so as to e when the line potential is high and discharge when it is low. This scheme cy little used on account of the high cost of operating and maintaining a ry. It is difficult to imagine under what conditions such a system would mmercially practicable, but if anywhere, it would be on a long line with load and small feeders. Typical calculations for floating batteries are given ndon's *Storage Battery Engineering*, Chap. XLIV.

ays of Reducing Drop in the Negative Side of Circuit. — Owing to ecessity of preventing the leakage of current from track rails into the earth, y be necessary to reduce, not the total drop in the negative system, but the in the grounded portion of the negative. This may be accomplished by se of insulated feeders connected to the track rails so as to drain the current the latter and thus reduce the drop in the rails, regardless of the drop in eeders themselves. Such feeders may be used with or without a booster. with boosters, this method is probably the most economical way of reduc- he drop in return rails where a large reduction is necessary to prevent rolysis.

Negative Feeder with Booster. — In the case where the load is uni- ly distributed over the line, the size of booster which must be installed in ubstation may be determined as follows:

t a = amperes entering negative feeder system per foot of line,
r = resistance of negative feeder system per foot,
R = total resistance of the feeder connecting the booster to the negative feeder system,
I = total amperes entering negative feeder system from the motors,
I_0 = amperes to be taken off by booster,
$\frac{I - I_0}{a}$ = distance from substation to the point at which the current in the negative feeders is to be zero,
l_1 = distance from booster tap to point in negative feeders where current is zero,
l_2 = the distance from the booster to the end of the line.

n the booster voltage is

$$RI_0 - \tfrac{1}{2}\, ar(l^2 - l_1^2).$$

he output of the booster is, of course, the product of the current and voltage. he total drop is

$$\tfrac{1}{2}\, ar(l^2 - l_1^2 + l_2^2).$$

Del Mar's *Electric Power Conductors*, Chap. V, for a more complete treatment.

'ormulas and Constants for Alternating Current Trolley Circuits. — tle information is available on the effective or a-c. resistance (*see Alternating rents*) and reactance of steel rails. As a rough approximation the a-c. re- tance of a rail at 25 cycles per second may be taken as 4 to 5 times its d-c. istance and the reactance of the rail as approximately the same as that of one re of a pair of No. 0000 wires at a distance apart equal to the height of the

trolley wire above the track i.e., roughly as 0.4 ohm per mile. As a m of fact the a-c. resistance depends upon the shape of the rail, its mag quality, the value of the current and the frequency; to a lesser extent inductance, and therefore the reactance, depends upon these same items.

Data from Tests on N. Y., N. H. & H. R.R. — The following were obtained by A. W. Copley from tests on the New York New Haven Hartford Railroad and reported in the Trans. A.I.E.E., 1908, Vol. 27, (2) p. 1 An analysis of these tests is also given by H. Pender in the Elec. World, Vol. 53, p. 1457. Copley's results showed that a considerable portion of current entering the track from the load leaked to the earth. The comb resistance r of any number of trolley wires, and track rails and earth, as d mined by Copley, can be represented by the following formula

$$r = \frac{p_1 r_1 + p_2 r_2}{100},$$

where r_1 = the resistance of each trolley wire separately, p_1 = the per cen the total current in this wire, r_2 = the a-c. resistance of each rail separa and p_2 = the per cent of the total current in this rail. Similarly, the comb reactance x of any number of trolley wires and track rails and earth return be represented approximately by the formula

$$x = \frac{p_1 x_1 + p_2 x_2}{100},$$

where x_1 = the reactance of a given trolley wire, x_2 = the reactance of a rail and p_1 and p_2 as above.

Pender gives the following values for trolley wire and rail separately, upon Copley's tests:

Item	Resistance, ohms per mile		Reactance,* ohms per mile	
	25 cycles	15 cycles	25 cycles	15 cycles
Single trolley wire, No. 0000 B. & S....	0.26	0.26	0.38	0.33
000 B. & S....	0.33	0.33	0.36	0.33
00 B. & S....	0.42	0.42	0.39	0.33
Single rail, 100 pounds to the yard.....	0.16	0.13	0.44	0.36

* For the trolley wire 25 ft. above the track, changing the height of the trolley 5 ft. up or down changes these values by less than 5 per cent.

The combined resistance and reactance respectively of the trolley wires and earth are given in the following table:

For any other weight of rail the a-c. resistance of the rail itself may be ta as roughly inversely proportional to the weight per yard. The reactan of the rail, however, is practically independent of its cross-section, for the m netic flux within the rail is relatively small compared with the total flux rounding the rail (*see Inductance*).

Formulas for Single-phase Calculations. — The calculation of power lost and drop in voltage between a load and the power house are c lated in the same manner as in the case of an ordinary single-phase a-c. ta

The figures marked thus ° are taken directly from the paper by Copley, whose tests confined to No. 0000 trolley wires; the other values are calculated by Pender.

The percentages of total current returning through the rails are test results on the ., N. H. & H. R.R., and refer to relatively long sections (over 5 miles); a greater ortion of current flows in the rails in the immediate vicinity of the load and power e. The proportion of the total current which will return through the earth will nd upon the nature of the soil and ballast; for any other division of current the ance and reactance can be obtained from the approximate formulas given above. proportion of current returning through the earth on the N. Y., N. H. & H. R.R. has greatly reduced since the above data were obtained, by the use of the three-wire m shown in Fig. 6.

ion line (*see Transmission Lines*). For a concentrated load (e.g., a single) the calculation is as follows: Let

V = volts between trolley wire and track;
P = kilowatts at the locomotive delivered to locomotive;
s ϕ = power factor of load taken by locomotive;
l = distance in miles, between power house and locomotive;
r = combined resistance in ohms, per mile of trolley wire, rails and earth return;
x = combined reactance, in ohms, per mile of trolley wire, rails and earth returns;
$R = rl$;
$X = xl$.

n the current taken by the locomotive is

$$I = \frac{1000\,P}{V\cos\phi} \quad \text{amperes,}$$

power lost is

$$p = \frac{R\,I^2}{1000} \quad \text{kilowatts,}$$

drop in voltage between the power house and locomotive is

$$v = \sqrt{(V\cos\phi + RI)^2 + (V\sin\phi + XI)^2} - V \quad \text{volts,}$$

the power factor at the power house is

$$\cos\phi_0 = \frac{1000\,(P+p)}{V+v}.$$

Digitized by Google

Example. — 2000 kw. at 25 cycles per second are to be supplied t locomotive at 90 per cent power factor and 10,000 volts at a distance of miles from the power house. The circuit consists of a No. 0000 trolley wire two 100-lb. track rails. Then $V = 10{,}000$, $P = 2000$, $\cos\phi = 0.9$, $\sin\phi = 0.4$ $l = 20$, $r = 0.29$ (assuming only 40 per cent of the current returning through rails), $x = 0.47$ (same assumption), $R = 0.29 \times 20 = 5.8$, $X = 0.47 \times 20 =$ Whence

$$I = \frac{1000 \times 2000}{10{,}000 \times 0.9} = 222 \text{ amperes},$$

$$p = \frac{5.8 \times (222)^2}{1000} = 286 \text{ kilowatts},$$

$$v = \sqrt{(10{,}000 \times 0.9 + 5.8 \times 222)^2 + (10{,}000 \times 0.435 + 9.4 \times 222)^2} - 10{,}000 =$$
2130 volts,

$$\cos\phi_0 = \frac{1000\,(2000 + 286)}{222\,(10{,}000 + 2130)} = 0.848.$$

Scheme of Connections Used by N.Y., N.H. & H.R.R. — The tribution system is shown diagrammatically in Fig. 6 where A is the tro

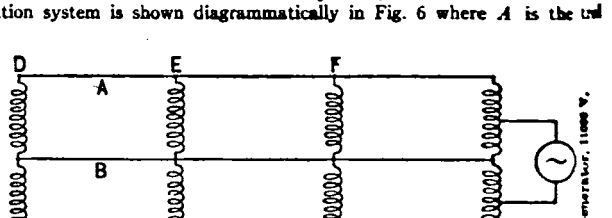

Fig. 6.

wires, B the track rails and C a feeder. These three sets of conductors connected at intervals of about two miles through auto-transformers D, E and The difference of potential between A and B, and between B and C is 11 volts and between A and C is 22,000 volts. The effect of this arrangement to practically give a transmission voltage of 22,000 with 11,000 volts at trolley, and to greatly reduce the current in the grounded conductors with a sequent reduction of disturbances to telephone lines.

MECHANICAL DESIGN OF OVERHEAD SYSTEM. — The va parts of the overhead system will first be described, and then the various of construction, span wire, catenary, etc. The American Electric Rail Engineering Association has adopted specifications for overhead line mater which cover most of the mechanical details pertaining to ordinary trolley li

Parts of Overhead Trolley Construction. — The trolley wire is secu to an "ear" by soldering, clamps or other means; the ear is bolted to a "s pension" which may or may not be provided with an insulating portion. Th suspensions are carried by span wires which in turn are fastened to the po or brackets, or may be fastened directly to the bracket. If the "ear" is n insulated, "strain" insulators are inserted in the span wire between the ear its point of attachment to the poles or brackets. A slightly different kind suspension, called a "pull-off," is used on curves. At turnouts "trolley

: be used to guide the trolley wheel. These various parts are illustrated in accompanying cuts.

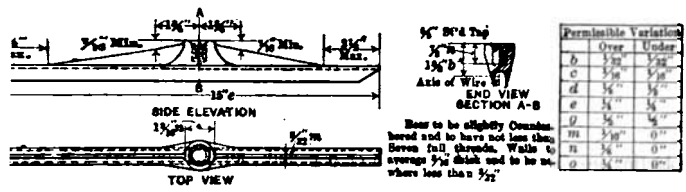

Fig. 7

Trolley Ears. — Figs. 7 to 10 are for round wire. Fig. 7 shows the dard straight-line ear of the A.E.R.E.A. It is made of cast bronze of approx-tely the following composition:

Copper	84 per cent
Zinc	10
Tin	3
Lead	3
	100 per cent

The ear shown in Fig. 8, which has a deep groove into which the wire is soldered type in common use. These ears may be provided with rings as in Fig. 9

Fig. 8. Fig. 9.

Fig. 10. Fig. 11.

Types of Trolley Ears for Round Wire

which guy wires are attached to relieve the strain at curves and for steadying line at intervals. Fig. 10 shows the type of ear used at points where the

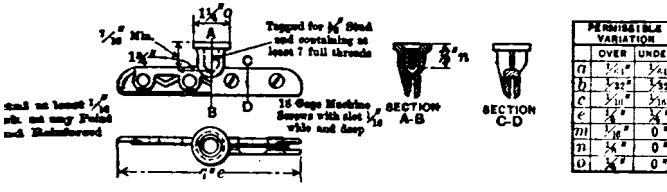

Fig. 12

olley is spliced, which should always be at an ear. Fig. 11 shows an ear with terminal for a feeder connection.

Figs. 12 to 14 are designed for grooved or figure "8" trolley wire. Special ooved or figure-8 wire affords a smoother running surface for the trolley heel or bow as the ear only grips the upper part, leaving the lower part solutely even. This construction is practically essential for bow trolleys. he design shown in Fig. 12 is the standard of the A.E.R.A. It is made of [illegible] which must conform with A.S.T.M. standards.

Soldering Trolley Wire to Ears. — The strain should be taken off the wire by a U-shaped clamp catching hold of it on each side of the ear. The

Fig. 13.

Fig. 14.

Types of Trolley Ears for Figure "8" Wires

soldering iron should weigh about 8 or 9 pounds, and should have a groove fitting half way round the wire. Special precautions should be taken not to have the iron unnecessarily hot.

Suspensions for Straight Line Work. — Fig. 15 shows an uninsulated suspension with ear attached for straight line work. Fig. 16 shows a suspension with strain insulators at each end; this is also used on curves for double-track

Fig. 15.

Fig. 16.

Fig. 17.

Fig. 18.

Fig. 19.

Fig. 20.

Types of Suspensions

work. Figs. 17 and 18 show solid insulated suspensions for span wire and side bracket construction, respectively. These types are frequently used, and are quite satisfactory if the insulating material used in their construction is properly made. Fig. 19 shows a section of an assembled cap and cone suspension. Fig. 20 shows a cap and cone suspension with ear attached. The cap and cone are made separate. This type is preferred by some engineers on account of the possibility of replacing injured bolts and insulation without removing the whole suspension. This advantage is partly offset by the greater liability to trouble due to multiplicity of parts, and this type of suspension is now little used.

Strain Insulators. — Fig. 21 shows a "globe" strain insulator, the type most commonly used. Fig. 22 shows a "Brooklyn" strain insulator. This type is used on wooden pole and light iron pole construction to draw span wires taut. It is also required even for heavy iron pole construction if spans are long and temperature variation great. Bolts may be provided at both ends if an extra amount of adjustment is required. A globe strain and a Brooklyn strain may be used in series where extra insulation is required.

Fig. 21.

Fig. 22.

Strain Insulators

Fig. 23.

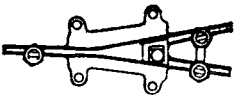
Fig. 24.

Pull-offs

Pull-offs. — Fig. 23 shows a cap and cone pull-off for single-curve construction and Fig. 24 a cap and cone pull-off for double-track curve construc-

ll-offs of the same type as the uninsulated and solid insulated suspen- n in Figs. 15, 17 and 18 are also used.

olley Frogs. — A trolley frog is a malleable iron casting used at or crossovers where trolley wires from different tracks unite. Its func- hold the diverging wires together and afford a smooth running path to r wheel when a car passes or enters a switch. A common type is illus- Fig. 25. Frogs are made for various divergence, and both right and left The usual angles are 8, 15 and 20 de-



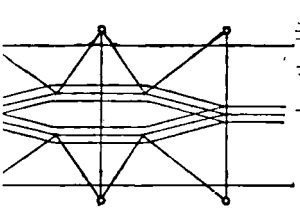


Fig. 25. Trolley Frog

d Tension in Overhead System. — attention must be paid to designing ead structure in such a manner that it stand the extra tension due to the contraction of the wires at low res and the extra loads due to wind and sleet, and a sufficient allow- d be made in the height of the trolley wire to take care of the extra sag xperiences at high temperatures. With a simple trolley construction ons in tension and sag may be calculated by a direct application of iven in the article on *Transmission Lines;* in the case of catenary n, the additional load due to trolley wire, clips, etc., is treated in vay as a sleet or wind load.

Suspension. — The following discussion applies primarily to span- de-bracket construction; catenary construction is treated in a sepa- n below. Details of standard parts are given in the A.E.R.A. Engi- nual.

ght of Trolley Wire Above Rail. — The height of wire varies ninimum of 16 feet and a maximum of 22 feet, the usual height being et. It is usual to raise the wire at railroad crossings to a height of nore above the top of rails. Catenary construction should be used ceeding 150 feet.

6. Simple Pull-off Arrangement

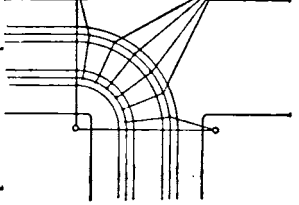

Fig. 27. Simple Pull-off Arrangement

e of Poles. — Bracket-arm poles on tangent construction should e backwards not exceeding 3 inches, and span-wire poles in hard ke of from 4 to 5 inches. In soft ground a rake of 12 inches is not

Center poles should be set vertically except at curves, where they away from the curve along the perpendicular to the tangent at that curve.

norage. — At both ends of every grade and curve, there should be t anchorage. If there are not many grades and curves, anchorages rovided at intervals of from ¼ to ½ of a mile. An anchorage is made

by means of a steel cable running from the trolley wire to one or more anch poles through an anchor ear and strain insulators.

Curves. — At curves in the track the trolley wire should be made t follow the curve by means of pull-offs or wires pulling the trolley wire outwa as shown in Figs. 26 and 27.

Wherever possible the pull-off wires should be radial to the trolley wire. Th however, requires a large number of poles, and is therefore impracticable i cities. In such cases, the bridle, bow-string or backbone construction shown Figs. 28, 29, and 30 is resorted to. In this construction the pull-off wir

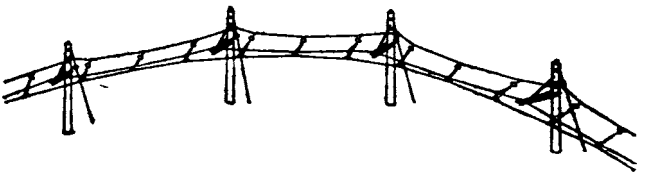

Fig. 28. Bridle Construction at Curve

instead of being anchored to individual poles are fastened to a wire which i stretched between poles. While this construction is almost universally used i cities, it is more expensive to maintain than single pull-offs, and is therefore no favored for interurban lines.

A combination of the two types of construction is shown in Fig. 31. Figs. 2 to 31 are from G. E. Co. publications.

Spacing of Pull-offs at Curves. — The number of pull-offs should b sufficient to keep the wire within about 2½ inches from the theoretical curv This may be accomplished by spacing the successive ears in accordance with th following relations:

Let L = distance between pull-offs in feet,
R = radius of curve in feet,
a = offset of wire in inches from theoretical curve, midway between pull-offs, the ears being assumed to lie on the theoretical curve.

Then,

$$L = \sqrt{\frac{2aR}{3} - \left(\frac{a}{6}\right)^2},$$

or

$$L = 0.815\sqrt{aR},$$

with an error less than ⅛ per cent for all radii greater than 40 feet.

If a is to be 2½ inches, then

$$L = 1.29\sqrt{R} \text{ approximately.}$$

If the ears are set exactly on the theoretical curve, the wire will depart 2½ inches from the correct position half way between the two ears; if the ears are set 1¼ inches from the curve, the mid-point of the wire will be only 1¼ inches when L is taken equal to $1.29\sqrt{R}$.

Offset of Trolley Wire at Curves. — It is usual, at curves, to offset the trolley wire from the center of the track (a) because the trolley wheel is tilted inward due to the elevation of the outer rail, and (b) because in order to keep the wheel on the wire, the latter must be so placed that the projection of the pole on the plane of the track is always tangential to the wire.

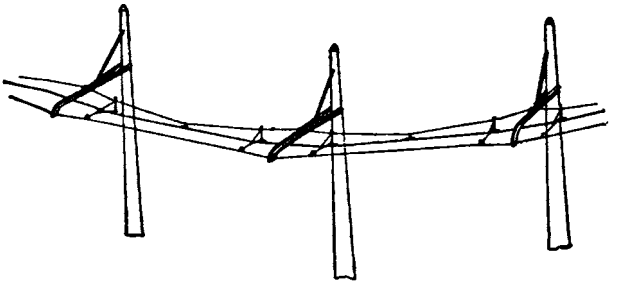

Fig. 29. Bow-string Construction at Curve

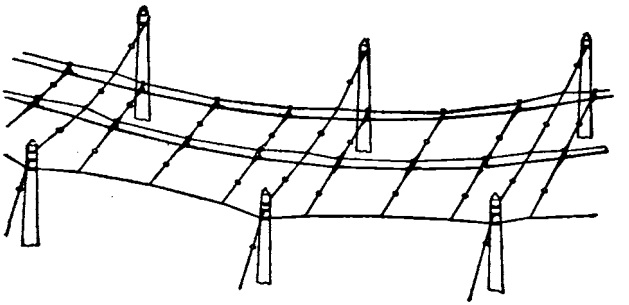

Fig. 30. Backbone Construction at Curve

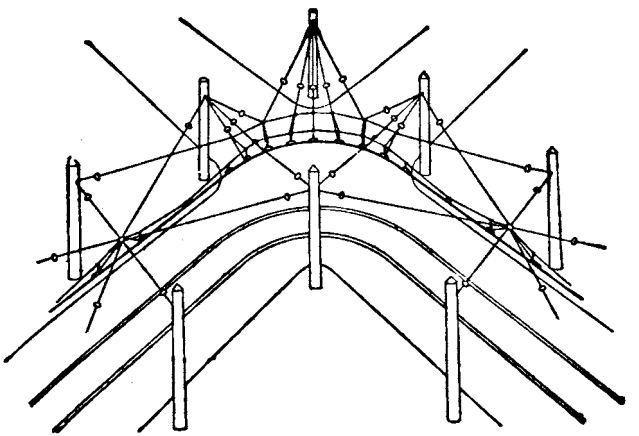

Fig. 31. Combination Construction at Curve

Digitized by Google

(*a*). The former offset, measured horizontally toward the inside of the curve, equals $h \tan \theta$, where h is the normal height of the wire above the top of rail and θ is the angle of elevation between the plane of the track and the horizontal. For standard gauge and wire 18 feet above the top of rail this offset is about $\frac{1}{2}$ inches for every inch of elevation.

(*b*). The latter offset, also measured horizontally toward the center of the curve, is calculated as follows, assuming the curve to be longer than the rail itself; for shorter curves the offset will be less. Let

R = radius of curve,

L = horizontal distance of center of trolley wheel to center of trolley base, usually about 11 feet,

G = distance from center of car to center of truck.

In the case where the trolley base is located over the truck center, as on cars with two trolleys, the offset is

$$R - \sqrt{R^2 - L^2}.$$

If the trolley base is located over the car center as on cars with one trolley, the offset equals

$$R - \sqrt{R^2 - G^2 - L^2}.$$

The total offset is the sum of the offsets (*a*) and (*b*).

Curves of Small Curvature. — If the curvature* is less than 1°, the poles are frequently spaced closer together and no pull-offs used. The following table gives the practice of the Denver and Interurban R.R. Co., which may be considered typical, the divergence of the wire from the theoretical curve being kept within 3½ inches.

SPACING OF POLES ON CURVES, INTERURBAN ROAD

Degree of curvature of track	Pole spacing, feet	Divergence of trolley wire from track center, inches	Degree of curvature of track	Pole spacing, feet	Divergence of trolley wire from track center, inches

Catenary Construction. — Modern practice regarding catenary construction is illustrated in the preceding table. The constructions on the N. Y., N. H. & H. R.R., and Pennsylvania R.R. are described in greater detail below.

Simple and Compound Catenary Construction. — Catenary construction may be divided into simple and compound. In the former the trolley wire or wires are carried by one or two messenger cables which are supported only at the poles, bents or span wires; in the latter, the horizontal wire or wires are carried by a messenger cable, which is itself suspended by another messenger cable which is supported at the poles, bents or span wires. The advantages of the compound catenary are greater flexibility, reduced stresses in the supporting wires, shorter hangers, better lightning protection and superior curve construction. (*See description of N. Y., N. H. & H. R.R., construction below.*) The simple catenary is sometimes made with two messenger cables from which the horizontal wire or wires are suspended by triangular frames.

To obtain a line which will not require frequent readjustment, the messenger cable must be installed with practically uniform tension throughout its length, making it necessary to have less sag in the shorter spans. For this reason certain definite pole spacings and corresponding hanger lengths have been standardized (*see next section below*).

TANGENT CONSTRUCTION

Number of Hangers per Span. Pantagraph or Bow Trolleys

Length pole spacing, feet	Number of points of suspension	Length of hangers, inches

spensions. — (*See also p.* 1841.) The number of suspensions depends speed at which the cars are to be run and upon whether a bow or wheel used. The three-point suspension in which, with 150 feet spacing, s are 50 feet apart has been found ample for wheel collectors at speeds m.p.h. With the sliding pantagraph or bow trolley an eleven-point has been found sufficient, with 150 feet pole spacing.

ngers. — (*See also p.* 1842.) Where only one horizontal wire is sus- om the messenger cable, the hangers should hang loosely from the should be screwed fast to the trolley wire. This permits the trolley e slightly as the trolley passes under it, thereby making the wire rible along its entire length. Where a steel contact wire is clipped to ntal conductor, the hangers are usually rigidly attached at both ends, lication of horizontal wires assures uniform flexibility, regardless of s.

nd Equipment or Erection. — Work should be done, as far as prac- h the aid of a construction train at least five cars long and equipped le scaffolds. With such a train the following daily results are attain-

	Men	Number erected
Erecting poles	26	117
Erecting brackets	18	150
Stringing catenary	17*	7 miles
Stringing and splicing trolley wire	12*	7 miles
Clipping messenger and trolley	13*	3½ miles

* Exclusive of train crews.

L EXAMPLES OF CATENARY CONSTRUCTION. — The amples are given to illustrate in greater detail the methods employed construction.

rk, New Haven & Hartford R.R. — The various types of con- ccessively adopted by this company are all for high-speed traffic. l construction consisted of a simple catenary system made rigid by

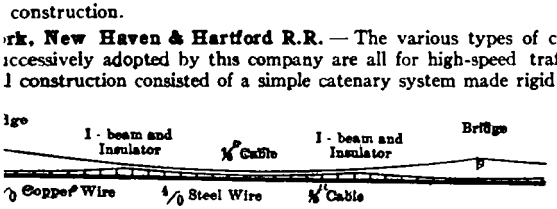

Fig. 33

two steel messenger cables with equilateral triangular steel pipe fferent lengths, joining them to the copper trolley wire. This having to be too rigid was modified by the addition of a steel contact wire rom the copper wire by clips midway between hangers. Considera- nomy and the desirability of securing better lightning protection doption of a compound catenary, that is one in which one messenger ported from another by suspension insulators, the upper cable being The copper wire is supported horizontally by suspensions of suit- s from the lower steel cable and a steel contact wire clipped to the

copper wire midway between hangers as shown in Fig. 33. Both of the ab types of construction involve the use of heavy lattice steel bents spaced 300 apart.

Pennsylvania R.R. — While both types remain in successful operation the N. Y., N. H. & H. R.R., a less expensive one was developed for the N York Connecting Railroad and the Philadelphia & Paoli Branch of the Pe sylvania Railroad. This construction is especially suitable where there opportunity to use guy poles instead of lattice bents. In this construct pairs of guyed steel poles, one on each side of the track, are spaced 300 f apart. The two poles of a pair are joined by two messenger cables as shown Fig. 34, making a small catenary system across the tracks with a vertical s

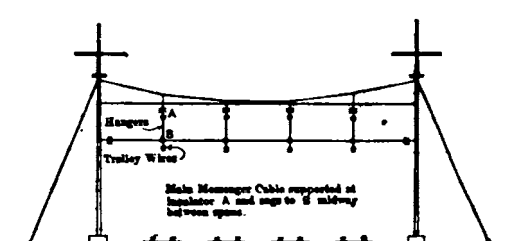

Fig. 34

pension rod over the center of each track. The upper of these cables has diameter of 5/16 inch and the lower of 1/2 inch. The vertical rods are 3/8 in in diameter and terminate in malleable iron clamps. An insulator consisting of three 10-inch porcelain disks is attached to each of these clamps and the main messenger cables suspended therefrom over the center of each track. These messenger cables consist of 1/4-inch double galvanized extra strong steel. The usual No. 2–0 grooved copper wire is suspended from this messenger cable by hangers 30 feet apart and a No. 3–0 phonoelectric contact wire is clipped 1 3/4 inches below the copper wire.

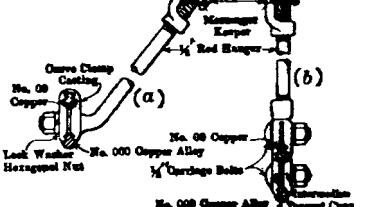

Fig. 35

The hangers used for supporting the copper wire are shown in Fig. 35. They are made of hot-galvanized steel.

To prevent side swaying of the lower wires in heavy winds a steady-brace is installed between poles and wires. These consist of steel wires insulated from the structure by strings of three porcelain insulators similar to those used to support the messenger cable. The contact wires themselves are insulated from it by single wooden strain insulators 6 inches long.

On the curves, steadies or pull-offs are used, but the hangers between the main messenger cables and the copper wires are spaced 15 feet instead of 30 feet as on tangents and the suspension rods are differently bolted as shown in Fig. 35.

e guys are 1 ½-inch rods attached to the poles through collars provided buckles. They are anchored in reinforced concrete blocks 8 feet or w ground and protected from the ground by 3-inch boiler tubes.

», Milwaukee & St. Paul R.R. — The 3000-volt trolley system of & St. P. R.R., comprising 660 miles of electrified trunk line, has two ntact conductors suspended by alternate hangers from the same This enables 2000 amperes to be collected by a copper-shod panto- ector at a speed of 60 m.p.h. The return circuit has an aerial con- ich is connected to the track rails every 8000 feet, preventing the : of dangerous voltages at rail joints in case of broken bonds.

onstruction. — In yards, wire cross-spans between poles, are used the messenger cables the insulators being suspended from the by ⅛-inch soft-steel cable. A horizontal steady-wire insulated slightly above the level of the contact wire supports the steady- which the contact wire is clipped. On curves, an additional insulated : is attached to the messenger wire at the poles. The messenger n reduced from ⅝ inch to ⅜ inch and the hangers are spaced 15 feet s and 10 feet on curves. A copper contact wire is not required.

d Sections. — Main-line conductors are usually divided into m cross-over to cross-over. Wherever conditions permit, sections are y staggering the contact wires laterally and running the two wires out 18 inches apart, each to a separate insulator. The ends are o avoid catching the pantograph.

s. — Turnouts are made by means of steel deflectors or frames the diverging wires at a fixed angle apart.

in Spans. — The stresses in the ⅛-inch cable of the original onstruction of the N. Y., N. H. & H. R.R. are as follows on a tangent an:

Condition	Tempera- ture, ° F.	Sag, ft.	Stress, lb.
Normal	60	6.42	7,550
Normal	−10	5.71	8,550
Sleet and wind	−10	6.46	14,750

s in the ⅛-inch cable of the original triangular construction of the [. & H. R.R. are as follows on a tangent 140-foot span:

Condition	Tempera- ture, ° F.	Stress, lb.
Normal	60	4930
Normal	−10	7100
Sleet and wind	−10	8400

in the copper wire and contact wire are negligible. Sleet is assumed : wire to a depth of one-half inch and the wind is assumed to exert of ⅜ of 8 pounds per square foot.

Digitized by Google

Hangers. — The longest hangers of the original triangular construct of the N. Y., N. H. & H. R.R. (140 feet apart) have a length of 15½ inc measured between centers of wires. The shortest hangers are 4½ inches l For main-line construction they are made of ¼-inch rods, for yards, of ⅜-i rods.

SPECIFICATIONS. — (*See also article on Specifications.*) Specificat for trolley wire are given under *Wires and Cables, Bare*, and for insulators *Insulators for Overhead Lines*. The specifications of the American Ele Railway Engineering Association, which refer to overhead trolley systems, as follows:

Specifications for Overhead Line Material (for 750 Volt Direct-Cur Direct Suspension).

Railroad Specifications for Electric Light, Power Supply and Trolley Li Crossing Steam and Electric Railways.

These two specifications aggregating 87 pages contain a great deal of valua data, including drawings of various detail parts and general layouts.

OPERATION. — The operation of overhead lines for low-speed cars pres few difficulties owing to the adaptability of the trolley pole and wheel at s speeds. With high-speed cars the case is different as the collector wheel rapidly and the line must be kept uniformly level, smooth and elastic throu out and all special work must be maintained in first-class condition. If the c lector vibrates in resonance with the loops in the contact wire, an increase in number of supports will usually cure the trouble.

Prevention of Formation of Sleet. — Sleet may be prevented from for ing on the wires by greasing the latter with petroleum jelly and if it does fo it may be easily removed by any of the numerous commercial forms of sl cutters.

Wear of Trolley Wheel, Bow and Trolley Wire. — The wear of t trolley wires is not serious either with wheel or bow collectors. On the lines the Indianapolis & Cincinnati Traction Co., a copper trolley wire lost less tha 1 per cent in weight after it had experienced 39,000 car movements, each c taking an average of about 40 amperes by an aluminum slider.

The vertical wear of the steel contact wire on the N. Y., N. H. & H. R.R. was 0.028 inch in thirty months, which is practically 4.5 per cent per year of the ful diameter of the wire (one-half taken to permit wire to be held in clips) which even on this vertical diameter basis, indicates a life of over 20 years; but as a matter of fact it will be much more than this, for the reason that as the vertical diameter lessens the breadth of contact increases throughout, thus diminishing the rate of vertical wear. There is practically no corrosion on the under side of the wire where there is much traffic, for the wire is covered with a film of grap deposited by the pantograph shoe (*W. S. Murray*). The upper part, however rusts and rain water washes the rust on to the roofs of the cars (*Amberg*).

Change in Length of Trolley Wire. — The change in length of copper due to changes in temperature is one of the greatest difficulties in the maintenance of overhead work. A drop of 100° F. in temperature will cause a copper bar to contract approximately 1 inch for every 100 feet of length. If it be restrained, at the ends this will cause an additional stress of 2500 pounds in a No. 0000 trolley. (*See Transmission Lines.*)

European catenary lines are usually maintained at constant tension by means of weights pulling on the free ends of the trolley wire at the end of every section.

Flashing. — Considerable trouble has been experienced with flashing on high-voltage d-c. lines. This has been largely overcome by placing a resistance shunt across the station buses to shunt out the harmonics set up by the shun

of the machine armatures. In addition to the above, flash suppressors consisting of electrically operated switches that kill the field of the excited d-c. generators, thereby killing the d-c. voltage instantly. riers are also used on the high-voltage commutators.

NG OF TROLLEY CIRCUITS. — Trolley lines have to be tested, sistance, and (2) for insulation from ground. The resistance may ed by grounding one end of the wire to the track rails and circulat- it at reduced voltage. The drop in the overhead lines may be using another trolley wire, a telephone wire or the earth as a ead. If the earth is used, the connections to ground should be suffi- from the track rails to be outside the zone of potential disturbance *olysis of Underground Structures*).

RS OF TROLLEY CIRCUITS. — The repair methods of four lways are given below.

lphia Rapid Transit Co. — The overhead line organization is in he Superintendent of Overhead Lines and is divided into maintenance uction crews, emergency crews, a pole crew and one special crew on and electric switch and signal maintenance.

ntenance and construction crews and the pole crew are under separate The emergency crews and the electric switch and signal crew report ie Superintendent of Overhead Lines.

ntenance and construction foreman has four crews, each consisting men, one helper and a driver. The pole gang consists of the foreman, oreman, five helpers and two drivers. There are also two men who rs to sidewalks and metal awnings in connection with the pole work. ni.e emergency stations, seven of which are manned for 24 hours id two for twelve hours per day. These stations care for approxi- miles of line each, taking care of line troubles, traffic blockades and t of the line repairs in the district. They, however, when needed, calls in other districts. The movements of these emergency crews led by telephone by an emergency operator at headquarters to whom is reported and who keeps a log sheet showing all movements of these ey do not leave their stations except on his orders.

these emergency stations are equipped with two-ton auto trucks elescopic towers. Four stations are each equipped with two-horse ower wagon and four horses. One of these wagon stations has also truck equipped for handling wrecks but not line troubles.

ion to the above there are tower trolley cars for heavy work located these stations.

United Railway Company. — The maintenance and construction consists of three gasoline power line wagons, one three-ton horse idlass truck, one single truck line car, and one double truck line car, vith hoist and windlass. The gasoline power wagons and line cars manned by one foreman, two line men, a driver or trolley man.

rgency station is located in the center of the city and serves twenty- of city line. Its equipment includes three gasoline power line wagons asoline wrecking and hose jumper wagon. These men are on duty ncy work during the day time and four at night.

rgency station is the headquarters for all equipment.

Traction System. — The line is divided, for overhead maintenance into districts averaging 90 miles in length. A line foreman and s are assigned to each district and are given a tower line car with rew.

COST OF COMPOUND CATENARY ON TANGENT, N. Y. N. H. & H. R.R. PER MILE OF SINGLE TRACK

(E. J. Amberg, 1915)

Item	2-track	4-track	6-track
Catenary Material	$2800	$2800	$2800
Catenary labor and work train	600	600	600
Steel work erected	2300	2200	3300
Foundations installed	800	800	800
Total	$6500	$6400	$7500

The cost per mile of 2400-volt, single-track distribution system (including feeders and bonding), on the Butte, Anaconda & Pacific Ry Co. was given by J. B. Cox as $5514 per mile of single track (1915).

EY SYSTEMS, UNDERGROUND.— (*See also Trolley Systems,*
This system is little used on account of its cost, the installations at , New York, Washington and London being the only notable ones. ial feature of all these systems is the underground conductor which from the car by a "Plough" extending through a continuous slot the tracks.

'ORK SYSTEM. — The most successful construction is the latest type, a brief description of which is given below.

l Description. — The street is excavated and cleared of obstructions ı of about 5 feet 6 inches and a depth of about 3 feet and cast-iron . 1) set in the excavation about 5 feet apart. The track and slot pported on these yokes and the whole system made solid with con- ı fills the excavation from the foundation to near the top of the rails / a tunnel under the slot free from masonry. The conductors are sus- his tunnel, by special strain insulators, no part of the electrical system ıded. The use of two insulated conductors avoids trouble in case ıl grounding.

The yoke shown in Fig. 1 is made in three parts. The lowest ı rests on the floor of the excavation is a 6-inch steel I-beam, 4 feet g. Two castings 6½ : are riveted to this, rving to support one ıd one slot rail. Fig. th slot rails in place ne track rail. The carried on a timber ch extends from yoke g the whole line. The e held to the yokes unk iron plates the ends of which project beyond the stringer and have accommodate bolts running through the yoke. These bolts serve ıal purpose of fastening the rails to the stringers as they also pass s which bear upon the foot of the rail. The rails are further secured s running to the center of the yoke. The slot rails are bolted direct and are connected to the track rails by long bolts every 30 inches.

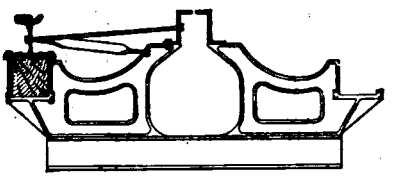

Fig. 1.

· Boxes. — A pair of cast-iron boxes are laid across from the slot track rails and bolted to them every 15 feet as shown in Fig. 2. ain the insulators ort the contact con- nside each box is a ves running normal k; resting on these bolted to them is a idge which holds the The top of the box l with a cast-iron ı is flush with the :e.

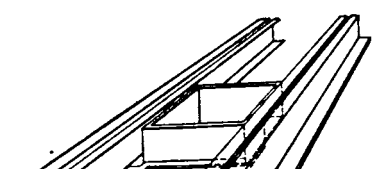

Fig. 2.

Work. — When the laid the tunnel which the conductors and ıing is formed with collapsible sheet iron, fitting closely to the center he yokes and run from yoke to yoke. The space from the bottom

Digitized by Google

of the insulator boxes to the road foundation is formed with boards. Con is then poured into the excavation completely filling every part but the and its offsets at the insulator boxes. The concrete is poured to wit height of a paving block of the rail tops. When the concrete is hard sheet-iron form is collapsed and pulled along to the next section. The at the bottom of the insulator boxes being collapsible are drawn out th

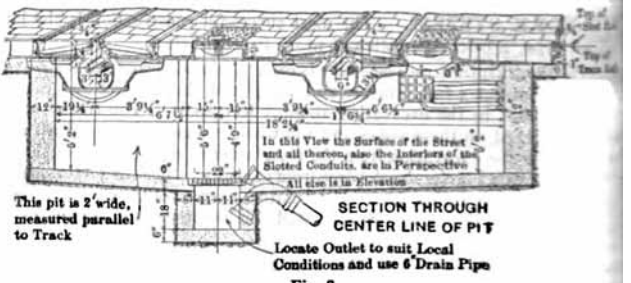

Fig. 3.

the handholes and are used again elsewhere. The depth of the comple tunnel is 18 inches from the base of the slot rails. A view of an older York City construction is shown in Fig. 3, which is taken from an artic the *Street Railway Journal*.

THE LONDON SYSTEM has alternate long and short yokes, the long fulfilling the same function as the New York ones, the short ones serving to give additional support to the slot rails. No stringers are used, the resting on hard-wood blocks at the yokes only.

THE BUDA-PEST CONSTRUCTION has the slot in the track rail saving considerable iron, but necessitating an excessively wide slot to acco date the wheel flanges.

COSTS. — The type of construction in New York City cost from $ to $100,000 per mile of track, exclusive of feeders, depending upon the cond under which it was installed. Due to the high cost of this system, its us not extended.

IS OF UNITS. — By the magnitude of any quantity is meant magnitude of this quantity as compared with some other quantity *ature;* e.g., a length of 10 inches means a length which is ten times of one inch. To measure a quantity, then, it is necessary either t first some fixed magnitude of the same nature which may be used rd of reference, or unit, or (2) to define the quantity in such a way it of measurement may be derived from the arbitrarily selected quantities involved in the definition.

ntal and Derived Units. — Units which are chosen arbitrarily fundamental" units; those which are derived from a set of fun- its are called "derived" units. All mechanical units can be de- set of three fundamental units; the three units ordinarily chosen ntal are those of length, mass and time. In relations involving changes, an arbitrary unit of temperature is also chosen; to ex- ical and magnetic quantities at least one electrical or magnetic arily chosen; to express photometric quantities the unit of luminous arbitrarily chosen. These arbitrarily chosen non-mechanical units uxiliary fundamental" units.

and Metric Systems of Units. — There are two systems of units in use in English speaking countries, the English and the metric, systems. The latter system is used universally by physicists ed countries and also forms the basis of the electrostatic and elec-

Digitized by Google

tromagnetic systems of electric units used by engineers as well as physici The English system of mechanical units, however, is used almost univers by English speaking peoples, in engineering, in commerce and in the arts; is also the basis of the system of thermal units used largely by engineers. gineers, however, are coming to use the metric system to a greater and gr extent for all purposes.

In both the English and the metric systems length, mass and time are ch as the fundamental quantities. In the English system the fundamental u for these three quantities are respectively the foot, the pound (avoirdu and the second; this system is therefore also called the foot-pound-sec system. In the metric system the corresponding units are the centim gram and the second; this system is therefore also called the centim gram-second, or c.g.s., system. The magnitudes of these fundamental u have been fixed arbitrarily by law; see below.

Absolute and Gravitational Units. — Two different units of force units derived therefrom) are used in both systems, viz.: (1) the unit of forc defined as that force which will give unit acceleration to unit mass, and the unit of force is defined as that force which will give to unit mass an acc ation equal to the acceleration of a freely falling body under the influenc "gravity" or the pull of the earth alone (*see Mechanics, Principles of*). The unit is called the "absolute" unit of force and the second the "gravitati unit of force, and derived units based on these two units are called abs and gravitational units respectively. The gravitational units are not def unless the latitude and elevation of the point at which the acceleration due gravity, usually represented by the symbol "g," is specified. By internati agreement (*Troisème Conf. Gen. des Poids et Mes., 1901, p. 66*) the v $g_0 = 980.665$ cm. per sec. per sec. ($= 32.1739$ feet per sec. per sec.) has chosen as the standard value for the acceleration due to gravity; this valu g may be called the "gravitational acceleration constant." The value 98 was chosen to represent the value of g at 45° latitude and sea level, but measurements give a slightly different value of g at this latitude and elevati the value 980.665, however, is retained as the *standard* value of g_0.

The gravitational unit of force in the English system is called the po and in the metric system the gram, the same names being used for the of force as for the unit of mass. This arises from the fact that unit mas a force exerted upon it by the earth, i.e., has a *weight*, numerically equal t mass, when the force is expressed in terms of this gravitational unit. (Th exactly true only at the latitude and elevation for which $g = g_0$, but the varia with both latitude and elevation is usually negligible in engineering work.*) absolute unit of force in the English system is called the poundal, but is pra cally never used; the absolute unit of force in the metric system is called dyne, and is the unit of force commonly used by scientists. In engineeri work the common units of force are the gravitational units, pound or gr and their multiples and submultiples.

The relation between the absolute and gravitational units of force are:

1 pound = 32.1739 poundals,
1 gram = 980.665 dynes.

Weight and Mass. — The word weight is used in two different sense viz.: (1) to mean the force with which the earth attracts a piece of matte

* The force acting on a mass of 1 pound at sea level at the equator is 0.997 pound, and at sea level at either pole of the earth is 1.002651 pound. An increase elevation of 10,000 feet diminishes the force acting on a mass of 1 pound by o 0.00096. See Landolt, Börnstein and Roth, *Physikalish-Chemische Tabellen*.

Digitized by Google

› designate a given mass or quantity of matter; in other words, weight › designate both force and mass. As commonly employed the term /ariably has its second meaning; that is, by a "weight of 10 pounds" a piece of matter which has a mass of 10 pounds. A weight (2nd 10 pounds has a weight (1st sense) of 10 pounds at 45 degrees latitude :vel (practically), but at any other latitude and elevation it has a it sense) slightly different from 10 pounds, and on the sun, for exam- have a weight (1st sense) many times 10 pounds.

connection it should be noted that a beam-balance when used in the /ay to compare two pieces of matter measures weight in the second it would "read" the same whether the measurement were made on or on the sun), that is, a beam-balance as ordinarily used compares l not forces. A beam-balance, however, is frequently used in testing nnection with a Prony brake, see *Index*) to compare a force produced hine with the pull on a standard mass (*or "weight"*) due to f great precision is desired the reading of the balance should then d for the value of "g" at the place of observation, but in ordinary nts the inaccuracy of the balance is likely to be much greater than orrection factor. For values of "g" at various places see reference bottom of preceding page.

ARDS OF THE FUNDAMENTAL UNITS. — The physical ıpon which the c.g.s. system of units is based, and the legalized f the foot and pound used in Great Britain and the United States ed below.

l of Length. — The standard meter (100 centimeters) is the dis- een two lines on a platinum-iridium bar carefully preserved at the Weights and Measures, at Sevres, France, when the bar is kept at emperature of zero degrees centigrade throughout. In the United ard (3 feet) was defined by Act of Congress, July 28, 1866, as

$$1 \text{ U.S. yard} = \frac{3600}{3937} \text{ meter},$$

y the British imperial yard is defined by law as

$$1 \text{ British imperial yard} = \frac{3600}{3937.079} \text{ meter}.$$

ring purposes the U. S. and British yards may be considered as

of Mass and Force. — The standard kilogram (1000 grams) as a is a cylinder of platinum preserved at the Bureau of Weights and t Sevres, France. The U. S. pound avoirdupois is defined by law *ress, 1866*) as $\frac{1}{2.2046}$ kilogram, but in 1893, the Superintendent of l Measures, with the approval of the Secretary of the Treasury, e pound to be

$$1 \text{ U. S. pound} = \frac{1}{2.204622} \text{ kilogram}.$$

imperial pound has the same value.

relations between pound and kilogram hold whether these units units of mass or as units of force, the unit of force being defined in

* Bull. Bureau Standards, 1904, Vol. 1, p. 380.

Digitized by Google

both cases as the pull of the earth on unit mass at 45 degrees latitude and level.

Standard of Time.—**The standard second universally adopted** is the $\frac{1}{86,400}$ th part of a mean solar day. The solar day is the interva time between two successive transits of the sun across a meridian of the e at the point of observation; this interval varies in length at different ti during the year, but the average length of the interval for one year is cons as far as can be determined by any known methods of observation.

STANDARDS OF THE AUXILIARY FUNDAMENTAL UNITS. The standards of temperature, dielectric coefficient, magnetic permeabili luminous intensity ordinarily used are defined below.

Standard of Temperature. — Two units of temperature, or tempera scales, are commonly employed, viz., the centigrade and the Fahrenheit s The relation between these two units results solely from the manner in w they are defined.

$$1 \text{ degree centigrade} = \frac{9}{5} \text{ degrees Fahrenheit.}$$

Due to the difference in the zeros of the two scales, a temperature of t_f deg Fahrenheit corresponds to a temperature of

$$t_c = \frac{5}{9}(t_f - 32) \text{ degrees centigrade,}$$

and vice versa,

$$t_f = \frac{9}{5} t_c + 32 \text{ degrees Fahrenheit.}$$

Standards of the Auxiliary Fundamental Electrical Units. — Three tems of electrical and magnetic units are in use, viz., (1) the c.g.s. elec static system, (2) the c.g.s. electromagnetic system, and (3) the practical sys In the c.g.s. electrostatic system the dielectric coefficient k of air at 0° C 760 mm. mercury pressure is arbitrarily chosen as unity. In the c.g.s. elect magnetic system the magnetic permeability of air under the same stand conditions is arbitrarily chosen as unity. In the practical system a con standard of the unit of resistance (called the ohm) is arbitrarily chosen *Units, Practical Electrical*); this unit resistance was originally designed t equal to 10^9 times the unit of resistance in the c.g.s. electromagnetic syst and within the limits of ordinary experimental error this relation may st considered exact.

Use of the Prefixes "Stat" and "Ab."— To designate the electri and electromagnetic units in the electrostatic and electromagnetic systems units respectively the prefixes "stat" and "ab" may be used with the name of t corresponding practical unit. For example, the c.g.s. electrostatic unit of qu tity may be called the statcoulomb and the c.g.s. electromagnetic unit of quant may be called the abcoulomb. For the names and definitions of the vari electrical and magnetic units see the article on *Electricity and Magnet Principles of*.

Standards of Luminous Intensity. — Two standards are in use, the int national candle and the hefner, the latter being used chiefly in Germany. S article on *Photometric Quantities* for the specifications for these units.

EXPERIMENTALLY DETERMINED CONVERSION FACTORS.— By conversion factor is meant the numerical factor which gives the magnitude one unit for any given quantity in terms of any other unit for the same quantity

Digitized by Google

e, in the expression 1 yd. = 3600/3937 meter, the factor 3600/3937 is
ion factor between the yard and the meter.
se of two units for the same quantity based on two different sets of
chosen units which are defined independently, the conversion factor
ained only by experiment. The more important experimentally
conversion factors are given in the paragraphs immediately following.

- and Water-column Pressure. — To convert pressure per unit
eight of mercury column the density of mercury must be known.
l Scheel (*Zeitsch. f. Instrk. de., 1898, Vol. 18, p. 138*) give the density
at 0° C. as 13.59545 grams per (cm.)³. Using the standard value
tational acceleration constant, $g_0 = 980.665$, the relation between the
. cm. and 1 cm. of mercury column at 0° C. is then

1. mercury column at 0° C. = 13332.6 dynes per sq. cm.

lensity of water as 1 gram per (cm.)³ at 4° C.,

m. water column at 4° C. = 980.665 dynes per sq. cm.

cal Equivalent of Heat. — Very useful units of energy are those
the mass of a standard substance and temperature, viz., the heat
ergy) required to raise the temperature of a specified mass of water
umber of degrees; see *Heat and Thermal Properties*. The experi-
ermined relation between the mean small calorie (i.e., the one-hun-
f the heat required to raise the temperature of 1 gram of water
o 100 C. at 760 mm. mercury pressure) and the erg is

1 mean small calorie = 4.1834×10^7 ergs.

nd Davis, *Steam Tables and Diagrams*, N. Y., 1912. From this
the relations (fixed by definition) given above between the yard
er, the pound and the kilogram, the value of the gravitational
constant g_0, and the two temperature scales, Marks and Davis,
relation

1 British thermal unit = 777.52 foot-pounds.

hermal unit as here used is defined as the $\frac{1}{180}$ th part of the heat
aise the temperature of 1 pound of water from 32° F. to 212° F. at
cury pressure. See also *Heat and Thermal Properties*.
imentally determined conversion factor between the energy unit
units of temperature and mass, and the energy unit based on the
h, mass and time, i.e., the unit of mechanical work, is called the
equivalent of heat."

between the Three Systems of Electrical Units. — The
relation, experimentally determined, between the c.g.s. electrostatic
electromagnetic system is that

1 abfarad = 9×10^{20} statfarads,

nsequence of the definitions of the various terms is equivalent to
mb = 3×10^{10} statcoulombs, the erg being the unit of
th systems.
nental relations between the c.g.s. electromagnetic system and the
em are

1 abcoulomb = 10 coulombs,
1 erg = 10^{-7} watt-seconds, or joules,

Digitized by Google

the erg being the unit of energy in the c.g.s. electromagnetic system as watt-second or joule the unit of energy in the practical system.

Relation between the International Candle and the Hefner. — experimentally determined relation is

1 hefner = 0.9 international candle.

MULTIPLES AND SUBMULTIPLES OF UNITS. — Multiples submultiples of the metric units are designated by the following prefixes; relations are *definitions* and are therefore absolutely exact.

micro = $\frac{1}{1{,}000{,}000}$	or	10^{-6}
milli = $\frac{1}{1{,}000}$	or	10^{-3}
centi = $\frac{1}{100}$	or	10^{-2}
deci = $\frac{1}{10}$	or	10^{-1}
deka = 10	or	10
hecto = 100	or	10^{2}
kilo = 1,000	or	10^{3}
myria = 10,000	or	10^{4}
mega = 1,000,000	or	10^{6}

The multiples and submultiples of the English units are given in bold type in the tables below.

CALCULATION OF CONVERSION FACTORS. — The conve factors noted above, which are either definitions or results of experiment, the basis for the calculation of the conversion factors for the various de units. The method of procedure is first to express one of the pair of units *A*, in terms of its component units (length, mass, time, temperature, cap or resistance, and luminous intensity), then express the magnitude of ea these units in terms of the corresponding component units of *B*; the va the resultant numerical factor is the conversion factor. For example, let i required to find the conversion factor between pressure in pounds per sq foot and pressure in dynes per square centimeter.

$$1 \text{ lb. per sq. ft.} = \frac{(1 \text{ lb. force})}{(1 \text{ ft.})^2}.$$

$$1 \text{ lb. force} = \frac{1}{2.204622} \times (1 \text{ kilogram force}).$$

$$1 \text{ kilogram force} = 1000 \times (1 \text{ gram force}).$$

$$1 \text{ gram force} = 980.665 \times (1 \text{ dyne}).$$

Therefore

$$1 \text{ lb. force} = \frac{1000 \times 980.665}{2.204622} \times (1 \text{ dyne}).$$

Also

$$1 \text{ ft.} = \frac{1}{3} \times (1 \text{ yd}).$$

$$1 \text{ yd.} = \frac{3600}{3937} \times (1 \text{ meter}).$$

$$1 \text{ meter} = 100 \times (1 \text{ cm.}).$$

Digitized by Google

$$1 \text{ ft.} = \frac{1}{3}\left(\frac{3600}{3937}\right) \times (100) \times (1 \text{ cm.}).$$

$$\frac{1 \text{ lb. force}}{(1 \text{ ft.})^2} = \frac{1000 \times 980.665 \times (3 \times 3937)^2}{2.204622 \times (3600 \times 100)^2} \times \frac{(1 \text{ dyne})}{(1 \text{ cm.})^2}$$

$$= 478.799 \times \frac{(1 \text{ dyne})}{(1 \text{ cm.})^2}.$$

$$\frac{(1 \text{ dyne})}{(1 \text{ cm.})^2} = 1 \text{ dyne per sq. cm.}$$

1 pound per sq. ft. = 478.799 dynes per sq. cm.

SIONAL FORMULAS. — Instead of writing the expression for a : in words, it is frequently convenient to express it in algebraic sym- . specific symbol for each of the fundamental or auxiliary fundamental example, let L stand for a length of 1 centimeter, M for a mass of T for a time interval of 1 second; then the unit of force in the c.g.s. tem (the dyne) may be written

$$F = MLT^{-2},$$

: same as 1 dyne = (1 gram) $\times \frac{(1 \text{ cm.})}{(1 \text{ sec.})^2}$.

, such as $F = MLT^{-2}$, where each letter represents the magnitude nit of the quantity for which it stands, is called a "dimensional for-)ure number, or a quantity which is the ratio of two units of the sions, such as an angle, has zero dimensions and does not appear onal formula.

nal formulas are useful for two purposes, viz., (1) as a systematic calculating conversion factors and (2) as a check of algebraic for- sing various relations. Unless one has a large number of conversion lculate it is probably simpler to use the direct method given in the ction. Certain quantities, for example, work and torque, may me dimensions although they are physically entirely different. ch quantities are physically different their conversion factors are The second use of dimensional formulas is based on the fact that n any set of terms connected either by equal signs, plus signs or must have the same dimensions.

plete list of the dimensional formulas for the various mechanical, ermal, and photometric quantities see Hering, C., *Conversion Tables*, . In the tables below are given, in the parentheses after the mensional formulas of the mechanical quantities in terms of length, ne, designated by L, M and T respectively. For the electrical and antities the dimensions are expressed in terms of electric potential quantity of electricity Q and time T. In the *c.g.s. electromagnetic* its Q may be expressed in terms of L, M, and T by the formula

$$Q = L^{\frac{1}{2}}M^{\frac{1}{2}}\mu^{-\frac{1}{2}};$$

lectrostatic system by the formula

$$Q = L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-1}k^{\frac{1}{2}}.$$

ms $VQ = L^2MT^{-2}$ = energy.

UNITS, PRACTICAL ELECTRIC. — (*See also Electricity and Magnetism, Principles of; Units and Conversion Factors.*) Following the recommendation of the Chicago International Electrical Congress of 1893, the following Act was passed by Congress. (Act approved July 12, 1894.) *Be it enacted, etc.* That from and after the passage of this act the legal units of electrical measure in the United States shall be as follows:

First. The unit of resistance shall be what is known as the international ohm, which is substantially equal to one thousand million units of resistance of the centimeter-gram-second system of electromagnetic units, and is represented by the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice fourteen and four thousand five hundred and twenty-one ten-thousandths (14.4521) grams in mass, of a constant cross-sectional area, and of the length of one hundred and six and three-tenths (106.3) centimeters.

Second. The unit of current shall be what is known as the international ampere, which is one-tenth of the unit of current of the centimeter-gram-second system of electromagnetic units, and is the practical equivalent of the unvarying current, which, when passed through a solution of nitrate of silver in water in accordance with standard specifications, deposits silver at the rate of one thousand one hundred and eighteen millionths (0.001118) of a gram per second.

Third. The unit of electromotive force shall be what is known as the international volt, which is the electromotive force that, steadily applied to a conductor whose resistance is one international ohm, will produce a current of one international ampere, and is practically equivalent to $\frac{1000^*}{1434}$ of the electromotive force between the poles or electrodes of the voltaic cell known as Clark cell, at a temperature of fifteen degrees centigrade (15° C.), and prepared in the manner described in the standard specifications.

Fourth. The unit of quantity shall be what is known as the international coulomb, which is the quantity of electricity transferred by a current of one international ampere in one second.

Fifth. The unit of capacity shall be what is known as the international farad, which is the capacity of a condenser charged to a potential of one international volt by one international coulomb of electricity.

Sixth. The unit of work shall be the joule, which is equal to ten million units of work in the centimeter-gram-second system, and which is practically equivalent to the energy expended in one second by an international ampere in an international ohm.

Seventh. The unit of power shall be the watt, which is equal to ten million units of power in the centimeter-gram-second system, and which is practically equivalent to the work done at the rate of one joule per second.

Eighth. The unit of induction shall be the henry, which is the induction in a circuit when the electromotive force induced in this circuit is one international volt while the inducing current varies at the rate of one ampere per second.

SECTION 2. That it shall be the duty of the National Academy of Sciences to prescribe and publish, as soon as possible after the passage of this act, such specifications of detail as shall be necessary for the practical application of the definitions of the ampere and volt hereinbefore given, and such specifications shall be the standard specifications herein mentioned.

NOTES ON THE ABOVE DEFINITIONS. — The specifications mentioned above were prepared by a committee, and their report, based on the best

* Later experiments give an e.m.f. of 1.4328 volts at 15° C.

Google

t had been done up to that time, was accepted and adopted by the Academy of Sciences on February 9, 1895.
on is called to the wording of the definitions of the three fundamental :

international ohm is based upon, but *not stated to be equal* to, 10^9 s of resistance; it is, however, *definitely defined* in terms of a column of

international ampere *is* one-tenth of the c.g.s. unit of current, and is be represented *sufficiently well for practical purposes* by the current osits a definite mass of silver per second under specified conditions.
international volt is the e.m.f. which will cause an international ampere rough an international ohm, and is stated to be represented *sufficiently actical purposes* by a definite fractional part of the e.m.f. of the Clark

ient investigation has shown that the figures for the silver voltameter 'lark cell are not equivalent. The e.m.f. of the Clark cell is really ernational volts at 15°.

'ICAL STANDARDS. — The Act of July 12, 1894, is still in force tage has been taken of the manner of stating how the international e practically realized to use as a standard of e.m.f. the Weston normal l of the Clark cell (*see Cells, Standard*).
l resistance coils (*see Resistors, Standard*) are used as secondary of resistance. These are usually accurately adjusted by the makers. .t accuracy is required these standard resistances should be sent to 1 of Standards for calibration. Much more accurate results can be n an ordinary laboratory by using properly calibrated secondary than by attempting to construct primary standards in accordance efinitions in the above Act.
of a voltameter for the calibration of current-measuring instruments r seldom employed. A more accurate method for ordinary laboratory determine, by means of a properly calibrated potentiometer (q.v.), drop produced by the current through a standard resistance.

UNLOADERS, COAL AND ORE. — (*See also Cranes; Motors, Industrial Applications of; Power Stations.*) Coal and ore unloaders may be divided into two distinct classes, namely, the stiff-leg type and the bridge type. Both are adapted to electric drive and each possesses certain advantages under certain conditions for which it is designed. Unloaders range in capacity from three to fifteen tons per bucket load. The capacity in tons per hour varies within wide limits, but records have been established where under normal operating conditions four 15-ton equipments unloaded 10,000 tons in five hours. The power required naturally also varies under different conditions, but an average of from 0.4 to 0.5 kilowatt hour per ton is not uncommon.

STIFF-LEG UNLOADERS (Fig. 1) are mainly used at receiving docks for unloading ore from the boat to railway cars or to a large concrete trough from which it is in turn transferred to the storage yards by means of ore bridges. The machine, as seen from Fig. 1, consists essentially of a massive pantograph the short leg of which forms an integral part of the carriage *C*. This leg is rigidly vertical, hence the stiff leg *L* which carries the bucket *B* must always be vertical. The weight of the moving parts of the link motion is nearly counterbalanced at *W* by the main hoist, rotation and bucket motors and their respective drums. The motor house on the carriage *C* contains the trolley motor and the magnetic control panels for all the above motors. The carriage is mounted on trucks and moves back and forth on the girder runway *G*. The girder structure supports a hopper with rotating gates which receives the ore from the bucket *B* and distributes it slowly to the weighing larry which in turn deposits it in the ore car underneath or in the concrete trough *I*. Cables from the main hoist drum at *W* are attached to the rear of the carriage. The operator rides in the bucket leg and has absolute control of lowering, opening, closing, bucket rotation, hoisting and trolleying movements. The entire girder structure is mounted on trucks and can be run along the dock at will by means of the bridge movement motor. Magnetic control is employed throughout and all motors except leg-rotation and bridge-movement motors are arranged for dynamic braking.

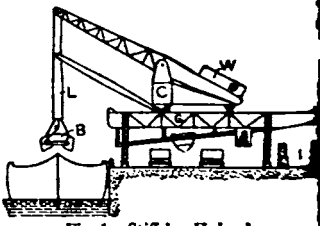

Fig. 1. Stiff-leg Unloader

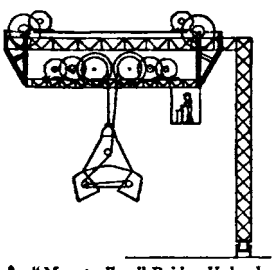
Cycles of Motor Movements. — The service of the main hoist and opening and closing motor is intermittent with continuous repetition of cycle often at the rate of one round trip per minute for several consecutive hours. The leg rotation motor is used chiefly in cleaning up the bottom of the boat between hatches and involves rapid and frequent reversals at irregular intervals. The trolley-motor cycle includes acceleration, free running, retardation, reversal and repeat with every bucket load hoisted. The ore-gate motor operates intermittently wherever ore is distributed to the weighing larry. The larry travel and hopper-gate motors both operate on a continuously repeated cycle of short duration. The bridge-movement motor is used only at irregular intervals for locating the bucket over the hatches.



Motor Equipment. — The following table shows the motor equipment of a modern unloader of the stiff-leg type. The main-hoist motor has a continuous rating, but all the others are rated on an intermittent basis.

TYPE OF MOTOR. — The selection of the most suitable type of motor f coal and ore bridge work must be determined for each specific installation b local considerations. In general the requirements are not quite as severe a those commonly included under the term "steel mill service," and standard indu trial motors in a few instances have been used for high-speed bridges with suc success. As a rule, however, especially for ore bridges, the mill-type motor i recommended, since even under the best conditions the short cycle, rapid an frequent acceleration, severe vibration, dirt and moisture, all demand the mo rugged construction.

The question of alternating- or direct-current motors is usually one of comparat tive first costs, costs of maintenance and operation. Where adjustable speed under variable load are required the induction motor with its constant-sp characteristics is somewhat at a disadvantage if compared with the direct-curre motor equipped with interpoles and best available control. For dynamic brak the direct-current motor also offers fewer complications in the control. Furth more, for the rack movement or trolley travel the acceleration losses are l for the series direct-current motor. On the other hand, the efficiency of tra formation and distribution of power is considerably higher for alternating- th for direct-current systems so that the apparent gain due to the characteristic o the series motor may be more than offset by the simplicity and ruggedness o the induction motor, the elimination of motor-generator sets, equalizer sets an in some cases even of static transformers.

S. — (*See also Boilers; Gas Engines; Pipes; Power Stations; Steam Steam Turbines.*) The following types of valves are used to control of fluids in pipes.

Valve. — The opening in this valve is perpendicular to the axis of the l is closed by a disk which moves across the opening. A gate valve t little resistance to the flow of the fluid, since when fully opened les a straight passage the full diameter of the pipe (*see Pipe and*

Valve. — In this valve the opening is in a partition parallel to and hrough the axis of the pipe. The opening is closed by a mushroom-isk which is screwed down against the partition. The name "globe" es from the globular form of the casing. The passage through a globe the general shape of the letter S, and consequently offers considerable to the flow (*see Pipe and Piping*). It is simpler in construction per than a gate valve, and the contact surfaces are more easily

Valve. — This valve has the inlet and outlet at right angles to each may therefore be installed in place of an elbow. The opening is at les to the inlet. The closing mechanism may be either of the gate or be type.

— This type of valve consists of a conical plug with a hole through licular to its axis, mounted in a suitable casing. The valve is opened g the plug so that the hole is in line with the pipe and is closed by plug a quarter turn. Cocks are frequently used on blow-off piping.

alves. — A stop valve is any valve that is controlled by hand or other ieans, and used to stop the flow of fluid in a pipe.

Valves. — A check valve is any valve which opens automatically pressure in the normal direction reaches a predetermined value, but losed when the pressure is less than this amount or is in the opposite Ordinary forms of check valves resemble a globe valve without a idle. The closing device may be a disk, ball or cup. When the disk l to swing about an axis like a hinge the valve is called a "swing check," alve," or "butterfly valve." When the disk or other device is lifted the valve is called a "lift-check valve." A check valve placed at f the suction pipe of a pump is called a "foot valve."

Valves. — Lift check valves provided either with a helical spring or l and lever mechanism to hold the valve closed under normal pressure as safety valves; the former type is called a pop safety valve, the ever safety valve. The pop safety valve has practically supplanted type, since it closes more promptly and is less liable to leak.

Valves. — Check valves used to relieve excessive back pressure in ric exhaust pipes are called "back-pressure valves," and when used ing to condensers to relieve excessive pressure are called "atmospheric es."

ng Valves are used when it is desired to obtain steam at a pressure hat of the boiler. In this type of valve the opening is relatively small, eam in expanding through this small opening has its pressure reduced. r size of opening for various rates of flow is maintained automatically ing the force produced on the closing mechanism by the pressure on essure side of the valve against the force produced on this mechanism al spring. The size of the opening then adjusts itself automatically in this balance irrespective of the rate of flow.

Digitized by Google

SELECTION OF TYPE OF VALVE. — For low-pressure work standard cast-iron valves with bronze seats have been more than satisfactory They are now made of a great many types, all of which give very good res The solid wedge gate is perhaps the earliest and the best known. The sp wedge type and the parallel two-gate type are also well known and larg sold. Globe valves are not usually used for steam work on account of t resistance offered to the passage of the steam, but for throttle valves and stop valves are still the standard. For high-pressure work and especially w superheated steam the use of the steel body valve with steel seats and di has becoms standard and many varieties of valves are now on the mark some of which are doing excellent work. Nickel-bronze and nickel are also u for seats and stems with good results. In choosing a valve for high-press and high-temperature work, great stress should be laid on the absence of cha for unequal expansion in the body and gates. The metal should be so pla that what expansion occurs will be equable in all directions and the gates designed that they cannot spring out of true under different degrees of h Such mechanism as may be used between the gates in a double-gate valve press them up against the seats should be as carefully designed as the body the valve, as small deflections in this part of the mechanism will prevent tig ness. The most satisfactory valves for this work have been of the doub wedge type, although there are good parallel seat and solid-wedge valves the market which have stood severe tests.

ELECTRICAL OPERATION OF VALVES. — (*See also Motors, Indu trial Applications of.*) The advantages of electrical motor operation for la valves is emphasized not only by the fact that such valves must be closed i very short time, which would be impossible with hand control, but also by t fact that remote control is very often essential, as, for example, in hydroelec power developments where it becomes desirable to control the gate valves fr the control switchboard. The service of valve motors is exceedingly intermitte and may vary from comparatively short intervals, such as once every hour, weeks or even months. Due to the intermittent nature of the service, efficien or power factor need not be considered in this kind of motor application, t main consideration being the most reliable system of operation.

Size of Motor. — The proper size of a motor for driving a valve will va with the duty and conditions under which the valve operates. A small val may only require a one-horse-power motor, whereas very large valves, su as the Stoney-Gate valves at Panama, require 40-horse-power motors. The r quired motor capacity also depends to a large extent on the pressure on t valve. When opening the valve, the torque is a maximum shortly after th time of unseating, that is, after the wedges have been released and the acti motion begins. The torque then drops some until the valve has opened abo one-fourth, after which it takes comparatively little power to complete the ope ing. When closing the valve, friction only needs to be overcome in starting i there is no pressure on the valve until it has begun to close. After the valve about three-fourths closed the pressure causes the torque to increase rapidl At the end of the closing cycle the torque does not, however, reach the valu did during the period of starting.

Type of Motor. — Either direct- or alternating-current motors may be use With the former the series- or compound-wound type is generally used as it giv a high starting torque. With the latter the squirrel-cage induction motor i most widely used for small- and medium-size valves, principally on account o its simplicity. To overcome the sticking when opening, the drive is sometimes provided with a "lost motion" so as to give a hammer blow. For alternating-

Digitized by Google

otors this is furthermore of value in that it permits the motor to speed nd gain in torque before the load comes on.

Equipment. — Where the size of the motor permits, the simplest control is to throw the motor directly on the line without the use of esistances. The automatic overload circuit breaker which should tection under normal operating conditions, must be prevented from ring the rush of starting current. This is readily accomplished either ircuiting the overload coil of the circuit breaker or by opening the s to the coil. The former is the preferable method as this will leave oad protection even though the coil is short-circuited. A push button provided for this purpose.

itches which will open the circuit when the gate has reached its limit hould always be provided. As a further precaution against over- o high closing torque the motors should preferably be geared to the s through efficient and reliable friction clutches.

e motors are too large to be thrown directly on the line, starting re- ust be provided. With direct-current series motors a permanent nd a running resistance are often provided. The permanent resist- ns fixed in the circuit and should be so dimensioned as to give the torque required. The running resistance is short-circuited at start- ie motor current drops to any desired value, at which time a current opens the shunt circuit of the contactor used for short-circuiting ice. This running resistance should be such as to prevent excessive ht load and to limit the torque should the valve seat itself before the sconnected. The same general scheme may be used with alternating- tors, but with these there is no danger of exceeding the synchronous

for Indicating Valve Positions. — When it is desired to indicate chboard the position of the gate throughout its range of travel, this be done by placing a number of sliding contacts on the inside of witch housing. These contacts are then connected with a row of nt lamps installed on the switchboard, and as the limit switch travels lamps on the board will light successively.

system, much more comprehensive, is used in connection with the rs at the Panama Canal. In connection with each limit switch there a "synchronizing transmitting device." This consists merely of a ator which is mechanically connected to and revolves with the limit is electrically connected to a small motor which is mounted on the tchboard and there mechanically connected to some sort of indicating as a pointer. When the generator at the valve revolves, the motor ird will follow in synchronism thus indicating the exact position of

VECTORS. — (*See also Complex Quantities.*) Any quantity which requ for its complete specification a magnitude and a direction is called a vec quantity. Such a quantity may be represented graphically by a line havi length equal to the magnitude of the quantity and a direction parallel to direction of the quantity. Such a line is called a vector. Its direction is general, specified by the angles which it makes with three arbitrarily ch lines or axes of reference. Vectors which lie in the same or in parallel pl are called co-planar vectors; the direction of a vector in the plane in which lies (or parallel planes) may be specified by the angle which it makes wit single line of reference in this plane.

Quantities which are completely specified by magnitude and "sense" (i whether positive or negative) are called scalar quantities. Forces, velociti displacements, etc., are vector quantities, while time, work, mass, etc., scalar quantities.

Vector Addition and Subtraction. — Since vector quantities cannot completely specified by ordinary numbers, the various operations of arithme such as addition, subtraction, multiplication and division have no mean when applied to such quantities. Analogous processes, however, are of gr value in dealing with them. For example, the resultant of two forces wh make an angle with each other is, by the ordinary parallelogram of forces, equal to the diagonal of the parallelogram formed by drawing from the free ends of the two lines representing the forces, lines parallel to these forces. That is, the resultant of OA and OB in Fig. 1 is the diagonal OC. Both the length OC and direction (the angle AOC) of the resultant is fixed by this construction. The resultant OC is called the vector sum of OA and OB. Similarly, the vector sum of OA and AB is equal to OB, or vice versa, AB may be called the vector difference of OB and OA. The angle XAB gives direction of this vector difference when OA is subtracted vectorially from O When OB is subtracted vectorially from OA the vector difference also has same length or magnitude, but is in the opposite direction, i.e., makes angle $180° - \angle XAB$ with OA.

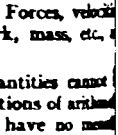

Fig. 1

Components of a Vector. — Any vector may be considered as made up any number of vectors which when added vectorially, as described above, gi a resultant vector equal to the given vector. It is frequently convenient analyzing problems involving vectors to resolve each vector into two comp nents, one parallel to and the other perpendicular to the axis of refere The first component is usually referred to as the horizontal component and second as the vertical component. It is readily proved that the horizontal com ponent H of the resultant (or vector sum) of any number of vectors is equ to the algebraic sum of the horizontal components h_1, h_2, etc., of the individu vectors, i.e.,

$$H = h_1 + h_2 + \text{etc.}$$

and the vertical component V of the resultant is equal to the algebraic sum the vertical components v_1, v_2, etc., of the individual vectors, i.e.,

$$V = v_1 + v_2 + \text{etc.}$$

The length of the resultant is then

$$S = \sqrt{H^2 + V^2}$$

Digitized by Google

akes with the axis of reference the angle σ where

$$\tan \sigma = \frac{V}{H}.$$

ical Representation of a Vector. — The geometrical representation plex quantity (*see Complex Quantities*) is a vector, i.e., the line repre- complex quantity has both magnitude and direction. Any vector may, therefore, be represented by a complex quantity, and the opera- ector addition and subtraction may be carried out by the ordinary of algebraic addition and subtraction of complex quantities. For ex- o vectors A and B may be represented by the algebraic expressions

$$\dot{A} = h_1 + jv_1,$$
$$\dot{B} = h_2 + jv_2,$$

nd h_1 and h_2 and v_1 and v_2 are the horizontal and vertical components re- , and the dots under A and B signify that $\dot{A}$ and $\dot{B}$ are vector quan- ie vector sum of $\dot{A}$ and $\dot{B}$ is then

$$\dot{S} = \dot{A} + \dot{B} = (h_1 + h_2) + j(v_1 + v_2),$$

the magnitude

$$S = \sqrt{(h_1 + h_2)^2 + (v_1 + v_2)^2},$$

igle

$$\sigma = \tan^{-1} \frac{v_1 + v_2}{h_1 + h_2}.$$

ication and Division of a Vector by a Number. — Multiplying a a real number n means taking a vector n times as long; dividing / n means taking a vector $\frac{1}{n}$ of the length of the original vector. The ultiplying a vector by an imaginary number jn is defined as a vector e length of the original vector and making a positive angle of 90° riginal vector. The result of dividing a vector by an imaginary is defined as equivalent to multiplying the vector by $\frac{1}{jn} = -j\frac{1}{n}$ equivalent to a vector $\frac{1}{n}$ of the length of the original vector and egative angle of 90° with the given vector. Hence the multiplication of a vector $h + jv$ by a complex number $n + jn$ is equivalent to lgebraic multiplication or division of two complex numbers (*see uantities*).

Product of Two Vectors. — Multiplication, in the ordinary sense, ctor by another has no meaning, since a vector is not a number but oth magnitude and direction. In the analysis of the more com- oblems of mechanics and electricity, certain expressions arise, how- are analogous to ordinary multiplication. One of these expressions quantity equal to the product of the magnitude of the two the cosine of the angle between them. This product is called the luct of the two vectors. The scalar product of the two vectors A $B \cos \theta$ where θ is the angle between them. If the vectors are as complex quantities

$$\dot{A} = h_1 + jv_1,$$
$$\dot{B} = h_2 + jv_2,$$

Digitized by Google

the scalar product is

$$h_1h_2 + v_1v_2.$$

Note that this has no relation to the algebraic product of the two expressi $h_1 + jv_1$ and $h_2 + jv_2$.

Vector Product of Two Vectors. — Another expression which arises a vector quantity at right angles to the plane of the two vectors and equal magnitude to the product of the magnitudes of the two vectors by the sin the angle between them. This product is called the vector product of the t vectors.

Example. — The vector product of the vector A by the vector B (Fig is $AB \sin \theta$, and is in the direction in which a right-handed screw, to the be of which A is conceived to be fixed, is advanced when A is turned through angle of less than 180° into coincidence with B. From this definition it fo lows that the vector product of B times A is equal but *opposite* to the vect product of A times B. When A and B are expressed as complex quantities t vector product of A times B is

$$h_1v_2 - h_2v_1.$$

Note that the algebraic product of the expressions

$$h_1 + jv_1 \quad \text{and} \quad h_2 + jv_2 \quad \text{is} \quad h_1h_2 - v_1v_2 + j\,(h_1v_2 + h_2v_1).$$

The real and imaginary parts of this expression are *not* equal to the scalar a vector products.

ON, LAWS OF. — (*See also Illumination, Laws of; Photometric ities; Photometry.*) Light enters the eye through the *cornea*, a thin, trans-, curved wall, and passes successively through the *aqueous humor*, the the *biconvex lens*, and the *vitreous humor* to an image on the rear wall *na*. The cornea and lens possess the image-forming function, and accom-ion to distance is given by the varying curvature of the lens. The humors ptical contact and preserve the size and form of the eye. The contraction ilation of the pupil gives automatic accommodation to the intensity and ity of light in the field of view. The retina adapts itself automatically sibility to the flux density of the light falling upon it; while comfortable covers a range of brightness of ten billion to one, the sensibility of the varies in the ratio of one hundred million to one.

retina comprises an elaborate structure of microscopic nerve terminals as rods and cones. In its periphery rods predominate, but the ratio of to rods increases steadily toward the axial region of *fovea*, where the cones y predominate. The directly visualized image falls on the fovea and the ness of perception diminishes markedly in passing to the periphery. At ow intensities rod vision predominates. At moderate and high intensi-one vision predominates. In the former state the relative sensibility to ue end of the spectrum is emphasized, in the latter state the relative sensi-to the red. As an optical system the eye has a chromatic aberration of imately two diopters.

EMENTS OF VISION. — Visual sensations in general are characterized tensity, extensity, quality and duration. Intensity refers to the aspects ion measurable photometrically, such as brightness and contrast, determin-ux density at the retina. Extensity involves the perception of contour, ective, relief, detail and distance. Quality discriminates between sensa-of color and non-color. Duration relates to the growth, fatigue, persist-nd intermittency of visual sensations.

ensity Relations. — For a given quantity of radiant energy, the luminous tion (light) varies with the wave frequency of the radiation, with its ity and with the time of exposure eye to it. The eye is most sen-and the ratio of light to energy maximum at a wave length of 0.000558 mm. in the green part e spectrum. Here the ratio of to radiation is about 0.0015 lu-per watt of radiation. From ave length the luminous equiv-of radiation decreases rapidly rd both shorter and longer wave lengths. It is about 0.0000006 lumen watt at wave lengths 0.00040 and 0.00073 mm. The data on the complete for ratio of light to radiation are given in the following table and in 1. These data are the means for about 200 subjects collected by Ives, ing, Coblentz and Hyde in four different laboratories. These data are cable to all moderate and high intensities. At very low intensities a ar curve displaced toward shorter waves obtains.

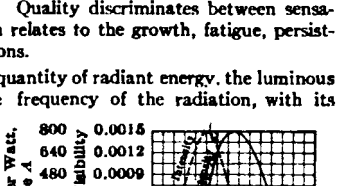

Fig. 1

Purkinje Effect. — Transition from vision at low intensity to high lves relative loss of sensibility to blue and gain of sensibility to red, so that lights of reddish and bluish hue respectively show a ratio of intensities h varies with the brightness of the field of view. This is known as the kinje effect. In fields above a brightness of one lumen per square foot the

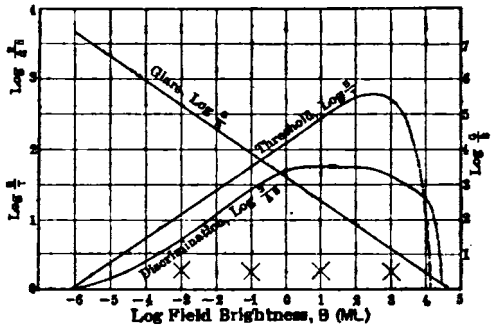
shift is slight. Photometric comparisons involving color differences should be made only in bright fields.

Intensity Sensibility. — For an eye viewing a field of a given brightness there exists for each brightness to which the eye is adapted (1) a minimum brightness just perceptible, (2) a ratio of brightness (contrast) just perceptible, (3) a maximum brightness just tolerable.



Field brightness		Difference fraction	Discrimination factor	Threshold limit	Glare limit

ief summary of the data on threshold limit, discrimination and glare given in the table at bottom of page 1888.

example, an average eye adapted to a field brightness of 0.1 m.l. can just ontrast of 1.037 : 1—the discrimination is about half (27/57) its maximum

The deepest shadow in which it can see anything is 0.0017 m.l. in ness and the brightest tolerable high light is 800 m.l.

l. Threshold, Discriminating Power and Glare Sensibility at Various Levels.

illuminating engineer is chiefly concerned with four quite distinct brightvels, namely:

0.001 m.l. (E.N.) Exteriors at night, street lighting.
0.01 m.l. (I.N.) Interiors at night, interior artificial lighting
1.0 m.l. (I.D.) Interior daylight lighting.
1.0 l. (E.D.) Exterior full daylight lighting.

glare sensibility (G) is a linear function of log field brightness (B) such that

$$\text{Log } G = 3.23 + 0.32 \log B,$$
$$G = 1700B^{0.32}.$$

reshold sensibility (T) is also a linear function of log field brightness at the highest intensities (over 0.1 lambert) such that

$$\text{Log } T = 0.66 \log B - 2.10,$$
$$T = 125B^{0.66}.$$

ility to **contrast** is nearly constant (about 2 per cent) over the wide of intermediate intensities with which vision is chiefly concerned.

RATE OF INCREASE AND DECREASE OF THRESHOLD SENSIBILITY

Time	$B_0 = 0$, $B = 25$m.l. Sensibility decrease	$B_0 = 25$m.l., $B = 0$ Sensibility increase
1 second	2.1 times	1.6 times
2 seconds	4.2 times	2.6 times
5 seconds	16.2 times	7.6 times
10 seconds	58 times	14.4 times
10 minutes	120 times	20.9 times

Effect of Alternate Exposures. — If an eye is fully adapted to a [illegible] of a given brightness, then suddenly exposed to a dark field it gains rapid sensibility as shown in the table on page 1889, while if adapted to dark and then exposed to a bright field it loses sensibility but at a lower ratio.

Since the loss of sensibility in a given interval is greater than the re[illegible] the net result of a succession of exposures to alternate light and darkness is a considerable *depression* of mean sensibility.

Color of Various Sources. — In monochromatic analysis white [illegible] is mixed with light of a pure spectral hue to match the color to be analyz[illegible] L. A. Jones gives the following color analyses of common light sources.

Source	Color	
	White	Hue
1. Sunlight	100	472
2. Average clear sky	60	472
3. Standard candle	13	593
4. Hefner lamp	14	593
5. Pentane lamp	15	592
6. Tungsten glow lamp at 1.25 w.p.c.	35	585
7. Carbon glow lamp at 3.8 w.p.c.	25	591
8. Nernst glower at 150 w.p.c.	31	586
9. Nitrogen filled tungsten:		
at 1.00 w.p.c.	34	586
at 0.50 w.p.c.	45	584
at 0.35 w.p.c.	53	584
10. Mercury-vapor arc	70	496
11. Helium tube	32	598
12. Neon tube	6	605
13. Crater of carbon arc:		
at 1.8 amperes	59	584
at 3.2 amperes	62	584
at 5.0 amperes	67	583
14. Acetylene flame (flat)	36	585

Extensity Relations. — Extensity is perceived largely through differen[ces] in brightness and color, by varying visual angles and by acuity, or the po[wer] of resolving detail. Acuity follows a logarithmic relation to brightness simi[lar] to the strength of sensation. The same practical lower limit, say from one to two lumens per square foot, affords a fair normal basis of acuity. Above this the gain in acuity is relatively much less than the increase in illumination. Acuity, however, is not independent of color, due to the chromatic aberration of the eye. Retinal images formed by approximately monochromatic light are sharper than those due to a rich spectrum. Luckeish (*see Elec. W., Vol. [illegible] p. 1252*) gives the data in Fig. 3 for the relative acuity with various colo[rs]. For near vision blue light is more readily focussed, whereas for distant visi[on] red light is more readily focussed.

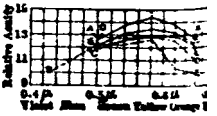

Fig. 3

Digitized by Google

lare. — The effectiveness of illumination is depressed to a marked
/ disturbing influences grouped under the term glare, which may be
ately defined as the relative overbrightness of part of the field of view.
glare, caused by the slowly changing adaptation of the eye when
from a dim region into a brilliantly lighted one, causes only temporary
t. Persistent glare, in addition to the depression of visual functions,
ighly injurious. No complete quantitative analysis of glare has yet
e. The following qualitative relations have been well established:

re effect, or reduction of visual effectiveness, increases as the glaring
proaches the eye. Glare increases as the ratio of the distance of the
urce to that of the visualized object from the eye diminishes. The
t which a light source ceases to be glaring depends on its intensity,
and position in the field of view.

e increases with the quantity of light received from the source.

e increases with the brilliancy of the glaring source and with its de-
ntrast to objects visualized. An automobile headlight is exceedingly
night, but not glaring by day. Any light source giving an after-
cessive in brilliancy. Glare due to this cause is accentuated by the
ency of the eye to wander from the object of vision and fix on the
urce, causing a fatigue of attention.

e increases as the retinal image of the glaring source approaches the
ie field of view. Depression of vision from side light is due in part
and in part to the dilution of the central image by light scattered
Glare due to bright walls and backgrounds is largely of the latter
glare from bright sources situated at an angle from the line of vision
6 degrees is generally negligible.

f practical cases of glare are due to directly visible light sources of
and brilliancy, to scattered light from side sources and backgrounds
ect reflection of bright images by glazed surfaces in the immediate
r. Prevention should be sought by the proper location and shading
irces, by creating suitable constrasts between the field and its
s and by avoiding the use of glazed surfaces, especially highly-sized

. — Below certain frequencies intermittent sensations retain a
distinctness and produce a flicker effect. If a critical frequency is
e sensations blend into a continuous effect equal in intensity to the
ity over the complete cycle. Examples are the rotating sectored
e electric lamp operated by alternating current. The vanishing
f flicker increases with the degree of variation from maximum to
nith the solid angle subtended by the object viewed and with the
its brightness. The vanishing frequency of flicker is higher for
or colored light. Within the common limits of practice the vanish-
y is between 30 and 45 cycles per second. Electric lamps display
le flicker in themselves or in illuminated objects at frequencies
cycles.

r Color Relations. — Non-colored sensations are white gray, and
r sensations differ in brightness in hue and in tone. The hue of
termined by the spectral position of its predominant component.
int depends on the degree of dilution with white or black. Thus
pink and claret may agree in hue, but differ essentially in tone.
ions are equal in brightness when they may be rapidly alternated
f view without the appearance of flicker.

thesis and Analysis of Colors may be accomplished by mixing red,
ue in proper proportions, or by diluting the predominant hue with

necessary to reproduce it. Tri-chromatic specification gives the mixing p portions of red, green and blue. Mono-chromatic specification gives the spe hue and the degree of dilution. The tri-chromatic analysis as determined the colorimeter (*see Photometry*) is of greatest practical utility. In this sy the proportions of red, green and blue found in average daylight, though equal, are taken as 33.3 per cent each to fix three color scales. The n proportions of these colors on the scales so established which reproduce given light serve to specify it and to compare its color composition with day

Relation of Color of Light to Appearance of Objects. — Ob appear in the colors which they reflect or transmit to the eye. To pro true color effects light must possess all the components necessary to re objects and possess them in proper proportions. If the spectrum is defici parts or its components differ greatly from the proportions in daylight it in general produce distorted color effects.

Artificial White Light. — With the exception of the carbon fi vacuum tube no artificial illuminant approaches closely the color value of light. White light may be approximated by synthesis by combining the of two sources, one excessive in red and the other excessive in blue, as the in descent electric lamp and the mercury arc. A closer realization may be obta from any incandescent lamp by means of a selective absorption screen w removes the excess of red and green light. The latter method involves a sacrifice of efficiency.

SUMMARY OF CONDITIONS FOR BEST VISION. — The su brightness of objects viewed should not be less than 0.0015 candle per s inch nor more than 1.5 candles. In terms of the illumination of ordinary paper these values correspond roughly to limits of 1 to 1000 foot-candles. value best adapted to any condition varies with the individual, the closen application the nature of the surroundings and the general degree of diff For reading by daylight 100 foot-candles is approximately the best cond

cial light approximately from 4 to 10. The degree of illumination is strongly influenced by the contrast between objects visualized and roundings. The high diffusion of daylight and the flatness of the con- ich it gives account in large measure for the higher illumination desired. seeing the objects viewed should be brighter than the surroundings, ontrast should not exceed 10 : 1. The illumination provided for work close application should be in inverse ratio to the reflecting power of minant surfaces. Directly visible light sources may generally be shaded a brightness of 2.5 candles per square inch with advantage to vision. ns outlined under *Glare* should be observed.

ccompanying table indicates the range of artificial illumination in lles which has been found satisfactory under practical conditions.

ion. — Vision is aided by the sharp definition of details down to an inge of 1 in 10,000. Reading is easiest with type subtending an angle r in 100. For comfort it should not be larger than 1 : 20 nor less than

sts in intensity are best at about 1 : 10, but should not be less than Contrasts as slight as 98 : 100 are readily perceivable in good light.

nity of light on the working area is important. Excessively bright titute an annoying glare and interfere with the fixation of vision.

ess of light is essential, as flicker causes rapid fatigue.

– A well-balanced spectrum is required for the true revelation of ors. Fatigue is most rapid in the extreme blue end of the spectrum violet radiations may cause injury if present in unusual quantity. ing a strongly dominant yellow-green hue gives the highest visual

n. — Complete diffusion tends to eliminate shadows, with the re- s of relief. The value of moderate shadows varies greatly with the ces, but is greatest where color distinctions are lacking.

EFFICIENCY. — The resultant of all conditions affecting vision is the somewhat loose term visual efficiency. This concept must take the fundamental discriminations of brightness, detail and color and ntenance of these faculties in use. Tests of visual acuity have been l as a working criterion of visual efficiency. As applied to the momen- of vision this criterion is unsatisfactory as it invites a semi-conscious r to offset fatigue. An ideal criterion must take account of the e of acuity in work, of the ease with which fixation of vision and re sustained, and of the general requirements of ocular hygiene. *Ill. Eng. Soc., Vol. 8, p. 40.*)

VOLTMETERS. — (*See also Ammeters; Wattmeters.*) A voltmeter is an instrument for measuring the potential difference, or voltage, between the two points to which its two terminals are connected. Any type of ammeter (q.v.) may be used as a voltmeter, but when designed for this purpose the coil which carries the current is made of a number of turns of fine wire, so that the moving element will be deflected by a very small current (from 10 to 200 milliamperes for full-scale deflection, depending upon the type) and to limit the current to this value a high resistance, contained within the case of the instrument, is usually inserted in series with the coil. The high resistance may be provided with taps brought out to additional binding posts, so that the same instrument will give full-scale deflection for say 75, 150 and 300 volts, depending upon which binding post is used in conjunction with the terminal marked "0" or "+." The range of a voltmeter may also be indefinitely extended by the use of multipliers (*see below*) or potential transformers (*see Transformer, Instrument*).

Current Taken by, and Resistance of, Voltmeters. — The current taken by voltmeters of various types for full-scale deflection, and the resistance per volt of full-scale deflection are usually as follows:

Type of voltmeter	Milliamperes for full-scale deflection	Ohms per volt of full-scale deflection *
Iron-vane type	83 to 60	12 to 17
Moving-coil type	20 to 10	50 to 100
Electrodynamic type	83 to 40	12 to 25
Hot-wire type	250 to 187	4 to 5.3

* For example, a moving-iron type voltmeter having a 150-volt scale would have a resistance of from $12 \times 150 = 1800$ to $17 \times 150 = 2550$ ohms. The current taken by the instrument would be from 83 to 60 milliamperes. Lower ranges in moving-iron and in electrodynamic voltmeters require larger currents for full-scale deflection, in order to keep down errors due to frequency.

When a d-c. voltmeter is connected to any two points on a network, its reading is in general lower than the previous potential difference between the points, because the voltmeter draws some current from the network. Let the voltmeter reading be V_1. If the voltmeter be now shunted by a resistance equal to its own, a second reading V_2, lower than V_1, will be obtained. The potential difference V can then be found from the formula,

$$V = V_1 V_2 / (2V_2 - V_1).$$

The above method gives correct results not only when the voltmeter is connected directly to the points but also when it is connected through "pressure wires" of appreciable resistance.

Temperature and Inductance Errors. — In order that a voltmeter calibrated at one temperature shall read correctly at all other ordinary temperatures, it is necessary that its total resistance shall change with temperature by only the small amount necessary to offset the resultant effect of temperature change in the springs, magnets, or other operative parts. To secure this condition, the resistance included in series with the active winding (which latter is usually made of copper wire) must have a very low temperature coefficient

in, constantan, and various other alloys may be used for this purpose; :s, *Resistance*. The total resistance of a permanent-magnet moving-coil :r, or of a voltmeter of the electrodynamic type should increase about cent per degree C. if its readings are to be independent of temperature. dded resistance in an a-c. voltmeter is wound non-inductively, either as coil or on a card. The total impedance is then only slightly greater total resistance for well-designed voltmeters used at ordinary lighting er frequencies. At higher frequencies the voltmeter will read lower of its higher impedance. If the reading is correct at the calibration y f_1, the reading at frequency f_2 may be corrected by multiplying by or $1+2\pi^2L^2(f_2^2-f_1^2)/R^2$, where R is the resistance, L the inductance. $f_1^2L^2/R^2$ and $2\pi^2f_2^2L^2/R^2$ are each small in comparison with unity. cases the term f_1^2 may be neglected.

pliers and Potential Transformers. — A voltmeter multiplier is n external resistor placed in series with the voltmeter. These resistors e of high-resistance alloys having a low temperature coefficient, and id non-inductively. If r and R are the resistance of the voltmeter e multiplier respectively, v and V the value of one scale division in volts ınd with multiplier respectively, then

$$V=v(R+r)/r.$$

$(R+r)/r$ is frequently called the "multiplying power" of the multiplier ıltmeter in question.

ltages above 750 volts potential transformers are to be preferred to s for a-c. circuits; see *Transformers, Instrument*.

ıstatic Voltmeters. — When the current taken by the ordinary form ter is an appreciable fraction of the load current or when the frequency igh, as in radio work, an electrometer (*see article on Electrometers*) static voltmeter may be used. The ordinary electrostatic voltmeter ciple the same as an electrometer, but is provided with a pointer and is so constructed as to be more readily portable than the ordinary ter which is read by means of a telescope and scale. Repulsion elec- oltmeters are also used, the principle of operation being the repulsion nductors charged with electricity of the same sign, as in a gold-leaf pe.

ser multipliers are sometimes used with electrostatic voltmeters; see *ers*.

ng of Voltmeters. — A voltmeter may be checked by comparing it andard voltmeter whose correction curve is known, or it may be irectly by means of a potentiometer and standard cell; see *Potentio-* lot-wire and electrodynamic voltmeters for alternating-current work ed on direct or alternating current; a moving-iron voltmeter should l by comparing it, on alternating current, with one of the other types been previously checked on direct current. Electrostatic voltmeters y employed commercially only for high voltages, and therefore must l on alternating current.

tions in Use and Installation, Costs, Bibliography, etc. — See on *Ammeters*.

WATER WHEELS AND THEIR SETTINGS. — (*See also Hydraulic Principles of; Power Stations, Hydroelectric; Water Wheels, Speed Regulation of*) —A water wheel is a machine for converting the energy of falling water into mechanical work. The old-fashioned undershot and over-shot wheels are now seldom used. In modern water wheels, usually called hydraulic turbines, the energy of the water is gradually transformed into kinetic energy as the water passes through a set of guides and vanes.

Work is the product of force times distance, and power is the rate of doing work. Let f be the total force in pounds exerted by the water on the runner of a turbine, let L be the distance in feet travelled by a point on the runner located at the center of pressure, and let t be the time in seconds for this point to travel this distance. The power developed by the water is then

$$P = \frac{f}{550} \cdot \frac{L}{t} \qquad \text{horsepower} \qquad (1)$$

The power developed by falling water may also be expressed in terms of the rate of flow in cubic-feet per second, Q, and the *net* effective head h, in feet. The potential energy of Q cubic-feet of water at an elevation of h feet is $62.4Qh$ foot-pounds. Hence for a rate of flow of Q cubic feet per second the *theoretical* power developed is:

$$P = \frac{62.4Qh}{550} = \frac{Qh}{8.814} \qquad \text{horsepower} \qquad (2)$$

It is important to note that in this equation h is not the difference in elevation between the intake and discharge levels, but is equal to this gross head H less the sum of the heads corresponding to the friction losses in the conduit system and the residual velocity where the water is returned to the stream.

All the energy developed by the water as it passes through the turbine is not converted into useful work. The ratio, e, of the power output of the turbine measured on the turbine shaft, to the theoretical power of the water, is the efficiency of the turbine. The output of the turbine may then be expressed by the equation:

$$P_0 = \frac{Qhe}{8.814}. \qquad (3)$$

Speed of Rotation. — In the conversion of energy by an hydraulic turbine the factor $\frac{L}{t}$ in equation (1) is the *linear speed* of the runner at the center of pressure.

If the linear speed is zero, it is evident that the power must be zero. If the linear speed is too great, approximately equal to the spouting velocity of the water corresponding to the head on the turbine, the pressure of the water on the runner is zero and again no power is produced. It is evident, therefore, that at some linear speed between these limits the power and the efficiency will be the greatest. In other words, the linear speed of the runner must be a fixed percentage (theoretically about 50 per cent) of the spouting velocity of the water, in order to obtain the best efficiency. Therefore, since the *speed of rotation* or revolutions per minute (commonly termed "speed" of the runner) varies directly as the linear speed, it increases with the head (and spouting velocity), if the diameter is constant. It also decreases as the diameter (and capacity) increases.

Consequently, for a given type of runner, low heads and large capacities require a low speed and, conversely, high heads and small capacities require high speeds. It is the object of turbine builders to keep the speed within

onable limits to suit the characteristics of the generators and other machin- and for this purpose many types of runners have been developed.

LASSIFICATION OF TURBINES. — Modern hydraulic turbines of two types: reaction turbines and impulse turbines. The basic difference reen the two types is in the runner.

eaction Turbines. — A typical low-head reaction turbine and runner are cated in Figs. 1 and 2. The water enters the runner through the guide

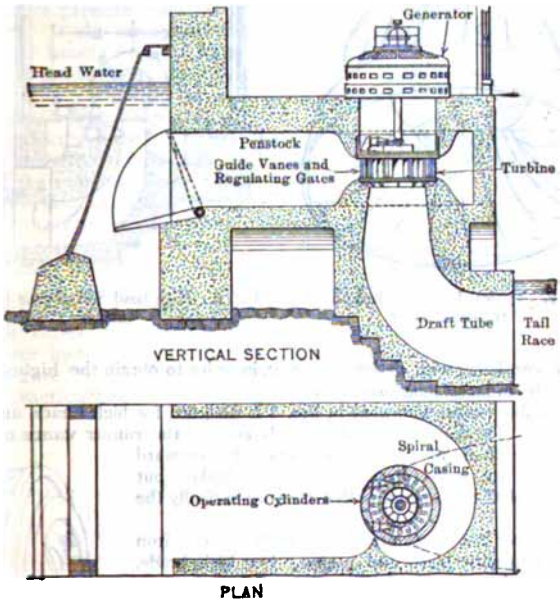

Fig. 1. Low-head Spiral-case Reaction Turbine

es and regulating gates. It passes inwards and downwards through the ner vanes to the draft tube.

Power is developed by the pressure and reaction of the water on the runner es, the runner being completely filled. Modern reaction turbines are adapt- e to all heads up to about 800 feet where the units are large.

mpulse Turbines. — A typical impulse turbine and runner are indicated ig. 8. The pressure head is first converted into velocity through the nozzle he end of the penstock, and power is developed by the impulse of the water acting upon the buckets on the rim of the runner.

The impulse turbine must never be submerged, it being necessary to allow water to fall away freely from the buckets. Small impulse turbines are uptable to all heads. For all capacities they are used exclusively for heads ater than about 800 feet.

Digitized by Google

CHARACTERISTICS OF REACTION TURBINES — The Runner.— Reaction runners vary in shape and design depending upon the conditions under which they are to be used. The runner indicated in Fig. 2 is designed for a low-head, large-capacity turbine. The diameter is made as small as

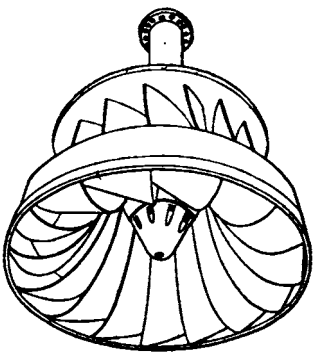

Fig. 2. Typical Low-head Reaction-turbine Runner

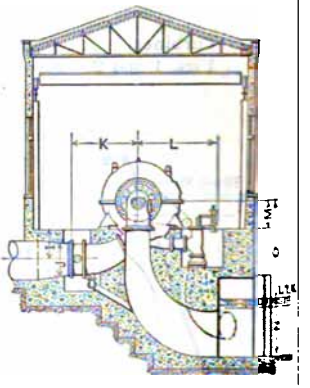

Fig. 3. High-head Spiral-case Reaction turbine

possible, consistent with desired capacity, in order to obtain the highest speed. This results in large, long runner vanes.

The double runner indicated in Fig. 4 is designed for high heads and small discharges. The diameter is relatively larger and the runner vanes narrower and smaller than in the former type. In outward appearance the two types are quite dissimilar; but the action of the water and pathof flow are basically the same.

Fig. 4. Typical High-head Double-discharge Reaction turbine Runner

Runners for low heads are usually made of cast iron or cast iron with plate-steel blades. For high heads, cast steel or bronze are often used to reduce the wear of the metal resulting from the high velocities.

No uniformity exists among turbine manufacturers in the methods of measuring the diameters of reaction runners. For this reason it is never possible to compare the diameter of a runner with that of another make; or even with a runner of another type of the same manufacturer. Diameters are therefore employed only for comparison of runners of the same type and, as relative diameters only are used, it is never necessary to know the actual points to which the diameter is measured when selecting the type and size of runner for a given installation.

The capacity of a runner is specified as a certain full gate capacity at a given head and speed.

The Gates. — In modern installation, wicket-gates are used because they present the least resistance to flow when in a part open position. Cylinder gates, consisting of a steel cylinder, moving axially over the opening to the

inner, are sometimes adopted for small installations and those designed to erate normally at full gate. Cylinder gates are not efficient when operated rt open, owing to the sharp contraction at the bottom of the cylinder.

Wicket gates are actuated by the governor or hand control through rods and vers. The gates of the turbine indicated in Fig. 1 are controlled by two erating cylinders located in the turbine pit. Oil is admitted by the gov-nor to the cylinders and the resulting movement of the piston rods revolves ghtly a shifting ring to which are connected the individual gate-links for oving the gates.

The Draft Tube. — The function of the draft tube is to utilize, by suction negative pressure below the turbine, the head between the turbine and the il race. It also serves to reclaim as much as possible of the velocity head of e water issuing from the runner, which is sometimes very great. They are creased gradually in area towards the outlet where the average velocity is ually from 3 to 10 feet per second, the higher velocities being for the higher ad installations.

The velocity of the water, when leaving the runner, is not strictly axial but, e to imperfect reaction and skin friction, has a swirling motion in the direc-n of the rotating runner. It is only the component of this velocity in the ial direction which can be reclaimed by the ordinary form of draft tube. It is for the purpose of reclaiming more of the residual velocity that a spiral pe of draft tube has recently been developed. It is, however, adaptable onomically only to special cases because of its relatively larger size.

Because of the draft tube, turbines can be set well above tail water in order be convenient at all times for inspection.

Draft tubes are sometimes constructed of steel plate; but more often, for e larger installations, they are shaped in the concrete of the power house bstructure.

The practical limit of the draft head is given by the equation:

$$h' = A + \frac{v_2^2 - v_1^2}{2g} - a \qquad (4)$$

ere h' = the maximum allowable draft head in feet, measured from the lowest tail water level to the center line of gates, for vertical turbines; or to the highest point of the discharge space of the runner, for horizontal turbines.

A = the pressure of one atmosphere in feet of water, normally about 34 feet at sea level. It decreases with the altitude. Two feet should be subtracted from the normal weight to allow for reductions during meteorological disturbances.

v_1 = the average velocity of the water in feet per second at the exit of the runner, measured at the point of minimum internal diameter of the runner band.

v_2 = the average velocity at the end of the draft tube.

a = a margin allowed for disturbances during load changes and vapor tension, ordinarily adopted as five feet, but should be larger for long draft tubes, low pressure heads and sudden load changes.

Friction in the draft tube will increase h', but is too small for consideration.

Settings. — Reaction turbines are adaptable to many types of settings, and e choice of type is governed by the relative cost compared with the efficiency the turbine and ease of operation. Typical examples of turbine settings are licated in Figs. 1, 3, 5, 6 and 7. The following are some of the more common pes of settings, of which many combinations are possible.

Digitized by Google

a. The turbines may be horizontal or vertical; that is, set with horizontal or vertical shaft.

b. One or more runners on the same shaft may be used.

c. For multiple runner turbines, there may be a separate draft tube for each runner, or each pair of runners may have a single draft tube located between them.

d. The turbines may be set in an open forebay or flume with shaft extending vertically to a generator above water surface, or horizontally through the wall to a generator on the opposite side.

e. The runners may be enclosed in a casing or prolongation of the pipe line. Such casings may be spiral or cylindrically shaped.

The tendency is towards single runner vertical turbines for low heads, and horizontal or vertical turbines with one or two runners for medium and high heads. More than one runner is seldom now used for vertical installations.

The open flume setting is common for very low-head installations utilizing small turbines. Such a setting is indicated in Figs. 5 and 6. In open flumes of ample size, the water approaches the turbine with low velocity and without disturbance. Consequently this type of setting possesses the highest degree of efficiency.

As the head becomes higher or the diameter of the curbine larger, the structural problems of open-flume construction become increasingly difficult. It is finally necessary to effect a reduction in size of conduit and a corresponding increase in velocity of flow, and some type of closed casing is then necessary.

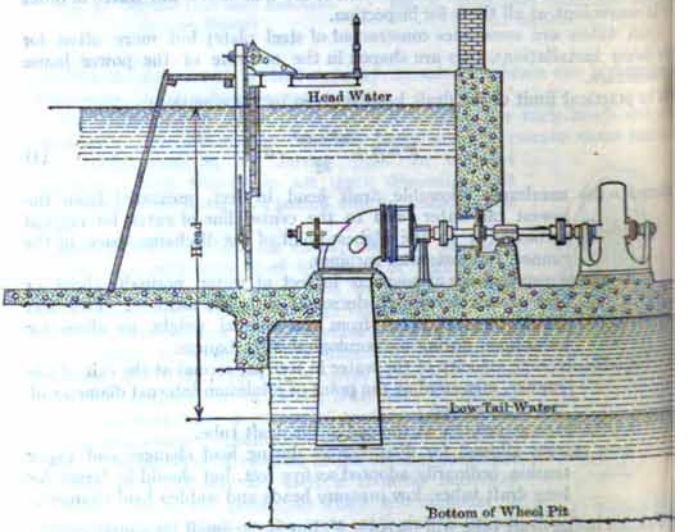

Fig. 5. Open-flume Setting for Horizontal Turbine

A cylindrical casing is indicated in Fig. 7. This type of casing cannot be made hydraulically efficient. Because of its shape, the water cannot enter the turbine with the absence of disturbance, so essential to best efficiency of operation. Cylindrical casings are less expensive than spiral casings, but are seldom

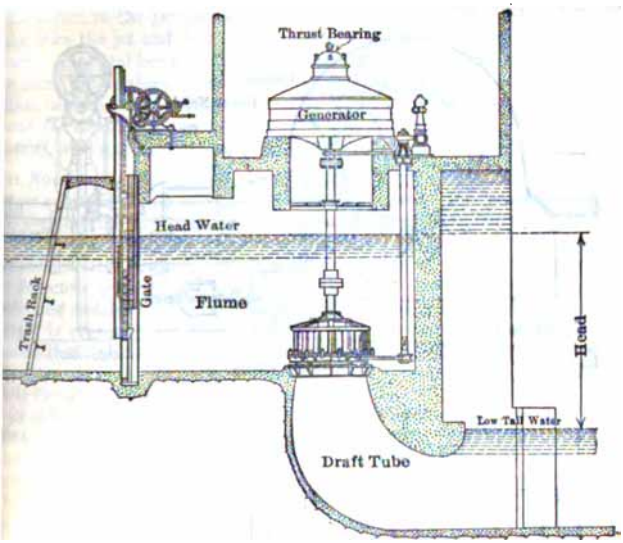

Fig. 6. Open-flume Setting for Vertical Turbine

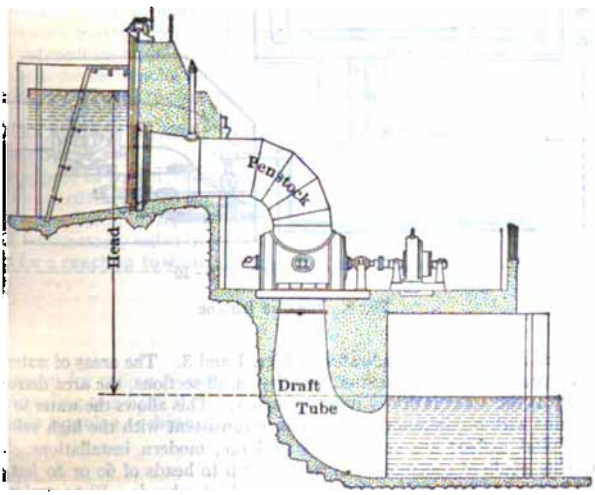

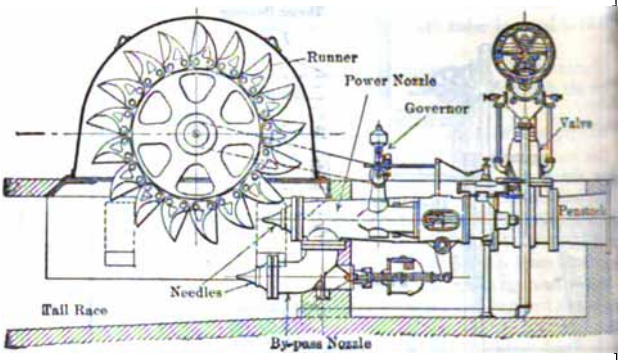

Fig. 7. Horizontal Cylinder-case Double-runner Setting

Google

now used for large units, except to effect a reduction in first cost at the expe of efficiency. They are usually made of plate steel or formed in the con of the toe of the dam.

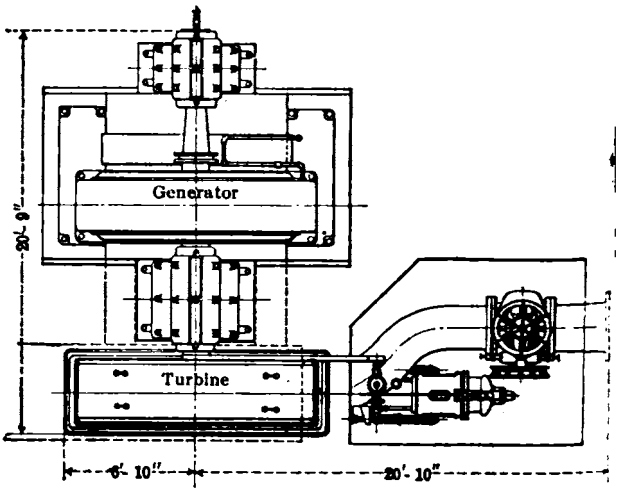

Fig. 8. Impulse Turbine

A typical spiral casing is indicated in Figs. 1 and 3. The areas of water pa sages are proportioned for constant velocity at all sections, the area decreasi gradually as the water is drawn into the runner. This allows the water to ent the turbine with a minimum of disturbance consistent with the high velociti used. Spiral casings are common to all large, modern installations. Th are usually made of concrete for large units up to heads of 60 or 80 feet. an of cast iron, cast steel or riveted plate steel for higher heads. Plate steel is co sidered inferior to the other materials for casings, but is often less expensive.

RACTERISTICS OF IMPULSE TURBINES. — The Runner. — s is shown a typical impulse runner, consisting of cast-steel or bronze bolted to the periphery of the wheel body. The buckets receive the from the jet and destroys its velocity, the water falling inertly to the The total head between the runner and the tail race is lost.

ch turbine there is one ratio of runner diameter to jet diameter which best efficiency. This ratio varies from about 12 to 15 depending upon and capacity of the unit. A ratio as low as 8 is practical under special s, with a sacrifice of a few per cent in efficiency.

ozzles. — The flow of water through the nozzle is controlled by a actuated needle valve as indicated in Fig. 8.

e turbines are commonly used for high-head installations with long in which the flow cannot be arrested quickly when a sudden reduction output is required. For this reason deflecting nozzles, by-pass valves ectors are used in order to eliminate the possibility of water-hammer. ing nozzles are provided with a ball joint, and when a sudden reduction is required, are made to deflect by the action of the governor, with that only part of the jet remains in contact with the buckets and the put is reduced. The needle valve then partly closes slowly, and coin- ie jet is returned to its normal position.

eflector acts on much the same principle as the deflecting nozzle. It a governor-actuated, hinged, curved vane which, upon a reduction nand, moves into and deflects part of the jet from the buckets. The hen returns to its normal position as the needle valve slowly closes.

st recent method of regulation consists of by-pass valves of various ney are usually operated by the governor synchronously with the the needle valve to an extent sufficient to retain a constant penstock hen are slowly closed automatically. Fig. 8 indicates a typical by- of the needle type.

s. — One or more runners may be used on the same shaft and one or les may be provided for each runner; but the usual arrangement, for medium capacity units, consists of a single runner with a single nozzle. urbines may be horizontal or vertical; but vertical installations are use the water cannot fall away as readily without interference.

constant, called the "unit speed" of the runner.

. **reaction turbine** at a given speed and gate opening,

$$\frac{R\sqrt{P}}{h\sqrt{h^{1/2}}} = K \qquad (5)$$

n for calling K the "unit speed" is that K is equal to the speed R ling to a head h of 1 foot and a power output P of 1 horsepower.

mpulse turbine,

$$\frac{R\sqrt{P}}{h\sqrt{h^{1/2}}} = 3.67, \qquad (5a)$$

cates the usual unit speed of impulse runners to be about 3.67.

Digitized by Google

Values of Unit Speed. — In equation (5a), if k and P are unity, $R = K$. The speed of the runner when generating. Turbine builders use the value of the unit speed at full gate opening as a basis for representing the speed characteristics of the various types of runners. For each type of runner there is one unit speed near which occur the best efficiencies for ordinary conditions of operations. High-speed runners are those requiring a high full-gate unit speed for best efficiencies and vice versa. The practical maximum unit speed for the standard modern reaction-type runner, without considerable sacrifice of efficiency, is about 95. Special runners have been developed recently, both in this country and abroad, which are claimed to operate satisfactorily at a unit speed of 150 or over, and several small units have been installed. With unit speeds greater than 95, considerable saving can be made in the cost of generators because a large single runner unit operating at 95 unit speed under a low head requires a speed of revolution much too low for economical generator design.

Efficiency. — The methods of calculating, from test data, the performance of an hydraulic turbine are too complicated to be given in the limited space here

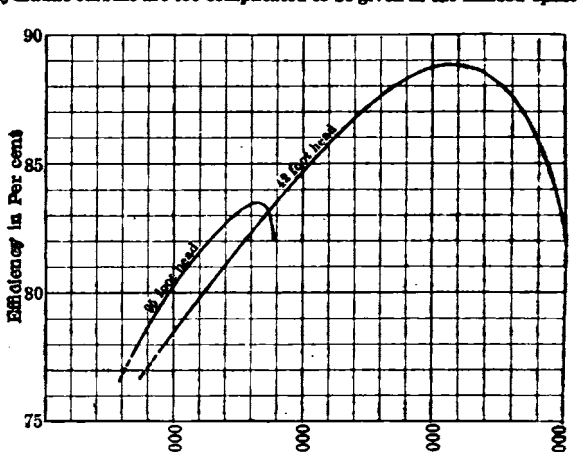

Fig. 9. Efficiency-power Curves of 46 In. Runner

available. Typical efficiency curves of a large reaction-type runner at two different heads are given in Fig. 9, and a typical efficiency curve for an impulse-type runner in Fig. 10.

It will be noted that the efficiency and power falls off quite rapidly as the head reduces. It is not possible to obtain a runner which will have good efficiencies for a wide range of heads for a constant speed.

The use of test data for the determination of probable turbine operating characteristics under practical conditions is influenced by the following considerations:

a. Other conditions being the same, the efficiency and capacity of a runner increases with its size, owing principally to the smaller influence of defects in fabrication and roughness of the water passages.

Digitized by Google

Fig. 10. Efficiency-power Curves of an Impulse Water Wheel

› setting of the turbine may differ from that of the test, a condition ten has a marked influence on efficiency and power.

efficiency and capacity decrease with service, particularly if there is . in the water to wear the runner and increase clearances.

bine manufacturers have patterns for only a part of the possible runner loreover the best speed of the runner is not always the best speed for expensive type of generator. Consequently, in many installations, it ›le to sacrifice a certain amount of adaptability and efficiency in order the first cost of the installation.

s Affecting Choice of Runner. — Complete data for the final ıtion of the type and size of runner most suited for a particular instal- in the possession of turbine builders only, and advice from that source ›ariably be obtained.

of runner and turbine setting should be adopted which will have the ıcteristics for the conditions under which it must be operated for the rtion of the time, and also possess reasonable characteristics for unusual .. Among the influences governing the choice of type are:

›d of low-stream flow, during which maximum efficiency is essential.
‹l of high-stream flow, during which maximum capacity only is essential.
:e of fluctuation in head. The runner must have sufficient capacity at head and also have reasonable efficiencies at mean and high heads.

characteristics, or the part-gate-opening periods. The efficiency ıuite rapidly for small gate openings and best efficiency is not usually e power.

conditions affecting the type of turbine setting.

NG OF HYDRAULIC TURBINES. — The "Testing Code" of the Builders' Society has been adopted by most hydraulic turbine manu- ıs a basis for comparing actual operating characteristics with the of the manufacturer. The object of the test is to determine the

efficiency, equation (3), at fixed speed under different conditions of load and (where possible) head; the capacity of the unit; and its general performance.

Tests under varying heads are not always possible in power developments, and it is sometimes not even possible to test under the effective head stated in the guarantee. It is permissible, however, to test under other heads, differing by not over 10 per cent from the contract head, provided the speed is changed in proportion to the square root of the head. The operating characteristics under contract head and speed can then be computed from the result of the tests under test head and speed.

The power input is given by equation (2). The quantity of water Q, may be measured in a number of ways, the principal of which are,

a. Weirs in the head or tail race.
b. Current meter measurements in the head or tail race.
c. Pitot tube in the penstock or conduit.
d. Floating screen in an open conduit.
e. Venturi meter in the penstock.
f. Titration or chemical method, in which a salt solution is introduced at the inlet and measured in centration in the tail race.

The net head, h, is the difference between the elevation corresponding to the pressure in the penstock near the entrance to the turbine casing (or water surface immediately above the turbine in open flumes) and the elevation of the tail water, this difference being corrected by adding the velocity head in the penstock at the point of measurement and subtracting the residual velocity head at the end of the draft tube.

The output, P_0, is usually measured electrically if the turbine-driven generator has been previously tested. One of the many forms of Prony brakes may be used for small units.

ER WHEELS, SPEED REGULATION OF.* — (*See also Hy-; Power Stations, Hydroelectric; Water Wheels and Their Settings.*) In a cial cases close speed regulation of water wheels is unnecessary, for ex- in pulp grinding, certain chemical processes and operating air com-. Even in these cases experience has shown that better results may be d when wheels are controlled by properly designed governors. For work, where the power is applied through the medium of belting, the of regulation is simplified by the large inertia effect of the pulleys ing.

ED VARIATION IN HYDROELECTRIC PLANTS. — For elec-nerators, which perhaps comprise the majority of installations, the ut-ety of speed regulation is required because the value of the electrical roduced is greatly lessened if the voltage and frequency are not uni-n the best large modern power plants speed variations greater than one per cent are exceptional. In smaller plants, since there are usually oportional load fluctuations, it is more difficult to maintain close speed n.

HOD OF REGULATION. — A change of load requires a change in ntity of water passing through the turbine in order that the power ill equal the new demand. This is effected through a change in the ing by the action of the governor.

ange in load demand occurs, and the turbine is not able at once to alter t to correspond, the surplus or deficiency of power will be absorbed or by the inertia of the rotating elements of the turbine and generator. n give up or receive energy only by means of a change in speed. Thus nanifestation of a change in load demand is a change in the speed of the

ors are sensitive to very slight changes of speed and start almost at djust the gate opening; but this cannot be done immediately. Conse-during the time required to make the adjustment, the change in the the rotating elements, corresponding to the surplus or deficiency of ust be made without too great a change in speed. Therefore the neces-ia of the rotating elements or "fly wheel effect" is fixed by the capacity t, the expected load change and the gate-closing speed of the governor. luences to be overcome in obtaining good regulation are:

: of sensitiveness of the governor, or the fact that the speed must m normal before the governor action starts.

governor cannot change the gate opening instantly. A common open flume settings or short penstocks is about two seconds. For h long penstocks, the speed of the governor must be much slower to inst excessive water hammer.

he case of long penstocks, a change in penstock velocity, resulting d change, necessitates a variation in head at the turbine to accelerate the velocity. This change in head is exactly opposed to that desired egulation.

Flume Setting. — In Fig. 1, assume the power demand, for an open allation to be represented by the line *ABCD*. After the instant, *X*, l change, the output of the unit is insufficient and the deficiency must d by the inertia of the rotating elements. Consequently the speed fall off as indicated. At *Y* the speed change is sufficient to affect the nd the gates begin to open. The rate of gate opening is not neces-stant, but will vary according to the characteristics of the governor en-flume conditions, the head is practically constant during the change the power output may be represented by the line *EFG*, which, for open

flumes, may be assumed to vary uniformly. The area *BCFE* represents the total deficiency in energy, ΔK, to be supplied by the fly-wheel effect of the unit. At Z the output is equal to the demand and, as indicated, no further reduction in speed occurs. As the speed is still below normal, the governor will continue to open the gates and the power will further increase. The excess output over demand, after time Z, will add to the speed of the unit until, at time W, the speed is again normal but the output is in excess of the demand. The speed will then rise above normal and the governor will start closing the gates. There is seen to be a tendency for the output to fluctuate above and below the new power demand. This feature is called "hunting" of the governor. In actual practice this does not occur to an objectionable extent, as the governors are provided with a compensating device or "anti-racing" mechanism which has the effect of dampening these fluctuations, and the speed is soon brought permanently to normal. This condition requires, however, that the capacity of the unit be somewhat in excess (usually 5 per cent to 10 per cent) of the maximum output to which the demand may suddenly change, otherwise there would not be available the necessary excess capacity to bring the speed back to normal after a sudden increase in demand to maximum demand occurs.

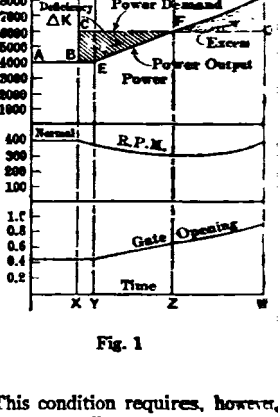

Fig. 1

Long Penstock Settings. — In Fig. 2, assume the power demand for a plant with a long penstock to be represented by the line *ABCD*. As in the previous case, the speed begins to be retarded at X, the moment of the load change, and at Y the governor action starts. The variations of gate opening and penstock velocities are indicated in the diagram. Part of the total head available for power is consumed in increasing the penstock velocity and the net head on the turbine decreases momentarily as indicated. The net result of the slowly accelerating velocity, combined with considerable reduction in net head, may be a momentary *reduction* in output as indicated by the output line. This reduction in net head, at the critical time when an *increase* in power output is most needed, is the chief influence opposed to good regulation with long penstocks. The velocity soon picks up, however, and the power output increases about as indicated by the line *EFG*.

As in the case of open-flume installations, the speed of the unit is a minimum at Z, when the output equals the demand; but the gate opening, penstock velocity and output continue to increase until the speed reaches normal at time W. The gates then start to close. The time interval between the sharp breaks in the head, penstock velocity, and output lines correspond to the time required for the wave of penstock velocity change to travel from the turbine to the upper end of the penstock and back again.* The deficiency in output ΔK, is indicated by the area *BCFE*.

For sudden *decreases* in load demand the characteristics indicated in Figs. 1 and 2 are simply reversed.

Water Hammer. —Water hammer is a term used to indicate the increase

* See article by N. R. Gibson, referred to in *Bibliography*.

ad caused by a reduction in penstock velocity. Negative water hammer e decrease in head resulting from an increase in penstock velocity. For en load changes the resulting water mer is very great and, for that reason, peed of gate movement must be very for long penstocks.

is not safe to use approximate equa- for the determination of water mer. Accurate methods are too in- te for presentation here and the r is referred to the article by N. R. on mentioned in *Bibliography*.

EGULATION APPLIANCES. — term "pipe line" is commonly used ndicate a long pipe extending from reservoir to the brow of the incline ng to the power house. The "pen- " extends from this point to the ines.

rge tanks are usually provided at the r end of long pipe lines in order to ict the excessive water hammer, or changes due to sudden load changes. f valves are often used at the lower of long penstocks for the same purpose.

rge Tanks. — A surge tank consists vertical pipe, considerably larger in eter than the pipe line, resting on the nd and connected to the pipe line, or ay be an elevated tank connected to pipe line by a riser pipe of the same naller diameter than the pipe line. fore-bays also serve the same purpose e surge tank. Surge tanks are feas- only when the difference in level between the lower end of the pipe line head water is not excessive.

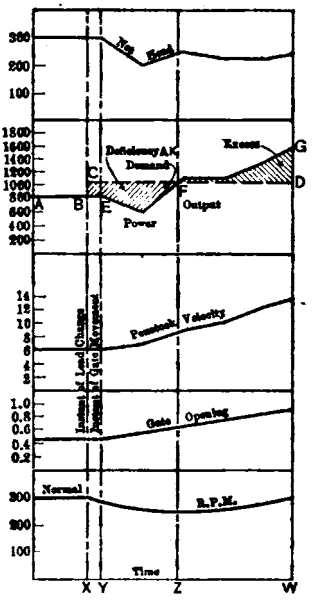

Fig. 2

he function of the surge tank is to store or supply water subsequent to a load ge pending the gradual adjustment of the flow in the pipe line.

he water surface in the surge tank is normally at the level of the hydraulic lent of the pipe line at that point. When a sudden demand for more power rs the deficiency of water is supplied by the tank and the water surface in tank lowers. The resultant increase in head between the tank and the ay serves to accelerate the velocity in the pipe line. When a reduction in ut occurs, the water surface in the tank rises and the induced head decreases low. The action is entirely automatic.

he influence of the rise and fall of water surface in the surge tank on the head at the turbine during a load change is also opposed to speed regulation; the head change with a surge tank is considerably less than corresponding r hammer without the tank.

eglecting the effect of friction, the rise or fall of water surface in the tank be expressed by the following equation:

$$h = v\sqrt{\frac{aL}{Ag}},$$

Digitized by Google

where h = the rise or fall, in feet.

v = the velocity change in the pipe line corresponding to the change f load, in feet per second.

a = the area of the pipe line, in square feet.

A = the area of the surge tank, in square feet.

L = the length of the pipe line, in feet.

g = the acceleration due to gravity = 32.16.

The value, v, for use in this equation, is the difference between the orig pipe line velocity and the velocity required for the new load, the latter responding to the head on the turbine at the time of the maximum deviation water surface in the tank from normal. Its value therefore depends upon turbine characteristics and the value of h. Consequently the solution of equation can best be accomplished by the cut-and-try method.

Restricted orifices are usually provided between the pipe line and the tank to dampen the surges and prevent them from continuing indefinitely or piling up due to the action of the governor in endeavoring to compensate for the resultant head changes.

Friction in the pipe line and in the restricted orifices have considerable influence on the action of the surge tank and the foregoing equation gives results too large for loads thrown off, and considerably too small for loads thrown on. For more exact methods of design the reader is referred to R. D. Johnson's article on surge tanks referred to in *Bibliography*.

Relief Valves. — Relief valves are serviceable only to compensate for sudden decreases in load demand. They are appliances attached to the lower end of the penstock and are designed to open automatically when a sudden decrease in demand occurs. By this means, a sudden large decrease in penstock velocity is avoided, the surplus water not needed for power being by-passed through the relief valve to the tail race. After the output has been adjusted, the valve slowly close. They are sometimes actuated by the rise in pressure; but are preferably synchronously opened by the governor to an extent corresponding to the closure of the turbine gates, the penstock velocity remaining nearly constant during the load change. Relief valves are very wasteful of water. Deflecting nozzles and jet deflectors of impulse turbines, described in *Water Wheels and their Settings*, also serve the same purpose.

CALCULATION OF SPEED REGULATION. — Open Flume Settings. —In Fig. 1, let:

p_0 = the initial horsepower output.

p_1 = the new power demand after time X.

T_1 = the time interval, in seconds, XY, after load change before the governor action starts.

T_2 = the speed of the governor or time, in seconds, YZ, for the governor to adjust the gates to the new load demand.

R_0 = the normal speed of the unit in revolutions per minute.

R_1 = the speed of the unit at time Z corresponding to maximum deviation from normal.

s = the percentage change in speed of the unit.

K = the foot-pounds of kinetic energy in the rotating elements at speed R_0.

ΔK = the energy change in the rotating elements due to change in speed from R_0 to R_1.

I = the fly-wheel effect of the rotating elements in foot-pound units, usually expressed in pounds at one foot radius, i.e., the weight which, at a radius of one foot, would have an equivalent moment of inertia.

N = the regulation constant of the unit.

Digitized by Google

For open flume settings, the average horsepower deficiency during the time erval XZ, assuming EF to be a straight line, is,

$$p = \frac{(p_1 - p_0)T_1 + (p_1 - p_0)\frac{T_2}{2}}{T_1 + T_2}.$$

The total deficiency in work for the interval XZ, which must be supplied from he inertia of the rotating elements, is:

$$\Delta K = 550(T_1 + T_2)p.$$

Therefore,
$$\Delta K = 275(p_1 - p_0)(2T_1 + T_2) \qquad (1)$$

From the laws of mechanics,

$$K = \frac{2\,I\pi^2 R^2}{g\,60^2} = 0.00017\,IR^2,$$

d
$$\Delta K = 0.00017\,I(R_1^2 - R_0^2).$$

Therefore,
$$R_1 = \sqrt{R_0^2 + \frac{\Delta K}{0.00017\,I}}.$$

From definition,
$$s = \frac{100\,(R_1 - R_0)}{R_0}.$$

Therefore,
$$s = \frac{\sqrt{R_0^2 + \frac{\Delta K}{0.00017\,I}} - R_0}{0.01R_0}. \qquad (2)$$

By neglecting T_1, which is small, Meade has shown that equation (2) may be itten, for small speed changes, in the following approximate form:

$$s = 81{,}000{,}000\,\frac{T_2}{IR_0^2}(p_1 - p_0) \qquad (3)$$

For full load change, equation (3) may be written,

$$I = \frac{81{,}000{,}000\,T_2 p_F}{S\,R_0^2} = N\frac{p_F}{R_0^2}.$$

ere
$$N = \frac{81{,}000{,}000\,T_2}{S}.$$

Therefore,
$$N = \frac{R_0^2 I}{p_F}. \qquad (4)$$

For open-flume plants or plants with negligible length of penstock as indicated Fig. 1, of the article on *Water Wheels and Their Setting*, I usually has a value ch that N will be at least 5,000,000.

A quick acting governor and a large fly-wheel effect make for good regulation. the fly-wheel effect is too small for the required regulation, the speed of the vernor must be increased or additional fly-wheel effect provided either in the m of a separate fly-wheel or by increasing the weight of the rotating parts of e generator. Either method requires additional expense and the choice uld be made to obtain the greatest economy.

Plants with Long Penstocks. — For plants with long penstocks, the out- t line, *BEF*, Fig. 2, and hence the deficiency of output, ΔK, cannot be

expressed by a simple equation. The fluctuations in head and penstock velo
are affected by the considerations of water hammer and stand pipe or s
valve characteristics. Each must be computed and plotted, from which
power output line can be determined from the turbine characteristics.
area *BEFC* or deficient work, ΔK, can then be computed for use in equation

HYDRAULIC-TURBINE GOVERNORS. — The governor proper
the device for automatically opening and closing the gates as the load on
turbine varies. The requirements to be met are (1) sensitiveness to s
variations in speed, (2) quickness in action, (3) steadiness and accuracy
moving the gates the proper amount, (4) ability to operate continuously w
minimum amount of attention.

Types of Governors. — There are two general classes of governors: (1)
"mechanical" type, which takes energy from the turbine itself, as requi
through a belt or gearing, and by means of friction clutches applies this en
at suitable times to the operation of the turbine gates; (2) the "hydrau
type, in which stored energy in the form of compressed air is made avail
when required to move the turbine gates through the medium of a liquid (usu
oil) acting against the piston in a hydraulic cylinder. The energy in the c
pressed air is thus transmitted by the liquid through a suitably controlled v
to do the work of moving the turbine gates, when necessary, and the ene
of the air is afterwards restored by pumping the same liquid back into the
tank. The operation of restoring the energy by pumping is gradual; while
operation of moving the turbine gates, by utilizing the energy of the compre
air, may be as rapid as desired.

Governors of the mechanical type were the first in the field, and, being sim
and cheaper to construct, have been very widely used. They have certain ob
tionable features, however, which have prevented them from being adop
under any conditions which require extreme nicety in speed regulation.
sequently, governors of the hydraulic type are almost exclusively used in la
and important power plants. When properly designed, they are capable
giving extremely accurate speed regulation and are thoroughly reliable. Su
governors are sometimes operated continuously night and day for weeks,
even months.

Connections between Turbine and Governor. — The connections betwe
a hydraulic turbine governor and the gates must be strong, direct and free fro
lost motion; otherwise the governor cannot perform its functions properl
Modern governors are built in many different types, so as to be readily adapt
for connections to any standard make of turbine. It is generally advantageo
to have the hydraulic cylinder of the governor located near the turbine gate
although for very large units the control mechanism of the governor may b
more conveniently placed on the floor above. For small turbines, which a
occasionally located in comparatively inaccessible places, it is sometimes nec
sary to place the governors at a considerable distance and connect them with th
turbine gates by means of rods and levers. Occasionally several turbines a
connected in this manner to a single governor.

Distant Control. — Large governors are frequently provided with suitab
electric devices by means of which the speed of the wheel may be adjusted fro
any distant point, thus permitting alternators driven by independent turbin
being brought to the same speed and angular position for parallel connection.

Rating of a Governor. — A hydraulic governor is usually rated in terms o
the energy, expressed in foot-pounds, which is developed by one stroke of th
piston, and the time, in seconds, required for a complete stroke (i.e., to com
pletely close or open the gates). The size of governor required for a given in

depends so largely upon the type of gate, head, etc., that no general be given here.

cations for Governor. — The following is taken from the standard ons of one of the large governor manufacturers:

ernors are each guaranteed to develop the energy, expressed in foot- ated below, and if not called upon to develop a greater amount of in that named, will completely open or close the gates to which they ed in the following number of seconds:

.....Governor,.....Foot-Pounds,.....Seconds,.....

vernors are further guaranteed: (*a*) to stand substantially steady speed does not vary; (*b*) to be dead beat in action and not to hunt; ct with maximum promptness for all load changes within the capacity bines to which they are attached; (*d*) to maintain the speed steady of one per cent under uniform load upon the turbines to which they d; (*e*) to begin to adjust the turbine gates when the speed has varied per cent; (*f*) after sudden decrease of load to bring the speed back in.....seconds; (*g*) to operate perfectly in parallel with other of the same make.

WATTHOUR METERS. — (*See also Ampere-hour Meters; Electrodynamometers; Wattmeters.*) A watthour meter consists essentially of (1) a small electric motor, which may be either of the commutator type, mercury disc type, or induction type, (2) a brake system composed of a disc of non-magnetic material (usually copper or aluminum) mounted on the armature spindle and so arranged that its edge rotates between the poles of one or more permanent magnets, and (3) a system of gears with numbered dials forming a suitable registering mechanism for indicating the number of revolutions of the armature or disc. One winding, called the "potential" coil, is connected across * (in shunt with) the load and the other winding, called the "current" coil, is connected in series * with the load, the connections being the same as for an indicating wattmeter; see *Wattmeters*.

Principle of Operation. — Motor-type meters are so constructed that the average torque exerted by the motor is proportional to the average power taken by the load. The brake system is so designed that the opposing torque, due to the eddy or Foucault currents induced in the disc as it rotates between the poles of the permanent magnets, is proportional to the speed of the disc. When the disc acquires a given speed the driving torque must be just equal to the opposing torque, and must therefore be proportional to the speed. But the speed of the disc is proportional to the average power, and therefore the total number of revolutions which the disc makes during any interval must be proportional to the total energy input during this interval, whether the power remains constant or varies. To determine the energy input to the load in watt-hours or kilowatt-hours it is therefore only necessary to take the difference between the dial readings at the beginning and end of the given interval, and multiply by the proper constant if the meter is not direct reading.

Sources of Error. — In a d-c. watthour meter the chief sources of error are the friction of the brushes (which is more or less variable), friction of the bearings of the motor and gear train, and air friction, the brush friction being by far the most important. In a-c. watthour meters, the lack of exact 90° phase relation between the impressed voltage and the magnetic flux due to the current in the potential coil may cause additional errors which vary with the frequency, power factor and also with the distortion of the wave form; in well-designed modern meters these errors are practically negligible. Instrument transformers (*see Transformers, Instrument*), introduce additional sources of error which may be undesirably large if the transformers are not properly designed. Devices and methods for overcoming, or of correcting for, these errors are described below.

Classification According to Service. — Watthour meters may be classified according to the service in which they are used, viz., (1) service meters for use in residences or factories, (2) switchboard meters for use in central stations and (3) meters for use in individual power installations and isolated plants. Meters for house service are generally front-connected, separately-sealed devices which can be installed and sealed to prevent tampering. Switchboard meters are generally back connected and of such design as to match other switchboard devices. "Meter-boards," equipped with the necessary auxiliary or protective devices, are frequently used with house meters, in order to insure proper connections and sealing.

COMMUTATOR TYPE OF WATTHOUR METER. — The commutator type of meter is now used only on direct-current circuits, although both

* Either directly or through suitable instrument transformers; see *Transformers, Instrument.*

tion meter was so highly perfected large numbers were used for alter-
rrent also. The motor consists of a set of stationary coils, commonly
ld coils, which carry the current, and an armature wound with small
h is connected across the terminals of the load or in shunt with the
rcuit; generally a series resistance is used to absorb part of the line
The connection to the armature is by a commutator and brushes, as
linary commutator type of shunt motor. Special attachments are
s added for very large capacities, such as double armatures astatically
and damping magnets inclosed in a laminated iron shield in order to
ay-field errors where heavy currents are used and heavy short-circuits
nt.
ld be noted that the operation differs from that of an ordinary shunt
hat the speed increases with increase of field strength, since its back
uch less than 50 per cent of the line voltage.
unt of the inductance of the windings of the commutator meter, it does
accurately on a-c. circuits unless properly compensated, the percentage
; greater the less the power factor.

sation for Friction; Light-load Adjustment.—Friction in a well-
atthour meter will be very small and will be noticeable only on light
per cent and below. To compensate for this friction, a "light-load
oil" is added, which is an auxiliary or compounding coil. This light-
connected in series with the armature. It is placed adjacent to the
› that its field strengthens the main field and produces a slight torque
t of the power and just sufficient to compensate for friction.

of Construction, Bearings, etc.—In the design of the modern
nt commutator type of watthour meter, great thought has been
: mechanical construction in order to obtain small air gaps between
ire and field coils, light-weight armatures and commutators and
ch will have very small friction and yet stand the wear and carry the
ie armature without undue sparking and pitting of the contact parts.
ur meter of the most approved design the field coils are wound with
pper strips and the armature winding is enamel-covered wire wound
sphere mounted on a spindle of light steel tubing. The lower bear-
all of the weight and the upper bearing is a guide bearing, as all
vertical shafts. The lower bearing consists of a steel pivot mounted
of the spindle or armature shaft, running on a jewel bearing. In
a good grade of sapphire is used for the jewel and is cupped and
as to provide a bearing with as little friction as possible. Of late
t deal of attention has been given to the bearings and in some cases,
on high-capacity meters with astatic armatures and a correspond-
weight, diamond jewels are being used with excellent results.
d jewel will last much longer than the sapphire before wearing
to increase the friction and thereby change the accuracy of the
cularly at light loads. See also section below on *Data on House-*
.

***of* Commutator Watthour Meters.**—Commutator-type direct-
rs are built in capacities ranging from 5 to 10,000 amperes, 100 to
Meters of this type are furnished with double current circuits for
rcuits, the maximum ampere capacity for three-wire meters being
mperes. Special meters have been supplied for 1200- and 2400-volt
its.

—Tests on direct-current commutator meters show that a meter
gn should start on two per cent of full load and should give accu-

racies about as follows: — To within 3 ¼ per cent from 5 per cent to ¼ lo
2 per cent from ¼ to full load. The Meter Code (*see Bibliography*) requi
d-c. watthour meters to run continuously on normal voltage and 2 per cen
rated current, and for higher loads to be accurate within the following limits

Per cent rated current.....	5	10	20	50	100	150
Maximum deviation, per cent..	7.5	3.0	2.0	2.0	2.0	2.0

For a summary of the meter accuracies required by commission regulati
city ordinances, and state statutes, see Circular No. 56 of the Bureau of Sta
ards, 1st ed., pages 234–5.

The Mercury-motor Watthour meter is manufactured for direct-curr
service. The motor element consists of a mercury chamber in which is submer
a copper armature. The line current enters and leaves the mercury through
electrodes diametrically apart. Since mercury has about fifty-five times
resistivity of copper, the major part of the current traverses the armature. T
mercury thus performs the function of the commutator and brushes of the co
mutator-type meter. A shaft attached to the armature passes through th
constructed to prevent the mercury from escaping when the meter is inver
Externally, this shaft carries a worm which engages with the register train, a
an aluminum damping disc moving in the field of a permanent magnet. T
copper armature is notched radially to direct the current flow in such a man
as to obtain the greatest torque, and carries a float so proportioned that th
is a slight upward thrust. In consequence, the lower bearing is a ring-st
jewel, while the upper end of the shaft is carried in a ring-stone end-stone be
ing. A laminated iron electromagnet having many turns of fine wire is connect
across the line, and sends through the copper armature a magnetic flux which va
in proportion to the line voltage. The driving torque is thus proportiona
the power supplied to the load. The damping at small and moderate loa
nearly all caused by the drag disc, but at full load and overloads the fluid f
tion of the mercury increases at such a rate as to cause a drop in the per c
registration curve unless compensated. Compensation is effected by pass
the line current through a few turns of heavy wire around the voltage elect
magnet.

Compensation for Friction, Light-load Adjustment. — For effecting
light-load compensation for friction, a thermal device is used in some cases, a
it is also possible to obtain compensation by shunting part of the potent
current through the armature. The thermal device employed is a therm
couple shunted around the mercury chamber, and heated from a resistance c
connected in series with the potential circuit. The small electromotive for
generated in the thermocouple sends a small current through the armatu
which is sufficient to overcome the friction of the moving parts.

Application of Mercury Meters. — Mercury-motor meters, on account
the low resistance of the current circuit, are particularly well adapted for u
with external shunts, since but a small potential drop in the shunt is requir
They are therefore used in comparatively large numbers for switchboard wo
where large currents are used and where external shunts can be conveniently
installed. They are much less subject to derangement by vibration than co
mutator meters.

Details of Construction. — The preceding description applies to the mercu
motor meter extensively used in the United States. Other designs differ
mechanical construction and in methods for obtaining light-load adjustment
The chief difference in mechanical construction is in the motor element, where
mercury chamber of non-metallic compound is used in some cases, and a Germa
silver chamber enameled on the inside in other designs. Armatures differ i

ne designs use a copper disc and others a copper drum or thimble. See tion below on *Data on House-Type Meters.*

city of **Mercury Watthour Meters.** — Direct-current mercury meters hemselves independent of ampere capacity, as external shunts are used. giving a capacity as high as 60,000 amperes have been furnished. Meters l for voltages up to 600 volts are regularly furnished and special meters :n supplied for 1200- to 3000-volt direct-current railway circuits.

racy. — The mercury-motor watthour meter above described is stated a load-accuracy curve at normal voltage which deviates from a straight ess than 1.5 per cent over a range of load of 5 per cent to 200 per cent

CTION WATTHOUR METER (Fig. 1). — This type of meter, the elements of which are illustrated in Fig. 1, has a laminated soft-iron which are mounted ent and potential . The current wind- its of a few turns of re, while the poten- has many turns of . The flux due to it coil is in phase load current, and ue to the potential approximately in e with the voltage load, since the coil is highly in- ee *Alternating Cur-* e poles from the igs are arranged e armature disc ween them and is cut by the alternating flux due to each wind-

le of Operation. — There are thus set up in the disc currents which each pole in approximately concentric circles, the induced currents two windings being in quadrature for a load of unity power factor ately only, unless a suitable phase compensator is used; see below). e current induced by the current coil passes under the pole of the oil and therefore through a magnetic field which is approximately in this current, and similarly part of the current induced by the poten- sses under the pole of the current coil and therefore through a mag- pproximately in phase with it; for power factors less than unity the rence between these currents and the magnetic fields through which s the same as the difference in phase between the load current and Hence a torque is produced on the disc having an average value pro- > the load supplied through the meter; see *Electricity and Magnetism. of.* A braking system similar to that employed in the commutator ter (see above) causes the speed of the disc to be proportional to this que, and therefore the number of revolutions is proportional to the plied.

Compensation; Lag Coil. — In order to make the induction watt- record correctly, especially for power factors less than unity, it is > cause the flux at the tip of the potential pole to lag 90 degrees behind

the voltage impressed on the potential coil. A method of securing this condition is to mount on the potential pole a closed winding the resistance of which can be varied by a resistance wire soldered to the terminals. This closed winding is sometimes called the "lag coil." In many designs it is a metal plate in the form of a closed loop.

Compensation for Friction; Starting Plate. — The light-load adjustment can be obtained by placing a short-circuited loop of copper adjacent to the potential pole so that it can be shifted in a plane at right angles to the axis of the potential coil. This loop has induced in it currents which produce a field out of phase with the flux from the potential coil, and the reaction between the two produces on the disc a slight turning moment independent of the current in the current coil. The amount of compensation can be varied by shifting the position of the light-load coil, or starting plate, as it is sometimes called.

Details of Construction. — The induction watthour meter is manufactured in several different types all based on the same principle of operation but differing in mechanical construction and electrical characteristics. The general type of construction is to mount the iron core and windings on a metal frame which carries the bearings for the armature, the core and windings being combined as a single unit in some designs, whereas in others the current and potential coils with their iron cores are mounted separately on a common frame or on the meter case. The other details of design consist of mounting the register train and damping magnets and arranging the full-load, light-load and power factor adjustments so that they are readily accessible. See also section below on *Data on House-Type Meters*.

Polyphase Induction Meters. — The polyphase induction meter in commercial use is nothing more than two single-phase meters with a common spindle connecting the two armature discs. The measurement of power with the meter is based on the two-wattmeter method for three-wire, three-phase and quarter-phase work (*see Wattmeters*), and a slight modification of the two-element meter is used quite extensively for four-wire, three-phase work. This modification consists of making a third current circuit by adding a winding to the current coils of both elements. Such a construction is quite accurate even on badly unbalanced voltages, the most accurate arrangement for such work being three separate single-phase meters, or a single meter which contains three single-phase elements.

Capacity of Induction Watthour Meters. — Induction watthour meters are supplied in standard capacities ranging from 5 to 300 amperes. Meters are generally used with self-contained potential circuits up to 600 volts and for higher voltages and current capacities potential and current transformers are used with 5-ampere 110-volt meters. When transformers are used, either a multiplying constant for the dial alone can be used in connection with the ratio of transformation of the transformers, or the ratio of the transformer can be included in the meter constant (see below), so that the register is direct reading with the transformers of proper ratio. For three-wire, single-phase circuits a

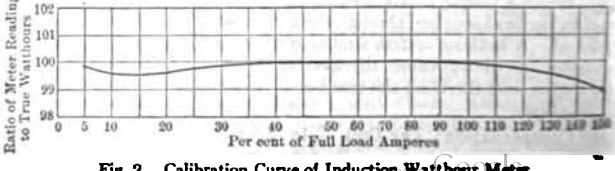

Fig. 2. Calibration Curve of Induction Watthour Meter

to obtain a special form of current transformer with double primary and a single secondary winding for connection to the meter.

acy. — Modern induction watthour meters are susceptible of a higher accuracy than the commutator or mercury-motor meter. Fig. 2 shows characteristic curve of an induction watthour meter. It is possible to special calibrations a combination of induction watthour meters and nt transformers which will be accurate to within 1 per cent over the range of commercial operation. The Meter Code (see *Bibliography*) a-c. watthour meters to run continuously, at rated voltage and frend unity power factor, with 2 per cent of rated current, and for higher e accurate within the following limits:

ent rated current.....	5	10	20	50	100	150
mum deviation.....	3.0	1.5	2.0	2.0	1.5	3.0

must also be adjusted for measurement on power factors of 75 per cent r cent to within 2 per cent and 4 per cent respectively. Other requireccuracy can be found in the Meter Code.

AYMENT METERS. — Standard watthour meters are sometimes a device whereby the circuit through the meter and load is closed the insertion of a coin into the device and remains closed only until redetermined amount of energy has been recorded by the meter, when again opens automatically. When so equipped the meter is called ent meter. The prepayment device may be either inserted in the neter, or it may be placed in a separate attachment electrically conhe meter.

R TYPES OF WATTHOUR METERS. — The descriptions of neters given above refer particularly to the types manufactured in States. Meters of the same general types are manufactured abroad, ertain other types. Among the latter, the Aron clock meter is worthy In this meter the potential coils are carried on two pendulums such a manner that they swing close to the coils carrying the line One pendulum must be retarded as the other is accelerated and to do tions are so made that the instantaneous polarity of the pendulum ays opposite while the current coils are always alike. The meter o iron and has no commutator and is, therefore, a very accurate device, although somewhat complicated and delicate of adjustment y commercial work.

ON SERVICE-TYPE METERS. — General data on service-type eters of different types are tabulated below. These data are approxire representative of modern practice in this country. The weights ions given refer to meters of 5 to 25 amperes rating, and are exceeded of greater rating.

G OF WATTHOUR METERS. — For laboratory tests the ld be mounted on a firm support and set level. These conditions obtain when the meter is permanently mounted for service; see below *llation*. For laboratory tests a bank of lamps or some form of rheoantom load" may be used for a load. The instructions given below th laboratory and service tests.

Instruments. — For d-c. measurements a portable ammeter and r a portable watthour meter may be used; for a-c. measurements ng wattmeter or portable watthour meter may be used. Two pacities should be provided, one sufficient to take care of the full

‡ Not including shunt.

load of the meter and the other small enough to read the light load with a pro[illegible] degree of accuracy.

The use of a portable watthour meter is now recognized as the stand[illegible] method for testing watthour meters up to 100-ampere capacity. There is [illegible] question as regards the accuracy of this method, since it is not necessary t[illegible] the load be constant. With the portable watthour meter, indicating instrum[illegible] and stop watches are unnecessary, and personal errors in reading are thus [illegible] reduced.

When indicating instruments are employed, a reliable stop watch is essen[illegible] for taking the meter speed. As a matter of safety, it is advisable to have [illegible] least two stop watches, one to serve as a check on the other in test. Too mu[illegible] care cannot be used in the handling of these watches and in giving them cons[illegible] checks with some local jeweler's standards. In checking the stop watch it [illegible] advisable to check at different points of the dial.

Precautions. — In order to insure accuracy, d-c. meters should not be test[illegible] until they have been connected in circuit with the voltage on for fully 15 to [illegible] minutes before the test is made. This enables the heating effect of the curre[illegible] in the potential circuit to become constant. If the meters are tested before th[illegible] consecutive readings may not check.

The testing instruments should not be allowed to measure the losses of t[illegible] potential circuit of the meter under test, or vice versa. In order to avoid th[illegible] the current circuits of the testing instrument should be connected in series wi[illegible] the meter under test, while the potential circuits of the testing instrument a[illegible] of the meter under test must both be connected across the line at the same ph[illegible] and between the generator and the nearer instrument.

A number of revolutions should be taken so that the time of observation s[illegible] be at least from 40 to 60 seconds. If the time is materially less than 40 second[illegible] undesirably large errors in the measurement of time are probable; a time interv[illegible] longer than 120 seconds is generally unnecessary.

Test Constant. — In checking a watthour meter the speed of the disk[illegible]

rectly, since too long a time would be required to obtain a suitable n the dials of the register. The relation between the number of revolu- the disc and the corresponding dial reading may be expressed by a multiplier, called the "test constant," which depends only upon the etween the disc and dial. Various manufacturers express this constant , viz.:

neral Electric Test Constant (K). — The number of watthours by the register per revolution of disc; its value is marked on the disc.

estinghouse Test Constant (K). — Westinghouse meters (except -6) are all adjusted for a certain speed at rated full load, which is on the nameplate. Meters of modern manufacture have a speed of and older forms of 50 r.p.m. Let N be the number of revolutions e corresponding to a rating of P kilowatts, then the test constant K er of watt-seconds per revolution of disc), as given in the instruction ied by this company, is $K = 60{,}000\,P/N$. For type CW-6 (direct- eters the test constant is the number of watthours per disc revolution.

t Wayne Test Constant (C). — For type K meters the number of for 36 revolutions of the disc; for types K_1, K_2, K_3, K_4 and K_5 the watthours for 1 revolution of the disc; the constant is marked on the

ican Test Constant (K). — The number of watthours per revolu- disc; it is marked on the meter name plate.

gamo Test Constant (K). — The number of watt-seconds per of disc; it is now marked on the name plate in the D-5 mercury- rs and on the register of the type H induction meters.

ion Formulas. — Let R = number of revolutions of disc, S or T = seconds for R revolutions, K or C = meter constant as defined above: ower corresponding to the speed of the meter is:

Type of meter	Meter watts
General Electric	$\frac{3600\,KR}{S}$
Westinghouse	$\frac{KR}{T}$
Fort Wayne, Type K	$\frac{100\,CR}{S}$
Fort Wayne, Types K_1, K_2, K_3, K_4 and K_5	$\frac{3600\,CR}{S}$
Duncan	$\frac{3600\,KR}{S}$
Sangamo	$\frac{KR}{S}$

Accuracy. — The meter watts as thus calculated divided by the as read on the test meter, and multiplied by 100, gives the per cent f the per cent accuracy is less than 100 the meter is running slow; n 100 it is running fast. The term "per cent accuracy" is open to

some objection, and "per cent registration" is coming to be preferred entirely satisfactory name has yet been found for this quantity.

Adjusting Speed of Meter. — If the error in the meter reading at full is in excess of the permissible error the speed should be altered by adjusting position of the permanent magnets or shunting part of their flux by the provided therefor. If the error at light load, say 5 per cent load, is excessive light-load adjustment should be altered to bring the speed to its correct va

Method of Using the Portable Watthour Meter. — The dial of the able meter reads directly in revolutions of the meter disc. At the instant mark on the disc of the service meter passes some arbitrarily chosen fixed p note the dial reading of the portable meter. Count the number of revolu of the disc of the service meter, and at the instant when a suitable whole nu of revolutions are completed note the dial reading of the portable meter a Let R_0 be the difference in the two dial readings of the portable meter, K_0 test constant of the portable meter, R the number of revolutions of the se meter and K its test constant. Then the per cent accuracy is KR/K_0R_0. course the test constants of the two meters must be expressed in the manner, i.e., as watthours per revolution or as watt-seconds per revolution

Testing of Three-wire and Polyphase Meters. — A three-wire meter be tested as a two-wire meter by connecting the current coils in series. three-wire meter will then read twice the number of watts actually supplied the test load. By using two sets of instruments three-wire meters may tested as actually used.

A polyphase meter is most readily tested as a single-phase meter with current circuits in series and the potential circuits in parallel. The read the meter is then twice the number of watts actually supplied to the test

INSTALLATION OF WATTHOUR METERS. — A watthour should always be mounted on a firm support, should be set with the dis and in a place where it will not be liable to be injured or subjected to m A firm support is particularly essential, as continual vibration of the meter cause it to "creep," since vibration tends to lessen the friction, and the compensation may then be excessive.

Meters should not be installed closer than about fifteen inches be centers, and should not be too close to conductors carrying heavy curre in the vicinity of iron girders, posts, water or steam pipes.

A check on its accuracy should always be made after the installation of a

Determination of the Capacity of Meter. — Before installing a some tests or accurate estimates should be made to determine the correct ca of meter, as it is not advisable to run a meter continuously above its capacity, and too large a meter means in general poor accuracy on light As a rough guide, the capacity of the meter should be one-half the total nected load for ordinary residences, three-fourths the total connected loa stores and offices, and 1 ½ times the connected load for elevator, hoist and motors taking a large starting current. When several such motors are on meter, the diversity factor will often permit the use of a meter capacity than their combined current capacity.

Precautions in Connecting Polyphase Meters. — Direct-current single-phase alternating-current meters are comparatively simple to instal connect properly, but all installations on polyphase circuits require con ably more care and knowledge to insure proper connections. Polyphase in tion meters must be connected properly in regard to phase relations, as o wise very inaccurate results will be obtained, which may not be apparent casual examination of the meter. The manufacturer's instructions show

ery carefully and the phase relations traced out to make sure that orrect. Practically all instrument transformers are now marked in inctive manner to indicate the relative instantaneous polarity of the nd secondary windings, in order to facilitate making connections.

TENANCE, REPAIRS AND DEPRECIATION. — It has been m experience that except for the very smallest central stations or g companies it is economy to maintain some systematic method of d caring for all meters on the system. For ordinary house service cept very large installations, readings are taken about once a month rs are examined and tested as required. Commutator-type and otor meters should undoubtedly be tested and put in good condition ce a year; induction meters may be left for two years and perhaps e examination, as the very slight change in accuracy is not enough to e expense of the test. With very large capacity meters, where the money involved is large, frequent tests are made and in some cases check and adjustment is made, and whenever necessary the meter complete overhauling and a spare meter installed in the meantime.

. — In making repairs on watthour meters, it is practically necessary n considerable equipment and a department for this class of work. h a department is available it is preferable to return meters to the er for all repairs except those of a minor nature, such as cleaning of rs on direct-current meters and inserting new jewels and pivots for earing. Manufacturers will usually supply repair parts at reasonable quite extensive repairs can be made by the central stations if they are uipped. In service the attention and care necessary vary with the ter, induction meters being by far the cheapest to repair and under ions such meters require the least attention of any type.

OF WATTHOUR METERS. — Ordinary service type com- eters for direct current range in price from $16 to $170. Switch- nutator meters in capacities from 800 to 6000 amperes range in price to $500. Shunted type commutator meters range from $100 for a meter to $200 for one of 5000 amperes capacity.

motor meters usually have external shunts. The meter itself is of apacity and sells for about $16 in the service type and $55 to $70 in oard type. Prices of shunts for these meters are approximately o-ampere, $30 for a 500-ampere, $40 for a 1000-ampere and $100 for ere meter.

acity single-phase service-type induction meters are sold for about ch; larger capacities and polyphase meters range from $35 to $70. l induction meters sell for $40 to $100; they are 5-ampere, 110-volt ned for use with instrument transformers, q.v.

e prices are approximate, and should be used only as a rough guide. of installing and connecting the meter varies considerably with s or requirements. Where no protective devices are used, and the irs the cost of the main line cutout and cutout box, the installation ompany may be about $2. Where the company furnishes the main ind box, with protective devices to prevent tampering, the instal- ill be about $10.

[ETERS. — (*See also Ammeters; Electrodynamometers; Electrometers; ks; Voltmeters; Watthour Metres.*) A wattmeter is a device for electric power and is particularly useful for measuring alternating- wer. Usually some form of electrodynamometer is used in which in the circuit or a known part of it is sent through one winding, the l; and a small current in phase with the e.m.f. across the terminals of is sent through the other winding, or potential coil; see Figs. 1 and 2. current in the potential circuit is drawn through a resistance as in r. For voltages above 150 to 750 volts, potential transformers (*see rs, Instrument*) are usually employed. In some cases specially-con- sistances, or multipliers, are employed in testing work up to 25,000 n higher. The moving coil is generally used for the potential circuit e convenient to carry through it a small current than a large one.

e of Operation. — In an instrument constructed and used as above he current in the current coil is practically proportional to the load each instant and the current in the potential coil is practically pro- the voltage v across the load at that instant. Hence the instan- que acting on the moving element at this instant is proportional to instantaneous power. The average torque acting on the moving ing each cycle of the current and voltage is then proportional to the er. If the free period of the moving system is large compared with f the current and voltage, then the steady reading will also be pro- the average power.

UCTION OF WATTMETERS. — The electrodynamometer ument is built in several forms, e.g., the original Siemens electro- r in various forms in which the moving coil is brought back to zero a torsion head from which the reading is obtained; deflection in- which the moving coil is allowed to advance through an angle until erted on it by the currents in the instrument windings is balanced ing torque developed in a spring or equivalent device. In the latter ument the position of the moving coil is usually read by means of pointer passing over a scale, graduated to read directly in watts or iples. In very sensitive instruments for laboratory use a beam of lescope and scale like those used with mirror galvanometers is em- lso *Electrodynamometers.*

n to the electrodynamometer type of instrument, induction watt- ating on the same general principle as the induction watthour *atthour Meters*), are sometimes used for switchboard and even for k, but they are not so generally useful through wide ranges of fre- voltage as electrodynamometer instruments.

n limited conditions electrostatic wattmeters (*see Electrometers*) ccessfully used; in this general class of wattmeters for special pur- included the cathode-ray oscillograph or Braun tube (*see Braun*

wattmeters, having two or more sets of current and potential wind- ting torque to a common shaft, are made for use on polyphase below under *Measurement of Three-phase Power.*

Different Types of Wattmeters. — Reflecting electrodynamom- rs for laboratory use are made for currents up to 100 or 200 amperes n circuits from a fraction of a volt up to 150 volts. Such instru- een specially constructed for larger currents and higher voltages. *Electrodynamometers.* Such instruments are chiefly useful for on circuits of low voltage and of low power factor where even

the small power required to operate the instrument makes the use of ord portable instruments inconvenient or impossible.

Portable wattmeters are usually made to give a full-scale deflection about two-thirds of the product of their rated amperes and volts, i.e., as i ment rated as 5 amperes and 150 volts would usually have a 500-watt For determining core losses and other service where the power factor wattmeters may be had giving full-scale reading with one-third or even one-fifth of the product of the rated amperes and volts. It is custom supply such wattmeters with a certificate showing the values of the equi phase angle α (*see below*) that have been determined, so that they may be where a high degree of precision is required on low power factor work.

Portable wattmeters are made in ranges up to 200 amperes and 750 Extra potential terminals are often supplied so that the instruments used on more than one voltage, e.g., 125 or 250 volts. Double current wi are also supplied, with a switch or links for changing the current range, a also usual to construct wattmeters having two current ranges and two ranges. This construction greatly increases the usefulness of the instru and is particularly useful when applied to the low power factor wattmet it makes it possible to use them for higher power factors by using say th ampere, 250-volt range for a load of 5 amperes at 125 volts.

Portable wattmeters for currents larger than 200 amperes and voltages than 750 volts have been successfully constructed but are not generally because the higher ranges can usually be taken care of with 5-ampere ra wattmeters in connection with calibrated instrument transformers.

Switchboard wattmeters are made single-phase up to 200 amperes a volts, and polyphase up to 50 or 100 amperes and up to 750 volts. ranges are usually taken care of by using 5-ampere wattmeters in con with instrument transformers.

METHODS OF CONNECTING WATTMETER TO LOAD; RECTION FOR POWER LOST IN WATTMETER. — A wattmet be connected to the load which it is to measure in either of the two ways trated in Figs. 1 and 2. When connected as in Fig. 1 the current thro

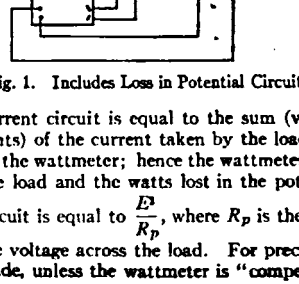

Fig. 1. Includes Loss in Potential Circuit

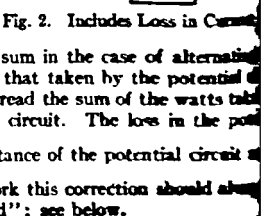

Fig. 2. Includes Loss in Curr

current circuit is equal to the sum (vector sum in the case of alternating rents) of the current taken by the load and that taken by the potential of the wattmeter; hence the wattmeter will read the sum of the watts take the load and the watts lost in the potential circuit. The loss in the pot circuit is equal to $\frac{E^2}{R_p}$, where R_p is the resistance of the potential circuit a the voltage across the load. For precise work this correction should alwa made, unless the wattmeter is "compensated"; see below.

In the second scheme of connection, Fig. 2, the current through the cu circuit is the same as that taken by the load, but the voltage across the pot

ait is higher than the voltage across the load by the voltage drop through the ent circuit of the instrument, and the wattmeter reads too high by an amount al to the watts lost in the current circuit. This loss is equal to $R_a I^2$, where s the resistance of the current circuit and I the load current. This loss is ally less than the loss in the potential circuit which occurs when the first me of connection is used. If no correction is made for the wattmeter loss scheme of connections shown in Fig. 2 should therefore be used. If the est precision is required, especially when a small-capacity wattmeter is used, connections shown in Fig. 1 should be used, and a correction should be ap-l. The resistance of the potential coil is usually stated on the case of the ument.

hen a voltmeter is connected to the load across AA' in Fig. 1, while the meter reading is being taken, a correction should also be made, if appre-le, for the power taken by the voltmeter. Calling R_v the resistance of the meter and multiplier, if any, and E the voltage across the load, the loss in oltmeter is $\frac{E^2}{R_v}$. In most cases the potential circuit losses in the watt-r and voltmeter are best determined by a direct measurement with the meter, using the test voltage and leaving the current circuit open. If the meter is connected across BB' in Fig. 2, then the power lost in it is not by the wattmeter, but the voltmeter reading is not exactly equal to the ge across the load, but equals the load voltage plus the resistance drop impedance drop, added vectorially, in the case of an alternating-current nt) through the current circuit of the wattmeter.

mpensation for Wattmeter Loss. — In the so-called compensated watt-rs a stationary compensating coil inside the instrument is connected in s with the potential coil, this compensating coil being so placed that the nt through it produces on the moving element a torque equal and opposite nt produced by this same current when it passes through the current coil. mpensated wattmeter should always be connected to the circuit, as shown g. 1; when so connected no correction for the loss in the wattmeter is ssary.

OURCES OF ERROR. — Due to the unavoidable inductance in the ntial circuit of a wattmeter, the current in the moving coil is not exactly hase with the e.m.f. impressed on the circuit; in addition there are other l inherent defects in wattmeters, such as eddy currents in windings, sup-s, etc., which tend to make commercial wattmeters more or less imperfect. e imperfections are more serious as the frequency of the circuit is raised the power factor is lowered.

r precision testing under service conditions when the best obtainable accu-is required, it is often desirable to apply corrections to wattmeter observa-to eliminate the errors due to phase displacement, or its equivalent, in the ntial circuit; when instrument transformers are used, additional phase dis-ment occurs, rendering such corrections especially important. In other where corrections cannot well be applied, it is useful to consider the mag-le of the error that will occur under any given conditions, in order to select ble instruments and transformers and to arrange the burdens connected to secondaries in such a way as to produce as near as may be the desired ts. In many cases indications that would otherwise be considerably in may be made to give results of satisfactory accuracy by correcting for phase acement in the wattmeter, and particularly in the instrument trans-ers.

Digitized by Google

here are many ways in which the necessary corrections may be determined applied but the following has been found satisfactory in practical work

Equivalent Phase Angle of Wattmeter. — All the errors in wattme may be considered as due to a certain phase displacement between the curr in the potential coil and the impressed e.m.f. of the circuit. This equival angle of phase displacement may be due to a variety of causes, but can be de mined for any given instrument from the following relations. Consider a w meter in which the current in the potential circuit lags α degrees behin e.m.f. impressed on the potential circuit, the meter being in all other resp perfect. If such a meter is used to measure the watts P supplied by a curre at a voltage E, this current lagging behind E by an angle θ, the wattmeter read $P_2 = EI \cos \theta_2$ watts, where $\theta_2 = \theta - \alpha$. Hence if a wattmeter is used measure a known load of P watts with I amperes and E volts, and the w meter reads P_2 watts, the equivalent phase angle of the wattmeter may defined by the relation

$$\alpha = \cos^{-1}\left(\frac{P}{EI}\right) - \cos^{-1}\left(\frac{P_2}{EI}\right).$$

This angle α is to be taken positive when the wattmeter reads too high on inductive load and negative when it reads too low on an inductive load.

For a given wattmeter and given potential coil this equivalent phase angle practically constant for all currents, voltages and load power factors, provi the frequency remains constant.

In the best portable and reflecting instruments α is usually + and very sm In a portable instrument built for a 125- to 150-volt circuit, when used o 60-cycle circuit, α may have a value of from +2 minutes to as much as + minutes. The phase angle varies directly as the frequency and inversely the voltage rating.

The phase angle of a wattmeter may be compensated by shunting a denser of capacity C around a portion R of the resistor in the potential ci If the equivalent inductance of this circuit be L, the relation for compensati

$$C = \frac{L}{R^2}.$$

Correction for Phase Angle of Wattmeter and of Instrument Tra formers. — Let α = the phase angle of the wattmeter, as defined above, β = phase angle of the current transformer, γ = the phase angle of the poten transformer (*see Transformers, Instrument*), P_2 = wattmeter reading correc for scale error and multiplied by the product of the corrected ratios of the c rent and potential transformers, E = voltmeter reading corrected for scale e and multiplied by the ratio of the potential transformer, and I = ammeter re ing corrected for scale error and multiplied by the corrected ratio of the curr transformer. Then the apparent power factor is

$$\cos \theta_2 = \frac{P_2}{EI},$$

and the true power is

$$P = P_2 \frac{\cos(\theta_2 + \alpha + \beta + \gamma)}{\cos \theta_2}.$$

The angle θ_2 is to be taken positive when the current lags behind the volt and negative when the current leads. Note that α, β and γ may also be p tive or negative angles. Values of the correction factor $\frac{\cos(\theta_2 + \alpha + \beta + \gamma)}{\cos \theta_2}$ given in Tables I and II. Note carefully the conditions, stated at the head each table, to which each table applies.

ctions should be applied separately, as above, to each wattmeter. When ircuit is balanced a single correction based on cos θ_2 for the whole circuit be used.

Example No. 1. — Given a single-phase circuit with lagging current in h the wattmeter reading corrected for scale error and multiplied by the cor- d ratios of current and potential transformers equals 24,520 watts, and the uct of the voltmeter and ammeter readings, similarly corrected, equals 35,600 amperes. Then $\cos \theta_2 = \frac{24,520}{35,600} = 0.689$. If the equivalent phase angle α e wattmeter is $+4'$ and if from examination of characteristic curves the nt transformer phase angle β is found to be $+48'$ and the potential trans- er phase angle γ is $-10'$, then $\alpha+\beta+\gamma = +42'$, and from Table I, the correc- 'actor is 0.9871. Whence the true power equals $24,520 \times 0.9871 = 24,204$ watts.

Example No. 2. — Given a single-phase circuit with leading current, in h the wattmeter reading, corrected as in example No. 1, equals 12,266 watts the product of the voltmeter and ammeter readings, similarly corrected, ls 24,532 volt-amperes. Then $\cos \theta_2 = \frac{12,266}{24,532} = 0.5$. If the equivalent : angle α of the wattmeter is $+5'$, the phase angle β of the current trans- er $+2° 33'$ and the phase angle γ of the potential transformer is $+38'$, $\alpha+\beta+\gamma = +3° 16'$ and therefore from Table II the correction factor to be is 1.0971. Whence the true power equals $12,266 \times 1.0971 = 13,457$ watts.

rors Due to Stray Fields. — Stray magnetic fields influence the reading wattmeter in much the same way as such disturbances influence the readings ther electrical instruments; see *Ammeters*. In unshielded instruments s due to stray fields may be quite large. Considerable errors are often d by the effect of neighboring instruments on one another. To avoid these s, high-grade American wattmeters are magnetically shielded.

CURACY OF WATTMETERS. — The question of the accuracy of rical instruments is discussed in detail in the article on *Ammeters*. High- e portable wattmeters may be obtained having a stated accuracy of 0.25 ent of full-scale value for single-phase or 0.5 per cent for polyphase watt- rs. It is not practicable to obtain as high accuracy in the latter, on account e impossibility of making both elements of the polyphase wattmeter follow tly the same scale law. This theoretical disadvantage of the polyphase meter is more than offset in practical use by its greater convenience and reduction in number of observations necessary, and its service accuracy, cially on fluctuating power, may even exceed that of single-phase watt- rs used for polyphase measurements. High-grade switchboard wattmeters be obtained having a stated accuracy of 1 per cent of full-scale value. Of se the higher the degree of accuracy demanded the more costly is the meter.

ESTING OF WATTMETERS. — Wattmeters are usually tested by g compared with other standard wattmeters, which have in turn been ained by special methods and their behavior under various conditions of determined. For examining the effect of low power factor on wattmeters, e-shifting transformers or generators having shifting fields are conveniently loyed. By these means low power factor conditions may be produced on ruments without the necessity of troublesome adjustments of reactances, lensers, etc.

fter a given instrument is known with certainty to give no sensible error on rating current due to structural defects, it is usually more convenient to te subsequent checks to detect any change in the instrument by using direct rent. The current and voltage are in this case determined by means of

suitable standard ammeter and voltmeter or by direct reference to potentiometer and standard cells; see *Potentiometers*.

MEASUREMENT OF THREE-PHASE POWER. — (*See also article by L. T. Robinson in General Electric Review, 1912, Vol. 15, p. 350.*) The measurement of the power supplied to a three-phase load may be effected in one or more of the following ways. The connections in each case may be made either directly or through proper instrument transformers, the latter being used for heavy currents or high voltages, or both.

Single (One-element) Wattmeter on Three-wire System. — The current circuit of the wattmeter is connected in series with one of the mains supplying the load and the potential circuit of the wattmeter is connected between the corresponding terminal of the load and the neutral. If the neutral point of the load, or of the transformers supplying the load, is not available, a "Y-box" (see below) can be used to establish an artificial neutral. If the load is perfectly balanced (*see Alternating Currents*) the power input is then three times the wattmeter reading. However, a three-phase load is seldom sufficiently well balanced even in the case of a three-phase motor load, to render this method of measurement an accurate one. In most practical cases it gives merely a rough approximation to the true power.

Y-Box. — The simplest form of Y-box consists of two equal non-inductive resistors connected in series, each of the free ends and the junction point being connected to a binding post. Each resistor has a resistance equal to that of the potential circuit of the wattmeter. One terminal of the potential circuit of the wattmeter is connected to the junction terminal of the Y-box and the other terminal of the potential circuit to the line wire in which the current circuit of the wattmeter is connected. The other two terminals of the Y-box are connected to the other two line wires respectively.

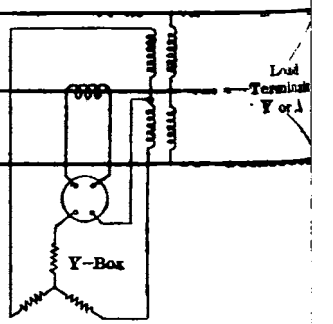

Fig. 3. Single-phase Wattmeter and Y-box for Three-phase Circuit

In the case of wattmeters designed especially for use with a Y-box, part of the resistance of the potential circuit of the wattmeter is placed in the Y-box, being connected permanently to the junction point between the other two resistors. A similar arrangement may be used as a multiplier. The connections of such a Y-box, wattmeter and instrument transformers are shown diagrammatically in Fig. 3.

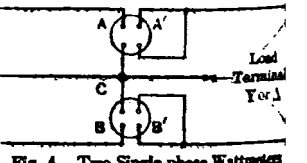

Fig. 4. Two Single-phase Wattmeters for Three-phase Circuits

Two-wattmeter Method for a Three-wire System. — The simple arrangement of two wattmeters shown in Fig. 4 will give exactly the total power in *any three-wire* circuit, provided each wattmeter by itself gives accurate indications. Aside from the sources of error, as noted above, which may affect the accuracy of a wattmeter on a single-phase circuit, the arrangement

it shown in Fig. 4 will give the true power for any condition of unbalan-
, wave-form, frequency, etc. It is also immaterial whether the load be Y
connected. The connections may be made directly as shown or through
current transformers and two potential transformers, the connections being
same as in Fig. 5, except that two separate wattmeters instead of a poly-
se wattmeter are used.

Rule for Adding or Subtracting Readings. — With the arrangement
wn in Fig. 4 the total power is always the *algebraic* sum of the readings of
two wattmeters. Since a wattmeter reads only in one direction, usually
he right, the two instruments must be so connected to the line that the needle
each instrument is deflected over the scale. For a balanced three-phase
l having a power factor greater than 50 per cent, the sum of the two watt-
ter readings, when the connections are thus made, gives the total power;
a power factor less than 50 per cent the difference of the two readings must
taken. When the power factor is not known, one can determine whether
sum or the difference of the readings should be taken by interchanging the
wattmeters, leaving unaltered the potential connections to the third wire
in Fig. 4); if the pointers of the two wattmeters deflect in the same direction
before add the two readings, if the pointers deflect in the opposite direction
, against the stop) take the difference. In making this test, care must he
en to connect the source side of each of the two lines (in which the current
l of each wattmeter is connected in succession) to the same binding post of
given wattmeter in each of the two positions.

When the load is *balanced*, and the two wattmeters are connected, as in Fig. 4,
that each gives a positive reading, the question as to whether the power
tor is above or below 50 per cent can be determined by changing the poten-
l lead of the lower reading meter from the common connection C to the line
which the current coil of the other wattmeter is connected. If the reading
is obtained is positive, the power factor is more than 50 per cent and the
dings should be added; if the reading is negative the power factor is less
an 50 per cent and the readings should be subtracted.

**Phase Difference between Voltage and Current in the Wattmeter
indings.** — In case the load is balanced it can be shown that if θ is the
wer-factor angle of the load, I the line current (current per wire) and E the
e voltage (voltage between wires), then the power read by one wattmeter is
$=EI\cos(\theta-30°)$, and the power read by the other is $P_2=EI\cos(\theta+30°)$.
he performance of the first wattmeter is the same as it would be on a single-
ase load having a power factor of $\cos(\theta-30°)$ and the performance of the
ond is the same as it would be on a single-phase load having a power factor
$\cos(\theta+30°)$. These relations should be borne in mind when making any
rrections for errors due to low power factor (see above).

Measurement of Power Factor by Two-wattmeter Method. —
rom the above relations it can be shown that the power factor of the load,
hen the load is balanced, may be calculated from the two wattmeter readings
and P_2 by the formula

$$\text{Power factor} = 100\cos\left[\tan^{-1}\left(\sqrt{3}\,\frac{P_1-P_2}{P_1+P_2}\right)\right] \qquad \text{per cent,}$$

hen the power factor is greater than 50%; and by the formula

$$\text{Power factor} = 100\cos\left[\tan^{-1}\left(\sqrt{3}\,\frac{P_1+P_2}{P_1-P_2}\right)\right] \qquad \text{per cent,}$$

hen the power factor is less than 50%, P_1 and P_2 both being taken as positive
n both cases and P_2 being the smaller reading.

Two-element Polyphase Wattmeter on Three-wire System. — Inst
of using two separate wattmeters, as shown in Fig. 4, the two wattmeters may
combined into a single instrument with but one shaft and pointer. The connections for such a two-element wattmeter, when instrument transformers are used, are shown in Fig. 5. For measurements where the power is badly fluctuating and especially when accompanied by low power factor, polyphase wattmeters may be more accurate and convenient. For ordinary polyphase service a polyphase wattmeter is not capable of as high accuracy as two single-phase wattmeters.

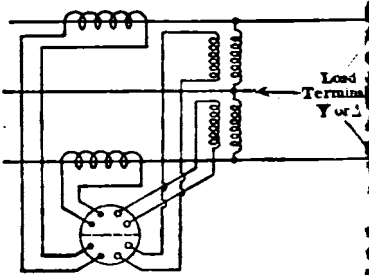

Fig. 5. Two-element Polyphase Wattmeter wi
Instrument Transformers

Determination of Power Factor with Two-element Wattmeter.
The two-element wattmeter reads directly the sum P_1+P_2, using the notat
in the previous paragraph. By reversing the connections of one set of poten
terminals to the corresponding potential transformer the meter may be made
read P_1-P_2. Hence by the use of a suitable reversing switch the power fa
of the load may be readily determined by taking two readings; see preced
paragraph.

Three Wattmeters for Three-wire System. — As noted above, where t
wattmeters, or a two-element polyphase wattmeter, is used on a three-
system, the phase difference between the voltage and current in each wattm
or element may differ greatly from the power-factor angle of the load.
example, in the case of a balanced load having a 50 per cent power factor,
current in one wattmeter differs by 90° from the voltage on the potential circuit of this wattmeter, and it should read zero watts, i.e., this wattmeter operates under the worst possible conditions as regards power factor, and consequently the phase-angle error (see above), particularly when instrument transformers are used, may be quite large when expressed as a percentage. It should be noted, however, that the reading of the wattmeter or element in which the large phase difference occurs contributes proportionally less to the total reading as this phase difference approaches 90°, and consequently the percentage error of the tota reading will be only a correspondingly small part of the error in this wattmeter or element.

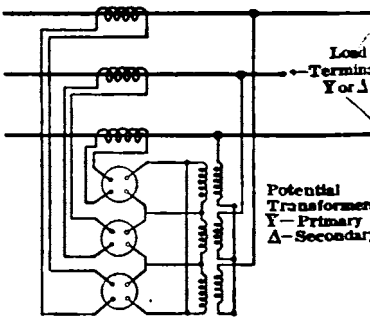

Fig. 6. Y-Δ Connections for Three Wattmeters
on Three-wire System

Where the highest accuracy is demanded, it is therefore theoretically advisable to use three wattmeters connected as shown in Fig. 6. It should be noted, however, that for most practical purposes the very slight gain in accuracy by such an

ment over the two-element wattmeter does not justify the expense of the nal wattmeter and instrument transformers. Again, a precision measure- f power with the three-wattmeter arrangement requires the accurate cali- and the accurate reading of three wattmeters instead of one.

asurement of Power in Four-wire Circuits. — When part of the load returns through a fourth wire, e.g., in an unbalanced three-phase system a neutral wire, at least three wattmeters or wattmeter elements are d to obtain a theoretically accurate measurement of the power. A two- : wattmeter having three current circuits may be used for the measure- f power on a four-wire system, and if the vectors representing the three s to neutral form a triangle will give results having as high an accuracy e obtained with a two-element wattmeter on a three-wire system. a three wattmeters are used, they should be connected in a manner to that used for two wattmeters on a three-wire system, i.e., each of the tential circuits should be connected between a main wire and the neutral id each of the three current circuits should be connected in series with responding main wire. When instrument transformers are used the es of the potential transformers are connected in Y, with the neutral nnected to the neutral wire, the three branches being connected to the res; the secondaries and the potential circuits of the wattmeters are also ed in Y, with the wattmeters Y-connected to the Y made by the second-

Two-element Wattmeter on Four-wire System. — When used on a e system the current coil of each element is divided into two like sections, section of each coil is connected with one section other coil, thus three groups of oils. Each group cted to a current ner as shown in which also shows nections of the l transformers, o of which are . With this ar- nt the instru- easures correctly ver supplied by aches of the sys- t for the third the power meas- that correspond-

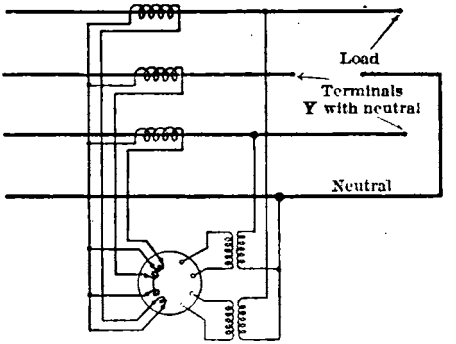

Fig. 7. Connections for Two-element Wattmeter on Four-wire System

ne current in this branch and the resultant (vector sum) of the voltages ral in the other two branches. Voltage unbalance or badly distorted and voltage waves will cause this resultant voltage to differ from the oltage to neutral in the third branch, producing an error in the measure- this third of the total power. Under ordinary conditions, however, or is not objectionably large for commercial measurements.

PHIC WATTMETERS. — These instruments are designed to draw art a curve of power against time, without any appreciable time lag. ruments of this type consist of a wattmeter element and of a time ele- The curve-drawing pointer is actuated either directly by the motion of

Digitized by Google

the moving part of the wattmeter element, or indirectly by a system of solen or a small motor, energized through relay contacts on the wattmeter moving p The purpose of the time element is to produce a steady motion of the paper the point where the curve-drawing pointer (pen) is in contact with it. T clock, which turns the paper rolls, is either of the hand-wound type or of t electric self-winding type. In several types the rate of the paper feed may t varied from ¾ inch per hour to as high as 6 inches per minute.

Semi-portable forms of graphic wattmeters are on the market, but the m accurate instruments are for switchboard use only. Large errors due to fricti between paper and curve-tracing pen or pointer, or due to change in level of t instrument, are not uncommon with certain types of graphic wattmeters.

PRECAUTIONS IN USE OF WATTMETERS. — In addition to t general precautions given under *Ammeters* (p. 37), the following special pa must be noted. A wattmeter has three distinct limits, namely, current, volta and power, no one of which should be exceeded. The potential of the movi coil must not be greatly different from that of the fixed coil, and the connecti must always be such as to ensure this condition, both in the use and in t checking of a wattmeter. This precaution is especially necessary when a external multiplier is used for high voltages.

COSTS, WEIGHTS AND DIMENSIONS OF WATTMETERS. — of 1920). — The following figures give a rough idea of the cost of wattmeters

Indicating wattmeters	Portable	Switchb
Single-phase:	$	$
Small size, unshielded or partially shielded	45- 72	32- 35
Regular size, shielded, high grade	72- 141	...
Round pattern, 7-inch diameter	...	52 100
Round pattern, 9-inch diameter	...	69- 103
Horizontal edgewise	...	54- 72
Polyphase (two-element):		
Regular size, shielded, high grade	132-197	...
Round pattern, 7-inch diameter	...	75 115
Round pattern, 9-inch diameter	...	96 124
Horizontal edgewise	...	75- 87

Current transformers are required for single-phase switchboard wattmeters of the electrodynamic type when the current exceeds 200 amperes or the volta exceeds 600 to 750 volts. The upper limit of current for polyphase switchboa wattmeters of the electrodynamic type ranges from 60 to 200 amperes. Fo induction wattmeters as now made, both single-phase and polyphase, the cu rent limit is 10 amperes. Potential transformers are required for all curre ratings when the voltage exceeds 600 to 750 volts.

Switchboard wattmeters are made in 4-inch, 7-inch, and 9-inch round patter and in horizontal edgewise pattern occupying a space on the panel 6 by 8 inches and projecting 7.6 inches from the panel.

High-grade shielded portable single-phase wattmeters measure about 5 by 9 by 6 inches high, and weigh from 9 to 12 pounds; polyphase wattmeters of the same grade measure from 8 by 8 by 10 inches high to 9.5 by 10.5 by 8 inches high, and weigh from 14 to 17.5 pounds.

VE ANALYSIS. — (*See also Alternating Currents.*) Any sine func- y of a variable t, that is, any function of the form $y = Y \sin(\omega t + \phi)$, be plotted as a wave, as shown in Fig. 1. The constant Y is called the

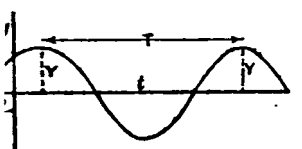

Fig. 1.

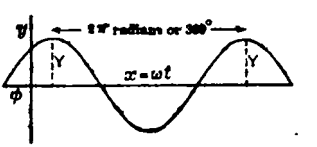

Fig. 2.

ximum value" of the wave, the constant ϕ the "phase" of the wave, and constant ω is called the "periodicity" of the wave. The distance between essive positive maxima (or between successive negative maxima) of such a e is called the "period" of the wave, and is usually represented by the ol T. The reciprocal of the period is called the "frequency," and is lly represented by the symbol $\frac{1}{T}$.

riod, frequency and periodicity are related as follows:

$$\omega = 2\pi f = \frac{2\pi}{T}.$$

he phase (ϕ) of the wave is also equal to the product of the periodicity by distance to the left of the origin at which the wave first crosses the t axis in ising direction; see Fig. 1.

plotting a wave it is usually more convenient to take as the distance along horizontal axis, not the value of the variable t, but the value of ωt. That is, ting $x = \omega t$, the equation for the wave may be written $y = Y \sin(x + \phi)$ Fig. 1 then reduces to Fig. 2. When the wave is thus plotted the distance ween successive positive maxima (or between successive negative maxima) qual to 2π radians or 360°, and the phase is the distance to the left of the in at which the wave first crosses the axis of x in the rising direction.

OURIER'S SERIES. — Any periodic function y of a variable t may be tted as a wave as shown in Fig. 3. If the function y and its first derivative h respect to t (that is, dy/dt) are finite l continuous for all values of t, then the ction y may be represented by a series of ns of the form

$$= Y_1 \sin(\omega t + \phi_1) + Y_2 \sin 2(\omega t + \phi_2) + Y_3 \sin 3(\omega t + \phi_3) + \text{etc.},$$

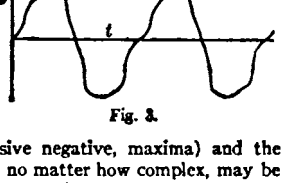

Fig. 3.

which $\omega = 2\pi/T$, where T is the period the given wave (i.e., the distance be- en successive positive, or between successive negative, maxima) and the and ϕ's are constants. That is, the wave, no matter how complex, may be resented by the sum of a number of sine waves whose frequencies are even ltiples of the period of the given wave.

This theorem is of great value in the theory of alternating currents (q.v.), ce any alternating current or voltage satisfies the above conditions. The ies is known as Fourier's Series.

As in the case of simple sine waves, it is usually more convenient in plotting

Digitized by Google

ıe distance along the horizontal, not the variable t, but the value of ωt, putting $x = \omega t$, the series for y may be written

$$y = Y_1 \sin(x + \phi_1) + Y_2 \sin 2(x + \phi_2) + Y_3 \sin 3(x + \phi_3) + \text{etc.}$$

mental and Harmonics. — The first term of the series, which has y equal to that of the given complex wave, is called the fundamen ceeding terms, having frequencies which are multiples of the fundame ency, are called harmonics. For example, the third term, or the one ing this term, has a frequency three times that of the fundament erm or sine wave is called the third harmonic, etc.

complex wave is such that the successive positive values of y for half wave are numerically equal to the successive negative values o ucceeding negative half wave, only the *odd* harmonics occur. Such called a symmetrical wave. Voltage and current waves are usual ical, and therefore contain only the odd harmonics.

ERMINATION OF MAXIMUM VALUES AND PHASES O ARMONICS BY INTEGRATION. — Consider the nth harmonic

$$y = Y_1 \sin(x + \phi_1) + Y_2 \sin 2(x + \phi_2) + Y_3 \sin 3(x + \phi_3) + \text{etc.}$$

value of $u_n = y \sin nx$ between the limits $x = 0$ and $x = 2\pi$, and int resultant curve, by planimeter, between these limits 0 and 2π. C U_n. Similarly, plot the value of $v_n = y \cos nx$ between the limits x $= 2\pi$, and integrate the resultant curve, by planimeter, between the nd 2π. Call this area V_n. Then

$$Y_n = \frac{1}{\pi}\sqrt{U_n^2 + V_n^2}$$

$$\phi_n = \frac{1}{n}\tan^{-1}\left(\frac{V_n}{U_n}\right).$$

ıe wave length of the fundamental corresponds to 360°. If the wav only the *odd* harmonics, as is usually the case in current and volta *e preceding paragraph*), U_n and V_n need be plotted only between th nd π. Calling U_n' and V_n' the corresponding areas, then

$$Y_n = \frac{2}{\pi}\sqrt{(U_n')^2 + (V_n')^2},$$

$$\phi_n = \frac{1}{n}\tan^{-1}\left(\frac{V_n'}{U_n'}\right).$$

ıethod, though cumbersome, is applicable to the determination of th n value and phase of any harmonic.

HER-HINNEN METHOD OF ANALYSIS.— (*Elec. Journal, 190 age 386; Electrotechnische Zeitschrift, 1901, Vol. 22, page 396.*) Thi s quite simple when the wave contains only the fundamental and th h and seventh harmonics. When even harmonics are present, or whe st higher odd harmonics than the seventh, certain corrections must b Since voltage and current waves usually contain only odd harmonics ɔm contain higher harmonics than the seventh, the simple metho corrections is usually sufficiently accurate.

s Containing only the Third, Fifth and Seventh Harmonics. — nine the nth harmonic (n equals 3, 5 or 7) divide the base of a half

Digitized by Google

into 2 n equal parts and measure the ordinates of the wave at the beginning of each of these sections of the base. Call these ordinates y_1, y_2, y_3 . . . y_{2n}, taking the y's positive if above the base line, negative if below. ll be zero, since the first section begins where the resultant wave crosses ase line.

en the ordinates of this harmonic at the points 1 and 2 are, respectively,

$$A_n = \frac{1}{n}[(y_2 + y_6 + \ . \ . \ . \ y_{2n-1}) - (y_3 + y_7 + \ . \ . \ . \ y_{2n-3})],$$

$$B_n = \frac{1}{n}[(y_2 + y_4 + \ . \ . \ . \ y_{2n}) - (y_4 + y_8 + \ . \ . \ . \ y_{2n-2})].$$

maximum value of this harmonic is

$$Y_n = \sqrt{A_n^2 + B_n^2},$$

the phase angle, calling the wave length of the fundamental 360°, is

$$\phi_n = \frac{1}{n}\tan^{-1}\frac{A_n}{B_n}.$$

hese formulas give the third, fifth and seventh harmonics (n = 3, 5 and 7 ectively). The fundamental is found by calculating

$$A_1 = -(A_3 + A_5 + A_7),$$
$$B_1 = y_0 + B_2 - B_4 + B_6,$$

re y_0 is the mid-ordinate of the half wave. Then

$$Y_1 = \sqrt{A_1^2 + B_1^2},$$
$$\phi_1 = \tan^{-1}\frac{A_1}{B_1}.$$

he equation of the given wave is then

$$Y_1 \sin(x + \phi_1) + Y_3 \sin 3(x + \phi_3) + Y_5 \sin 5(x + \phi_5) + Y_7 \sin 7(x + \phi_7).$$

e *effective* value of the given wave is

$$Y = \sqrt{\frac{Y_1^2 + Y_3^2 + Y_5^2 + Y_7^2}{2}},$$

d the *average* value is

$$Y_{av'ge} = \frac{2}{\pi}\left[Y_1 \cos\phi_1 + \frac{1}{3}Y_3 \cos 3\phi_3 + \frac{1}{5}Y_5 \cos 5\phi_5 + \frac{1}{7}Y_7 \cos 7\phi_7\right].$$

In using the above formulas strict attention must be paid to algebraic signs.

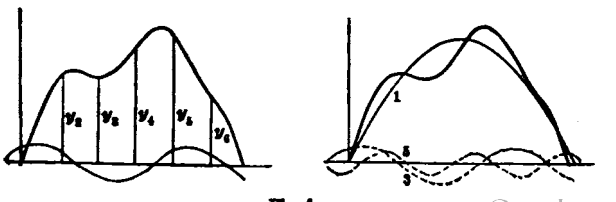

Fig. 4.

Digitized by Google

Example. — Find the third harmonic in the wave shown in Fig. The values of the six ordinates are found by measurement to be 0, 676, 940, 1004 and 554 respectively. Then

$$A_3 = \tfrac{1}{3}(1004 - 660) = 114.7,$$
$$B_3 = \tfrac{1}{3}(676 + 554 - 940) = 96.7,$$
$$Y_3 = \sqrt{(114.7)^2 + (96.7)^2} = 150,$$
$$\phi_3 = \tfrac{1}{3}\tan^{-1}\frac{114.7}{96.7} = 16.6°.$$

Similarly, for the fifth harmonic,

$$A_5 = -92.8 \text{ and } B_5 = 37.4,$$
$$Y_5 = 100 \text{ and } \phi_5 = -13.6°.$$

For the fundamental,

$$A_1 = -114.7 + 92.8 = -21.9,$$
$$B_1 = 940 + 96.7 - 37.4 = 999.3,$$
$$Y_1 = \sqrt{(21.9)^2 + (999.3)^2} = 1000,$$
$$\phi_1 = \tan^{-1}\frac{-21.9}{999.3} = -1.25°.$$

Hence the complete expression for the given wave, taking as the origin point at which the resultant wave crosses the base line in the rising direction

$$y = 1000\sin(x - 1.25°) + 150\sin 3(x + 16.6°) + 100\sin 5(x - 13.6°).$$

The *effective* value is then 718 and average value 673.

WEIGHTS (MASSES) OF MATERIALS. — (*See also Mechanics, Principles of.*) The density of any substance is the mass of that substance per unit volume. Or, using weight in the ordinary sense as equivalent to mass, the density may also be defined as the *weight* per unit volume. The numerical value of the density of any substance depends upon the unit in which the mass or weight is expressed and also upon the unit of volume used; see *Units and Conversion Factors*. However, it is quite common to state the density of a substance in grams per cubic centimeter, without naming the units, and when so expressed the density is numerically equal (practically) to the specific gravity.

The "specific gravity" of a substance is defined as the ratio of the weight (mass) per unit volume of that substance to the weight (mass), expressed in the same unit of an equal volume of water. To make such a statement exact the temperature of the water should be specified. There is no general agreement as to the temperature of reference, though water at 0° C. is commonly taken as the reference temperature. For gases, air at 0° C. and 760 mm. mercury pressure is frequently taken as the reference substance instead of water.

Variation of Density of Water with Temperature. — The following table gives the results of measurements by Thiesen, Scheel and Diesselhorst (*Landolt, Börnstein and Roth, Physikalisch-chemische Tabellen, 1913*).

G, ELECTRIC. — The heat of the electric current is used in ocesses for welding metals, both ferrous and nonferrous. The ıay be tabulated as follows:

lesignation	Varieties		Kind of current at weld
e welding	Butt welding		A-C.
	Spot welding		A-C.
	Seam (or line) welding		A-C.
: welding	Using discharge from static condenser		D-C.
	Using electro-magnetic discharge		D-C.
ng	Carbon arc		D-C. (though A-C. may be developed)
	Metal arc	With bare electrodes	Usually D-C. but occasionally A-C.
		With flux covered electrodes	Either D-C. or A-C.

APPLICATIONS OF ELECTRIC WELDING. — Arc Welded , good many years ago the Seamless Steel Boat Company of Wakefield uilt successful all-steel life boats in which the joints in the shell re welded by the carbon arc process before being pressed into ıe *Dorothea M. Geary*, a boat with a length of 42 feet and a width nd driven by a 50 horsepower gasolene engine, was built with most nting done by arc welding using bare metal electrodes. It was n Lake Erie in 1915.

the British Admiralty, using flux-covered electrodes, built an arc ton Cross Channel barge. It is 125 feet in length and 16 feet wide. re was built in France an arc-welded barge 65 feet long by 15 feet welding work was all done by women. In 1920 the *Fullagar*, a ster built by Messrs. Cammell Laird and Company, and entirely was launched at Birkenhead. The *Fullagar*, which is driven by an bustion engine of the type designed by the late Mr. H. F. Fullagar, of 10 knots and a length of 150 feet.

cases are mentioned as being of interest because the displacement of arc-welding for making the joints in the shell plating, foreshadows y immense field for arc welding.

y there is a very large amount of arc welding in ship construction In the space of this article their mere enumeration would be impospical may be mentioned: repairs of boilers, stern frames, stems, s, windlasses, shaft-brackets, rudder gudgeons, and fuel tanks. s, anti-submarine bulges have been attached to hulls and their

Digitized by Google

ıell plates have been arc welded, such undertakings exceeding in magni-
ıe welding of complete vessels of moderate tonnage.
The Times Engineering Supplement," for April, 1920, Caldwell enumer-
follows the advantages of arc welding in ship construction:
With the elimination of marking off, drilling or punching, countersinking
ulking, a considerable economy in time and labor can be effected.
By the reduction in width of laps and size of butt straps a saving of from
per cent of material can be effected.
Welded joints can be made to withstand greater stresses than similar
joints, and can be made equal in strength to the ship plating.
Once the practice is standard a reduction in the weight of the shell plating
possible without reducing the safety factor.
A welded joint is oil and water tight up to its breaking point, whereas
and caulked joints are liable to leak badly at as low as 25 per cent of
ıtimate strength.
While these may be described as general advantages, there are specific
here electric arc welding possesses even greater attractions. For example,
sent expensive smith-work involved in making complicated knees, angle
frames, etc., can be replaced by notching, bending up, and welding the
ıt a fraction of the present cost, and it provides an ideal method of secur-
ngs, etc., to water-tight bulkheads without piercing them, and of making
ight joints round pipes, etc., where these have to pass through bulkheads.

Welding in Railway and Other Shops. — Several of America's great
s each employ many dozens of arc welding operators in repair work on
:ives and are thereby effecting great economies. In street railway shops
economies are obtained; as also in boiler shops, foundries, blast furnaces,
es, machine shops and mines.

ding in Manufacturing. — Not alone arc welding, but also (already on a
rge scale) resistance welding, are being applied in the manufacturing of
s of products of steel and other metals. The use of such methods is
ng at an enormous rate.

ding Steel Buildings. — In England the steel work of the roofs of several
uildings has been joined entirely by arc welding and the saving of time
ney as compared with riveting has been shown to be very great. This
r to be a very important field for electric welding, both arc welding and
ıce welding.

SISTANCE WELDING. — The art of welding metals by passing a
tage alternating current across the surface of contact of the metals to be
was worked out and made a commercial success by Professor Elihu
on in the 80's. This process, which is known as resistance welding, is in
ide use and is so familiar to all engineers that there is no occasion for
ıan the briefest review.
any given application of resistance welding, the engineering problems
relate chiefly to the design of machines for holding the parts, bringing
ıto suitable juxtaposition, regulating the mechanical pressure and rate of
e of the parts toward one another at various stages of the process of
; the metal at the surfaces of contact, arresting the process at the proper
, and the regulation of the current to the most suitable amount at all
of the process. Careful consideration requires also to be given to the
ıl shapes of the two surfaces to be brought together and of the proportions
parts in the neighborhood of these surfaces. For some applications the
sults are obtained by welding a third (and otherwise superfluous) piece of
to each of the two parts to be joined.

Digitized by Google

Most metals in reasonable states of purity can be joined to one another by the resistance process. Welds can also be made between some alloys. Practically all grades of steel are readily welded. Different metals can also, in some instances, be welded to one another. The current, for resistance welding, is usually supplied from the low-voltage secondary of an alternating current transformer, but direct current might under certain circumstances be used to advantage.

Butt Welding. — When, in the resistance process, the parts to be welded to one another are "butted" together, the current passing through the entire section of metal near the weld, the term butt welding is often employed. In all resistance welding the heat is generated within the metal and not brought to it from the outside as in other processes.

Spot Welding. — When, in resistance welding, the current is passed transversely across two plates which it is desired to joint at many places (or spots) the term spot welding is employed. Spot welding has been employed for many years for thin plates of metal. It has recently been applied to the welding of steel plates of thicknesses up to one inch. This latter development is described more fully in a later paragraph.

Seam Welding. — When, in resistance welding, the point of introducing and carrying away the current moves along a line so as to make a continuous weld along that line, the term seam welding, or line welding, is employed.

SPOT WELDING OF THICK PLATES. —Spot welding of thick plates is an alternative to the long established process of riveting and bids fair to be very extensively employed in most kinds of work now using rivets. As important examples may be mentioned the construction of steel ships, steel buildings and, in general, in many uses of structural steel. Where the parts can be brought to the welding machine, the process is especially attractive. But portable spot welders have been developed and have been used with success in ship construction.

Duplex Spot Welder. — (Fig. 1). — The usual construction of commercial spot welders for use in shipbuilding is similar in general appearance to so-called bull-riveters. The largest spot welder yet built for actual use in ship fabrication has a six-foot gap and operates from a 60-cycle circuit. This outfit is a stationary machine in the frame of which two transformers are incorporated and to which the steel plates and shapes are brought. Bulkheads, frames, floors and other parts are constructed with it, and are then transported by cranes to their places in the ship. This six-foot-gap machine has the capacity to weld two three-quarter-inch-thick plates. It provides a pneumatic pressure of 60,000 pounds and a current of 50,000 amperes. It is called a duplex welder and welds simultaneously two spots, each of some 1.5 inch diameter, in about 30 seconds.

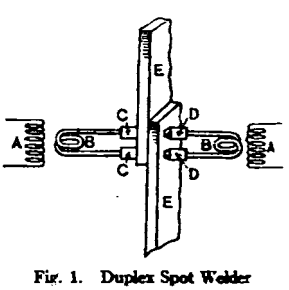

Fig. 1. Duplex Spot Welder

The arrangement is shown diagrammatically in Fig. 1. The outfit comprises two transformers, one located on each side of the plates to be welded. The current crosses the plates in one direction between two electrodes and then back again between two other electrodes. Thus the two secondaries and the two joints make four elements connected in series.

presents its secondary.
id *D* represent water-cooled copper electrodes.
id *F* represent the two plates to be welded.

ypical 60-cycle portable welder of this type ving a 27-inch gap weighs only 2800 pounds, ng the transformer (which is embodied in the ire), and welds plates of a thickness of half h with a current of about 30,000 amperes. quired pressure for such work is some 25,000

experimental work, currents up to 100,000 s have been employed in improvised spot g machines, and pairs of one-inch-thick steel have been welded.

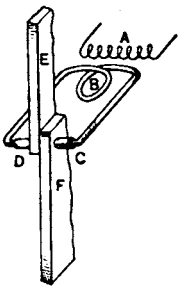

Fig. 2. Simplex Spot Welder

ght Car. — Although until very recently elding has generally been employed only for thin plates, mention should be made of the 50-ton gondola freight ich was completely spot welded in 1911 by Mr. J. A. Osborne, Chief er of the American Car and Foundry Company of St. Louis, Mo. ince that time, this car has been in regular service on the C. B. & Q. y. In 1918, Mr. Osborne reported that the welded joints have suc- y withstood the severe stresses of continuous hard use. The spot built by Mr. Osborne in 1911 for this undertaking was demonstrated to ible of making sound welds with plates of ¾-inch thickness. It had a throat and housed an 85-kw. transformer with a secondary giving s on open circuit. The welding points of the copper electrodes had a er of ¾ inch.

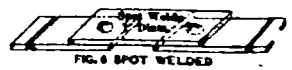
Welding Versus Riveting. — Spot welding would appear to have l advantages over riveting for a great variety of important work now done by riveting. By employing spot-welding great savings are l through eliminating the laying out and punching of the rivet holes, e subsequent reaming when the holes do not match up. Furthermore s avoided the reduction in cross-section and strength occasioned by the ty for the rivet holes. With spot welding there is a great saving in al through the reduction in overlap made practicable as compared with) or three rows of rivets which often have to be employed. Tests show eater strength can be obtained with a single row of spot welds than with ıt triple riveting.

ed of Spot Welding. — At p. 175 of Vol. 38 (1919) of the Trans. A.I.E.E., hn Martin of the American Bureau of Shipping reports as follows:
one test performed in the writer's presence, 32,000 amperes with a volt-

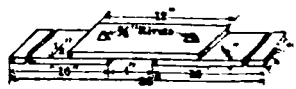
Digitized by Google

age of 4, successfully spot-welded pairs of ⅝ inch to 2.5 inches ship steel plates together, the diameter of the spots being 1 inch, the pitch 3 inches, and the hydraulic pressure 7½ tons. The time of the current was 15 seconds. 15 feet was welded in 30 minutes. The spots sheared at 56,000 pounds, or partly pulled and sheared at 60,000 pounds. Water and oil-tight joints resulted without calking. For plates of the same pitch, calking or arc fillet welds would be required for water-tight joints; though by lessening the pitch and decreasing the diameters of the spots, practically the same water-tight results could be had."

Power Required for Spot Welding. — In a paper entitled *Practical Applications of Electric Welding*, read by F. P. Vaughan on October 15, 1920, before the Engineering Institute of Canada, the following table of data applying to the spot welding of mild steel plates is given:



Thickness of plates, S.W. gage	Total welded thickness, inch	Power, kw.	Time, seconds
24	0.044	4.3	0.6
22	0.056	4.6	0.8
20	0.072	4.7	1.0
18	0.096	5.3	1.2
16	0.128	6.3	1.8
14	0.160	6.6	1.8
12	0.208	8.0	2.5
10	0.256	9.0	3.0



Spot Welding Combined with Arc Welding. — Arc welding (described later) may be used in combination with spot welding, the former being relied upon not only for calking but to contribute to the total strength of the weld. Some tests comparing ordinary riveted joints with this method of spot and arc jointing are described at page 95 of Vol. 38 (1919) of the Trans. A.I.E.E. as follows:

FIG. 3 FILLET AND SPOT WELDED

FIG. 4 FILLET WELDED

FIG. 5 RIVETED AND FILLET WELDED

FIG. 6 SPOT WELDED

FIG. 7 RIVETED JOINT

The specimens were made up of the following combination:

1. Spot and fillet welded, Fig. 3 (two samples made).

2. Fillet welded—made by welding fillets about two inches in length at the ends of the plates, Fig. 4 (two samples made).

3. Riveted and fillet welded, Fig. 5 (one sample made).

4. Spot welded—made by welding two spots approximately one inch in diameter, on the plates, Fig. 6 (two samples made).

5. Riveted joint, made by riveting a 0.5-inch by 4-inch by 12-inch plate with two plates 0.5-inch by 4-inch by 16-inch, using two ¾-inch rivets and a 4-inch lap. Fig. 7 (one sample made).

esults of the test show the comparative strength of the joints as follows:

	Ultimate load, Pounds
ınd fillet welded (average of tests on two samples)	50,350
welded (average of tests on two samples)	37,500
d and fillet welded (only one sample made)	35,000
relded (average of tests on two samples)	28,000
d joint (only one sample made)	13,000

Use of Resistance Welding. — At p. 146 of Vol. 38 (1919) of the .I.E.E., Mr. Hermann Lemp, a pioneer in resistance welding, in compar- ance welding with arc welding (described later), writes as follows:

ı one considers the vast quantities of mild steel products daily welded iited States alone (by the resistance process of Professor Elihu Thomson) , with unskilled persons operating automatic and semi-automatic y, with a speed unexcelled by the arc-welding process, the writer may ned for drawing attention to one characteristic feature of the process; that parts to be welded are substantially protected against contact oxygen of the air, and what few oxides may be formed near the edges ively squeezed out of the joint by the pressure exerted on completing

In addition, all kinds of metals and alloys, some of which are termed le, are successfully welded thereby. Crane chains, harness rings, le rims, bicycle tubing, wire fences, carriage tires, metal wheels, etc., d daily in such quantities as would astonish any one when confronted ıal figures. In the welding of valve flanges to cylinders of Liberty motors at Detroit, the Thomson Process (of resistance welding) easily the gas and electric-arc processes, as regards both speed and excellence l product."

D OF BUTT WELDING BY RESISTANCE PROCESS AND T OF ELECTRICITY CONSUMED. — Mr. Vaughan gives ing table as applying to the butt welding of "ordinary bar iron, wheel ;, cycle rims, shafting and piping and various forms of rods, etc." by ınce process.

ection of metal at the weld, square inches	Approximate power consumption		
	Maximum kw. per weld	Duration of weld, seconds	Kw.-hr. per weld
0.25	10	15	0.075
0.50	15	20	0.13
0.70	20	30	0.2
1.0	25	35	0.3
2.0	40	60	0.7
3.0	50	90	1.25
5.0	65	208	3.75
7.0	80	315	7.0
9.0	95	400	10.5
10.	105	428	12.5
11	115	453	14.5
12	125	475	16.5

Digitized by Google

For butt welding round copper rods by the resistance process, Mr. Vaugh values are:

Size		Power, kw.	Time, seconds
Diameter, inches	Area, square inches		
¼	0.05	5	4
⅜	0.11	7	5
½	0.20	14	7
⅝	0.31	19.5	9
¾	0.44	28	12
⅞	0.60	35	14
1	0.79	48	17
1⅛	0.99	63	21

SEAM (OR LINE) WELDING. — A seam welder may be so desig as to have the weld made between a wheel rolling on a bar, or between t wheels rolling together. For thick plates, the design with two wheels roll together is probably the most suitable. Mr. R. E. Wagner, who has had w experience in the design and use of seam welders, has given the writer the follo ing tabulated data applying to the seam welding of mild steel plates:

Thickness of each plate, inch	Speed making line weld, in feet, per minute	Corresponding current, amperes	Pressure in pounds per square inch
0.0140	5	3500	2,200
0.0625	2.5	7000	13,000
0.0938	2.5	8000	22,500

In the above table the pressure is calculated on the basis of having a contac area in each case of 1/32 square inch.

The voltage of the welding circuit on open circuit may vary from 2 to 10 volt depending upon the impedance introduced into the welding circuit by its desig The actual drop across the weld will vary between ¼ and 1 volt. The plat at the line of welding must be free from scale and rust. A properly mad seam weld has a strength at least equal to that of the plates which are welde together.

PERCUSSIVE WELDING. — Mr. L. W. Chubb invented the process o percussive welding in 1905.

Percussive Welding with Static Condenser. — At that time the method consisted in discharging a static condenser simultaneously with the delivering o a percussive blow in a direction to force together the two metal parts to be welded The process was applied chiefly to welding together relatively small wires, th largest being No. 12 B. & S. gauge. The ends of the wires are cut with suitabl

ters and the resulting chisel edges arranged to make a right-angle inter- thus starting the discharge of energy at a central point of contact. urrent density is stated to be about 400,000 amperes per square inch. xcess is suitable for welding together wires of utterly different material platinum to lead, tungsten to aluminum, and aluminum to copper.

romagnetic Percussive Welding. — More recently an electromagnetic of percussive welding has been developed by Mr. Chubb and is adapted heavy work. Stored up electromagnetic energy is released under such is as to establish a short arc between the surfaces to be welded. This iversed by a very heavy current for less than a tenth of a second and in that time to melt these surfaces. They are immediately forged by a hammer blow. The secondary current approximates 30,000 per square inch at an arc drop of from 20 to 40 volts, and it only flows ll fraction of a second. The heat is so localized that the weld is effected expenditure of a minimum of energy. It is claimed that the energy l per weld is only a very small part of that required in resistance weld- th the electromagnetic process of percussive welding parts up to ½ ieter are readily welded and it is anticipated that the method will soon ped to be applicable to much larger welds.

of Application for Percussive Welding. — It is claimed that percus- ing permits of readily welding together very unequal sections, since duration of the process precludes difficulties due to unequal heating n or difference in melting points. For example, small rods may be heavy plates. In tool manufacture, steel alloys may be welded to l steel. Brass and copper parts may, by the percussive process, be steel parts. Percussive welding has been described in more detail er presented by Mr. Chubb before the American Electrochemical October, 19 nd more recent developments have been described . F. Miner before the A.I.E.E., in June, 1920.

TRIC ARC WELDING. — The technique of electric arc welding cally nothing in common with that of butt and spot welding, although lly identical objects are in some cases obtained by both methods. wever, the associated circumstances will indicate which of the two lectric welding should be employed. While butt welding and spot re applicable to almost all kinds of metals, electric arc welding is nfined to the welding of steel.

ntering upon the consideration of electric arc welding, it should be it that it is one of the two main subdivisions of an art which is often **autogenous welding**, but which will here be designated **fusion**

Welding. — The term fusion welding is employed to comprise gas nd electric arc welding. Gas welding does not come within the scope icle, and it must suffice to state that the process in its simplest form simultanelusly fusing with an oxyacetylene flame (1) the material r the surfaces which it is desired to join, and (2) some material (which similar in composition) in the form of a rod, the tip of which is sub- the heat of the flame. The oxyacetylene flame is directed with one the welding rod is manipulated with the other hand.

of Electric Arc Welding. — Electric arc welding may be subdivided al classes. The two broadest classes are:

a. Carbon arc welding.
b. Metal arc welding.

Digitized by Google

In carbon arc welding, an arc (usually several tenths of an inch in length established between a carbon or graphite electrode (usually a carbon electrode and the two pieces of steel which it is desired to join. This carbon electrode manipulated with one hand and a welding rod is fed into the weld by the other hand. The manual activities in carbon arc welding are seen to be quite similar to those in gas welding. In neither case is it necessary for the material of the welding rod to traverse the arc.

In metal arc welding, there is a fundamental difference in this latter respect since in metal arc welding of mild steel, instead of having a carbon electrode for one terminal of the circuit, the arc is established between a steel welding rod (or welding electrode) and the two steel parts requiring to be joined. There is always a distance of preferably not over one-tenth of an inch between the end of the welding rod and the work. This distance is bridged by an electric arc.

Kinds of Work Not Requiring Welding Rod. — Both for carbon arc welding and gas welding, the edges of the parts to be joined sometimes may be so designed as to obviate the need for any additional material; in other words no welding rod is necessary in such cases. In Fig. 8 is shown a case where it is not necessary to use a welding rod, since it suffices to simply melt the adjacent flanges with an arc.

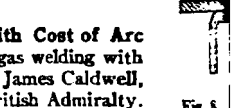


Fig. 8.

Comparison of Cost of Gas Welding with Cost of Arc Welding. — Quite a thorough comparison of gas welding with metal arc welding was made in 1917 by Major James Caldwell, then of the Controller's Department of the British Admiralty. This comparison is reproduced at p. 85 of Vol. 38 (1919) of the Trans. A.I.E.E. Since that date there has been a great deal of careful study given to the subject. For thoroughly first class welds, the speeds formerly credited to gas and arc welding are not obtained even by the most skilful operators. The author has made every effort to arrive at reasonable values for the various data involved and has compiled the results in the following table as representative of his opinion. The table indicates that gas welding has the advantage over metal arc welding for plates of 1/16 inch thickness, both as regards speed and cost. From 1/8 inch to 3/4 inch thickness, the author credits both methods with the same speed, but the advantage as regards lower cost increases rapidly for the metal arc method with increasing thickness of plate. For thicknesses of 7/16 inch and 1/2 inch both speed and cost are very decidedly in favor of metal arc welding. The costs (1921 basis) by the two methods are plotted in the curves in Fig. 9. Plenty of authority can be found for differing with the present author's results, since speeds over twice as great as those in the table have often been claimed by welding specialists as being representative. The speeds in the table are such as can be maintained by a fairly skilled welder during an eight-hour day and under thoroughly favorable conditions. The plates to be welded are assumed to be laid flat and at a convenient height for the operator to work. It is also assumed that the edges have been prepared and that the plates are clamped and all ready for welding. As regards the consumption of electricity it is assumed that the welding is done from a 110 volt circuit with a rheostat in series with the electrode. With a motor generator set the consumption would not be enough different to much affect the aggregate cost of (1) electricity, (2) electrodes, and (3) labor.

Welding Machinery. — The voltage at the arc is only some 15 to 20 volts, consequently while welding, some 85 per cent of the electricity consumed is wasted in the rheostat when operating from a 110-volt circuit. By interposing a motor-generator set transforming to lower voltage, the efficiency while welding may be considerably increased notwithstanding the losses in the motor

Thickness of metal in inches	Oxy-Acetylene							Metal arc (bare electrodes)

generator set. But in the intervals between welds there are no losses with t former outfit, while with the latter outfit the running light losses in the mot generator set detract from the "all-day" efficiency. It will be readily s

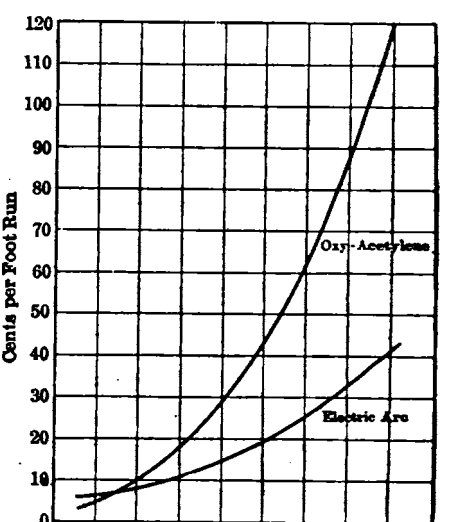

Fig. 9.

that all the attendant circumstances must be taken into consideration in det mining upon the most suitable plant to install for arc welding.

Each of several manufacturers has placed on the market types of weldi apparatus with characteristics for which advantages are claimed and realiz Even brief descriptions would occupy too much space for this article. Furth more it is the author's opinion that substantially equally good arc welding c be done with any of the best known types of machines, and it resolves it down to a question of relative costs and economy of operation. These featu should be given careful comparative study before purchasing a welding plan but it is much more a question of economics than of obtaining the best weld This latter object depends chiefly on having good operators and good materia

With a-c. welding a transformer is employed, but while the efficiency is goo the power factor is very bad. This does not disqualify a-c. arc welding, bu should be taken into account in balancing the advantages and disadvantages.

Speed of Arc Welding and Energy Consumption. — The speeds of makin butt welds by the arc process with various thicknesses of steel set forth in th preceding table are not necessarily applicable to other than the material the employed and all the attendant circumstances. The attainable speed for firs class arc welds is a function of (1) the skill and disposition of the operator, (2 the kind of circuit from which he welds and the characteristics of the intermedi ary welding apparatus and the voltage, (3) the length of the arc which the opera

Allowance for Waste of Electrode Material. — Based on researches involving the welding of ten tons of half-inch-thick ship plate, Spraragen has concluded that out of 100 per cent weight of electrode,

70 per cent is deposited in the weld,
12 per cent is burned or vaporized,
18 per cent is wasted as short ends.

Angle of Bevel of Welding Edges. — As to the effect of the preparation of the welding edges on the speed of welding and the quality of the weld, tests were made by Spraragen at the author's request. In each case ½-inch thick ship plate was used, and a weld 3 feet long was made in a flat position with 5/32-inch diameter bare electrode and a "free distance" of ⅛ inch. The welded plates were cut up and subjected to standard tensile and bending tests. The results are shown in the table at bottom of page 1955.

Fig. 14

Fig. 15

Preparation of Bottom Edges. — In Figs. 14 and 15, Spraragen shows two specimens of half-inch plate both prepared with 60-degree edges, and with the same "free distance" of ⅛ inch. In Fig. 14 the bottom edges are sharp, while in Fig. 15 shoulders are provided. The results were:

Fig. No.	Speed of welding, feet per hour	Pounds of electrode wire needed per foot of weld	Pounds of electrode wire used up per hour
14	2.3	1.1	2.5
15	2.8	0.9	2.5

Wagner's Tests of Relation of Speed to Current. — With skilled welders the speed of arc welding may be increased considerably when larger currents are employed. Also, up to a certain value, the strength of the weld is greater the greater the current. This is brought out by Mr. R. E. Wagner in a series of tests on ½-inch tank-steel plates. The plate edges were prepared with

Current in amperes	Size of electrode, inch	Tensile strength in pounds per sq. in. after grinding off the raised parts of the welds
80	5/32	37,000
125	5/32	50,000
150	5/32	57,000
180	5/32 and 3/16	63,000
220	5/32 and 3/16	66,000
275	3/16	62,000

Data of Speed and Cost of Welding a Large Steel Tank with Bare Electrodes. — In 1918, Wagner welded a 12-foot-cube tank of half inch steel and purposely employed a great variety of types of joint including those already shown in Figs. 10 to 13 and also those shown below in Figs. 17 to 20, and a number of other types. The speed of welding was 3.0 feet per hour. The weight of the steel in the tank was 16,000 pounds, and the weight of electrode used up was 334 pounds, of which 299 pounds was deposited in the welds. The total welding time was 165 hours, corresponding to using up electrodes at the rate of just 2 pounds per hour. The total length of weld was 501 feet, the weight of electrode used up per foot of weld thus being 0.60 pound. 0.29 pound of welding wire was deposited and 0.33 pound was used up per kilowatt hour of electricity. The diameter of the welding wire was 5/16 inch. Six different operators worked on the job and the average current per operator (when actually welding), was 13 amperes. The per cent of time welder was welding was ascertained to be 6 per cent.

Fig. 17

Fig. 18

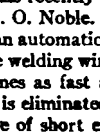

Fig. 19

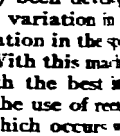

Fig. 20

Automatic Arc Welding. — Machinery has been developed permitting automatically feeding the welding wire at such a rate as to maintain a steady and very short arc. A direct current type has recently (1920) been developed for the General Electric Company by Mr. P. O. Noble. Any variation in the length of the arc is immediately corrected by an automatic alteration in the speed of the motor controlling the rate of feed of the welding wire. With this machine the speed of welding is from two to five times as fast as with the best hand operators. Time lost in changing electrodes is eliminated by the use of reeled welding wire. This also eliminates the waste of short ends which occurs with hand welding with the usual 18-inch straight welding rods. As further advantages may be mentioned the even deposit of the electrode metal which minimizes defects and produces uniform welds which are stronger and more effective than with the hand process. The uniform arc and uninterrupted feed reduce the power consumption.

At pages 150 to 157 of Vol. 38 (1919) of the Trans. A.I.E.E., Mr. H. D. Morton describes his work in the development of automatic and semi-automatic arc welding machinery and gives illustrations of a semi-automatic machine and of some work done with it.

Flux-covered Electrodes. — In America practically all metal arc welding is done with bare-wire electrodes. In England, on the contrary, flux-covered electrodes are much the most extensively employed. The limits of space will not permit describing the nature and variety of the flux coverings employed.

From the lack of interest displayed in America on the subject of flux-covered electrodes, it may be inferred that for the great bulk of electric arc welding entirely adequate results are obtained by the much cheaper bare electrode. The author's opinion is, however, that a higher grade of work can be obtained by the use of suitable flux-covered electrodes in the hands of operators skilled in their use. Especially with respect to ability to withstand tests of their ductility and to withstand fatigue tests he believes that welds can be made with flux-covered electrodes which can probably not be equalled with bare wire electrodes. It would not appear that this justifies the greater outlay, for ordinary

:. The use of electrodes with other than the very best flux-coverings may y lead to welds much inferior to those obtained with bare electrodes of good ity.

ıe present (1921) cost of flux-covered electrodes ranges from 60 cents per ıd for electrodes with steel cores of ⅛-inch diameter down to 40 cents per ıd for those of 0.16-inch diameter. Taking a mean value of 50 cents per ıd of steel in the electrodes, and assuming for the speed of welding, quantity ectrodes and amount of electricity per foot of weld, the values taken in table previously given for bare electrodes, there results for the cost per in the two cases the following values:

COMPARATIVE COSTS OF MANUAL BUTT WELDING FOR VARIOUS THICKNESSES OF MILD STEEL

Thickness of metal, inches	Speed of welding, feet per hour	Outlay in cents per foot of weld, for (1) electricity, (2) electrodes, and (3) labor	
		Using bare electrodes	Using flux-covered electrodes
1/16	16	6.0	7.3
1/8	13	8.0	10.2
3/16	10	11.0	14.8
1/4	8	14.0	19.0
5/16	6	18.8	25.7
3/8	4 1/2	25.1	34.2
7/16	3 1/2	32.9	45.5
1/2	3	41.7	60.7

D-C. and A-C. Electricity for Arc Welding. — Arc welding is, in America, ıally done with d-c. electricity. In England a-c. electricity is in much greater than in America for arc welding. It is more difficult for the welder when . is used, especially when he employs bare electrodes. But with some kinds flux-covered electrodes, a-c. may be used without any notable difficulty in nipulation as compared with direct-current. When a-c. is used, every pre- ution should be taken to guard the operator from shock, notwithstanding the r voltage employed.

Comparison of Strengths of Riveted and Arc Welded Joints. — p. 870 of the *General Electric Review*, for December, 1918, Mr. H. Jasper Cox Lloyd's Register of Shipping, published the following tabular comparison of : tensile strengths of riveted and arc welded joints of ship plates of half-inch d three-quarter inch thickness,

Digitized by Google

Thickness, inches	Diameter of rivet, inches	Total sectional area, square inches	Breaking stress, pounds per square inch	Strength of plain plate, pounds per square inch	Percent strength of joint
		Triple-riveted lap joints			
0.49	¾	.....	42,400	61,400	69.0
0.53	¾	.....	38,300	54,700	61.5
		Lap weld with full fillet at both edges			
0.514	.....	10.02	45,300	63,600	71.0
0.73	.....	8.76	40,330	59,600	68.0
		Butt weld (not strapped)			
0.505	.....	10.66	61,000	63,600	96.0
0.76	.....	9.88	54,680	59,600	91.5

Comparative Costs of Joining Ship Plates by Riveting and Welding. The following are British figures and would not necessarily apply in America but they give a good illustration of tendencies. They are taken from an article by Caldwell in *The Times Engineering Supplement* for April, 1920.

Thickness of plate in inches	Description of joint	Diameter of rivets, inches	Cents per foot *
5/16	Single riveted lap	¾	43
	Light welded lap	.....	30
	Double riveted lap	¾	81
	Heavy welded lap	.....	40
½	Single riveted lap	⅞	51
	Light welded lap	.....	38
	Double riveted lap	⅞	91
	Heavy welded lap	.....	47
	Double butt strap	⅞	120
	Heavy butt weld	.....	47

* On the basis of one pound sterling = $4.

CARBON ARC WELDING. — Where carbon electrodes are used, the electrode is connected to the negative terminal of the circuit. The process is especially suitable for quick work requiring the melting of large quantities of material, such as in filling blow holes and in salvaging defective castings and forgings. It is also used for much other work, such as welding long seams which may be so designed with abutting edges as to permit of effecting the weld by simply fusing these edges without adding electrode material. An example of such a joint has already been given in Fig. 8.

Digitized by Google

carbon arc welding the arc is very long (of the order of an inch or so), and considered that this entails the disadvantage that the weld may be badly ed.

rrent Employed in Carbon Welding and Size of Elec-s. — A reliable trade bulletin the accompanying data as ble values for the current for n arc welding.

Class of work	Amperes
Light welding	150 to 250
Medium welding	250 to 350
Heavy welding	400 to 600
Very heavy welding	600 to 1000

e same bulletin gives the ac-anying data for the maximum nt for carbon electrodes of var-izes.

Diameter of carbon electrode, inch	Maximum current, amperes
¼	100
½	300
¾	500
1	1000

ll higher currents can be used by employing graphite electrodes, but their r cost usually disqualifies them for use as welding electrodes.

eed of Carbon Arc Welding. — It is found that for depositing or build-p metal on flat surfaces where the work is accessible and under otherwise able conditions the following data hold:

Current in amperes	Pounds of metal deposited per hour	
	For continous work	For short jobs of 10 minutes or less
200	1.5	3
300	3.0	6
400	4.5	9
500	6	12

us carbon arc welding, in virtue of the higher current customarily employed, nuch faster process than metal arc welding.

utomatic Welding with the Carbon Arc. — Automatic machinery has in use for several years for welding together abutting flanges with the carbon With the kinds of joint shown in Fig. 8 it is not necessary to supply any ional metal. The carbon simply travels along parallel to the abutting es and the arc raises their temperature to the point where they flow together. rbon arc welding is usually performed with direct current but sufficient rch will probably lead to the development of successful welding with carbon rodes and an a-c. arc.

ND PRESSURE. — *(See also Structures, Simple; Transmission Lines.)* d pressure is a subject upon which little exact information exists, although y experiments have been made and much study given to the subject by engi- s and scientists. Among the unsettled questions are:

The relation between pressure and velocity.
The variation of pressure with size and shape of exposed plane surfaces.
The direction and intensity of pressure upon non-vertical surfaces.
The intensity of pressure upon non-planar surfaces.
The total pressure upon a number of parallel bars or other members placed by side.
The decrease of pressure upon leeward surfaces.
The lifting power of the wind.

ELATION BETWEEN INDICATED (U. S. WEATHER BUREAU) ID VELOCITY AND ACTUAL VELOCITY.—The indications of the nometers used by the U. S. Weather Bureau do not give the *actual* wind city, but give values considerably higher than the actual velocities, as n in the following table:

LATION BETWEEN INDICATED AND ACTUAL WIND VELOCITY

Indicated Velocity, mi. per hr.	Actual Velocity, mi. per hr.	Indicated Velocity, mi. per hr.	Actual Velocity, mi. per hr.
10	9.6	60	48.0
20	17.8	70	55.2
30	25.7	80	62.2
40	33.3	90	69.2
50	40.8	100	76.2

n the U. S. Weather Bureau reports the indicated and not the actual wind cities are given. However, as the anemometers used give the *average* velocity several minutes, the instantaneous velocities due to sudden gusts may be siderably greater than the indicated velocities; the indicated velocity prob- y more nearly represents the "gust" velocity than the actual average velocity. ll calculations of maximum wind pressure it is therefore recommended that *indicated* velocity be used.

ELATION BETWEEN PRESSURE AND VELOCITY. — The pres- e varies about as the square of the velocity, the results given by different erimenters for the pressure due to a *normal wind on a plane surface* rang- from

$$P = 0.005V^2 \quad \text{to} \quad P = 0.0032V^2,$$

ere P = pressure in pounds per square foot,
V = actual wind velocity in miles per hour.

The latter of these values represents the results of unusually careful experi- nts by Stanton (*see Minutes of Proceedings of the Institute of Civil Engineers, ls. 156 and 171*) upon the intensity of pressure on plates varying in size from to 100 square feet and is probably more nearly correct than the higher value. the Stanton formula the values are reduced to correspond to a temperature 60° F. and an atmospheric pressure of 14. 7 pounds per square inch.

The influence of size and shape of exposed surface is an important question d is not well understood, although it is known that the resultant pressure a large surface may be taken as less per square foot than that on a small

surface, since the maximum intensity of the wind is due to gusts of comparatively small cross-section.

Formulas for Pressure on Plane Surfaces when Wind is not Normal. — The pressure upon vertical plane surfaces may be taken as normal to the surface and equal in intensity to the assumed wind pressure. Upon surfaces which are not vertical, the pressure is usually considered to be normal to the surface but lower in intensity than upon vertical surfaces. The variation in pressure with respect to the slope is not well understood and a number of empirical formulas are in use, among which are the Duchemin formula

$$P_n = P \frac{2 \sin i}{1 + \sin^2 i},$$

and the Hutton formula

$$P_n = P (\sin i)^{(1.84 \cos i - 1)},$$

where P = intensity of normal pressure upon the vertical surface,
P_n = intensity of normal pressure upon the given surface,
i = angle made by surface with the horizontal.

The following theoretical formula results from the assumption that the wind always blows in horizontal lines, and that if the pressure be resolved into normal and tangential components, the tangential component may be neglected:

$$P_n = P \sin^2 i.$$

This formula gives lower values than the empirical formulas and probably gives too low results since it makes no allowance for the reduction in pressure on the leeward side which is known to occur, and which may in part be attributed to the influence of the tangential component. It should also be noted that the wind does not blow uniformly in horizontal lines but may deviate considerably from the horizontal.

The values given by these three formulas are tabulated for comparison, with an assumed value of 30 pounds per square foot for P. In the absence of further experience upon this phase of wind pressure it would seem wise to use one of the empirical formulas instead of the theoretical one. The Hutton formula is used quite generally by structural engineers in England and the United States.

Pressure on Non-Planar Surfaces. — The pressure upon non-planar surfaces is important in the case of chimneys, standpipes, and other similar objects.

Upon the same assumptions as made in the preceding paragraph it may be demonstrated that theoretically the pressure on a cylinder is two-thirds of the total pressure on a plane diametrical section. This value is quite generally used. The pressures thus obtained lack experimental proof but are probably more nearly correct than the pressure obtained by the same method upon plane surfaces.

Effect of Reduction of Pressure on Leeward Side. — The pressure upon the windward side of an exposed surface is a function of the density and velocity of the air currents. The pressure on the leeward side is also a function of the shape of the surface, and has been shown by numerous experiments to be less than the static pressure of the air current. The resultant total pressure upon a surface is in consequence not only a function of the direct pressure on the windward side, but also of the pressure on the leeward side, which in turn is a function of the form of the surface. No algebraic formula can be given which will give the pressure on surfaces of varying shape with any considerable degree of precision.

Wind Pressure on Wires. — H. W. Buck (*Trans. Int. Elec. Cong. St. Louis, 1904, Vol. 2, p. 318*) gives the following formula for the pressure due to a normal wind on a stranded wire:

$$P = 0.0025 V^2,$$

75	28.0		
80	29.1		
85	29.7		
90	30.0		

here P is the pressure in pounds per square foot of projected area of wire ength times diameter) and V is the velocity in miles per hour. This formula based upon tests made on a 950-foot span at Niagara Falls; the wind elocities were measured by a U. S. Weather Bureau anemometer corrected give actual average velocities.

PRACTICAL RULES FOR WIND PRESSURE ALLOWANCE. — he many uncertainties connected with wind pressure make worthless the ttempts to specify with precision its magnitude and direction. In the lack of dditional information and further theoretical studies there seems to be no eason for deviating from the common rules which have been used for many ears with satisfactory results.

Bridges. — The portal, vertical and horizontal bracing are usually proporioned for a wind pressure of 30 lb. per sq. ft. on the surface of the applied load, nd on the exposed surfaces of the floor system and both trusses. The pressure n the applied load is considered as a moving live load, and the other pressure is a dead load. For structures of ordinary spans the wind stresses are computed upon the unloaded structure for a pressure of 50 lb. per sq. ft. In the lesign the maximum stress computed by either of the above methods is used.

Buildings. — For wind pressure on roofs and buildings it is common practice to allow 30 lb. per sq. ft. acting horizontally upon the sides and ends of buildings, or on the vertical projection of roofs. It is also very important to figure the wind stresses on the steel frame considering it as an independent structure without walls, floors or partitions, since failures often occur in erection.

Transmission Poles and Towers. — For transmission towers a pressure as low as 13 lb. per sq. ft. has been used. This is perhaps warranted by the

fact that such towers are comparatively low and not exposed to the highest wind pressure. In the report of the Joint Committee on Overhead Line Construction (*Trans. N.E.L.A., 1911, Vol. 2, p. 521*) the following is recommended: "The wind pressure on the poles, or towers, shall be assumed at 13 lb. per sq. ft. of the projected area of solid or closed structures and 1½ times the projected area of latticed structures."

Wire Spans. — In the report of the Joint Committee just referred to it is recommended that the spans be designed for "a wind pressure of 8.0 lb. per sq. ft. on the ice-covered diameter (ice coating ½ inch in thickness), at a temperature of 0° F."

LIFTING POWER OF WIND. — In the case of a very rapid reduction of atmospheric pressure, as in a tornado, it is often observed that building roofs are lifted and walls blown outward. This phenomenon is due to the air in the building which is under more or less restraint, changing pressure less rapidly than the outside air and thereby producing a difference in pressure. This lifting action doubtless occurs to a greater or less degree whenever the external pressure is reduced, and should be guarded against by anchoring roofs securely to the walls.

Tests 1994
Specification for Annealed Copper Wire 1994
Specification for Hard Drawn Copper Wire 1996
Specification for Bare Concentric Copper Cable: Hard, Medium-Hard, or Soft 1998
Installation 2000

l wire may be either solid or stranded, i.e., made up of a number of smaller es twisted or braided together. A large bare stranded wire is usually called are cable. Data on the insulation and protection of wires and cables will found in the article on *Wires and Cables, Insulated*. Data on resistance es will be found in the article on *Wires, Resistance*, and data on the prop-ies of the various metals will be found in the articles on *Aluminum*, *Copper*, d *Steel*.

PER CENT CONDUCTIVITY. — The definitions, constants and tables in s article are all in accord with the 1920 edition of the *Standards of the A.I.E.E.* r cent conductivity refers to the "International Annealed Copper Standard." the assumption of a resistivity temperature coefficient of 0.00393 at 20° C. is per cent conductivity is only 0.283 per cent higher than the conductivity erred to Matthiessen's Standard (*see Resistance and Conductance*). If the gth of a given wire is L cm., its cross-section A sq. cm. and its resistance at ° C. is R_{20} ohms then the per cent conductivity of this wire is

$$C = \frac{15.328\,L}{88{,}900\,AR_{20}} \quad \text{per cent.}$$

Annealed or soft-drawn copper usually has a conductivity of 100 per cent, rd-drawn copper a conductivity of about 97 per cent. Ordinarily hard-awn aluminum has a conductivity of 61 per cent. The conductivity of iron steel wire ranges from 8 to 16 per cent.

DIMENSIONS, RESISTANCE AND WEIGHT. — The following bles for copper and aluminum are compiled from the tables in *Circular o. 31 of the Bureau of Standards*, except that for stranded aluminum on p. 1977. he table for steel wire is compiled from that published by the American Steel nd Wire Co.

nductivity,
of 100 per cent conductivity wire at 20° C. (from table),
of wire of conductivity C at any temperature t° C.,

$$R_t = R_{20}\left[\frac{100}{C} + 0.00393\,(t - 20)\right].$$

*Let C = per cent conductivity, R_{20} = resistance of 61 per cent conductivity wire at 20° C. (from table), R_t = resistance of wire of conductivity C at any temperature t° C., then

$$R_t = \frac{61\ R_{20}}{C}\left[1 + 0.004\,(t - 20)\right]$$

Google

ALUMINUM CABLES

commercial sizes of stranded aluminum cables, made by the Aluminum any of America, are not circular mil or A. W. G. sizes, but are of such sections as to give the same conductivity as even circular mil and A. W. G. of copper cables of 97 per cent conductivity. In the following table the our and the seventh columns are taken from a pamphlet entitled "Instruc- for Installation and Maintenance of Aluminum Electrical Conductors" by the Aluminum Company of America, in 1914.

W. G. gage or circular mils		Usual number of strands	Diameter of bare cable, inches	Resistance at 25° C. or 77° F.*		Weight in pounds	
per (97 cent) valent	Aluminum 61 per cent			Ohms per 1000 feet	Ohms per mile	per 1000 feet	per mile

per-clad Steel Wire. — This wire consists of a steel core and a con- coat of copper permanently welded thereto. It is used chiefly for long ransmission and telephone wire. It is made in several grades, which in the relative amounts of steel and copper. The grades are designated e corresponding conductivity expressed as per cents of Matthiessen's ard; e.g., 40 per cent grade has a conductivity of 40 per cent.

re C = per cent conductivity,
R_{40} = resistance of 40 per cent conductivity wire at 23.9° C. (from table),
R_t = resistance of wire of conductivity C at temperature t° C.,

$$R_t = \frac{40\,R_{40}}{C}\,[1 + 0.00432\,(t - 23.9)].$$

e temperature coefficient is approximate only.

loy Wires of High Tensile Strength. — Copper alloys having a low uctivity, but having a tensile strength from 50 per cent to 100 per cent ter than that of copper are sometimes used where strength or hardness primary requisite, as in long spans of small wires or for trolley wires. The eport Brass Co. make a wire known as "phono-electric wire" which has nductivity of 25 per cent and a tensile strength ranging from 68,000 nds per square inch for No. 0000 B. & S. gauge to 85,000 pounds per square inch for No. 18 B. & S. gage.

Digitized by Google

Trolley Wire. — Trolley wires of two different sections are in use in t United States. The sections shown in Fig. 1 are known as the "Americ Standard" and the sections shown in Fig. 2 as the "Figure 8" sections.

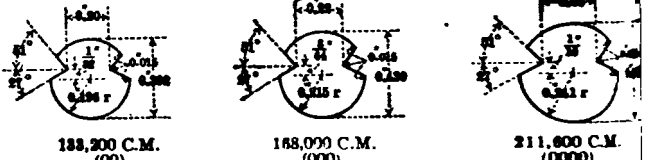

Fig. 1. American Standard Trolley-wire Sections

American Society for Testing Materials recommend that the sizes be specifi in circular mils, and not as gage numbers; the sizes shown in the figure ca in the area of the cross-section from the gage numbers given in parentheses less than 5 parts in 1000.

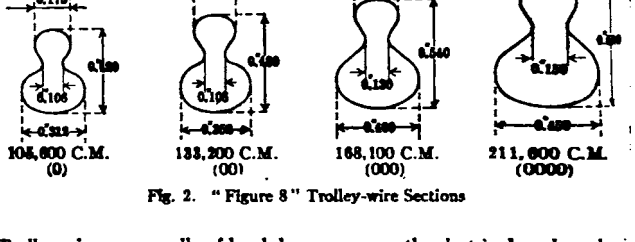

Fig. 2. "Figure 8" Trolley-wire Sections

Trolley wires are usually of hard-drawn copper; the electrical and mechani properties are the same as for round hard-drawn wire of the same cross-sect Copper alloys, such as phono-electric wire (*see above*), are sometimes used trolley wires.

FACTORS AFFECTING DIMENSIONS, WEIGHT AND RESIS ANCE OF STRANDED WIRES. — Individual stranded wires or cables a of four different types, namely: (a) bunched wire; (b) wire braids; (c) co centric-lay cables and (d) rope-lay cables.

Bunched Wires. — Bunched wires are used especially for those extra flexi cables known as cords, wherein the individual wires are so small that concentr stranding is not necessary to keep them together. The wires are assembl parallel and then generally given a slight twist. Sometimes they are ke together by being wound with soft cotton thread which also serves to preve adhesion between the insulation and wires.

Wire Braids. — In the flat form, wire braids are used for potential leads, et in lighting cables, where a flexible flat conductor is necessary. Tubular w braids are also frequently formed over the insulation of cables in order afford mechanical protection. Cables for naval or military purposes and f automobile work are frequently thus protected.

Concentric-lay Cables. — A concentric-lay cable is a stranded conduct composed of a central core surrounded by one or more layers of helically la

s. A rope-lay cable is a stranded wire made up in the same manner by stranded wires instead of individual solid wires for the core and layers. cores of concentric-lay cables may be composed of one, two, three or four of equal diameter. A five or six wire core would not be symmetrical seven wires would themselves constitute a core and a layer.

Number of Wires in Concentric-lay Cables. — The following table all the possible concentric-lay cables with eight or less layers of equal wires and formulæ for calculating the number of wires with any number yers.

NUMBER OF WIRES IN CONCENTRIC-LAY CABLES

(All wires of same diameter)

Number of yers over core	Number of wires in core			
	1	2	3	4
0	1	2	3	4
1	7	10	12	14
2	19	24	27	30
3	37	44	48	52
4	61	70	75	80
5	91	102	108	114
6	127	140	147	154
7	169	184	192	200
8	217	234	243	252
n	$3n^2+3n+1$	$3n^2+5n+2$	$3n^2+6n+3$	$3n^2+7n+4$

e number of wires per layer increases by six for each successive layer when ore has one wire, the first layer over the core having six. With cores having than one wire, the increment per layer is not constant.

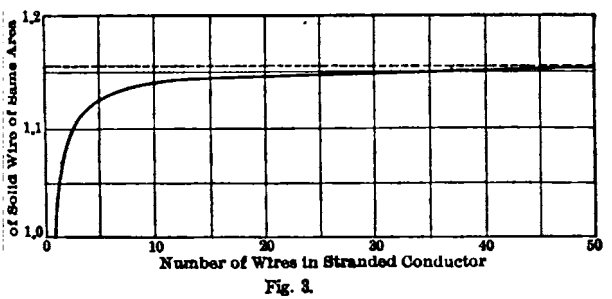

Fig. 3.

Diameter of Concentric-lay Cables. — The diameter of the circumscribing circle of any of the above cables is equal to $(2n + b)$ times the diameter ch wire, where n is the number of layers over the core and b has the following s: 1 wire in core, $b = 1$; 2 wires in core, $b = 2$; 3 wires in core, $b = 2.155$; es in core, $b = 2.414$.

e relation between the number of component wires and the diameter of the is shown in Fig. 3.

Weights in lb. per 1000 ft. of all bare copper cables are computed by multiplying the circular mils by 0.00309.

Digitized by Google

e-lay Cables. — As already noted, a rope-lay cable is made up in the way as a concentric-lay cable except that stranded wires are used for re and layers instead of individual solid wires. Rope strands are used ge conductors which would be too stiff if stranded concentrically. The las for regular concentric-lay cables may be readily modified to apply to ty cables, as each stranded wire bears the same relation to the rope as ndividual solid wire does to the concentric-lay cable. The following table the principal forms of rope-lay cables.

WIRES IN ROPE-LAY CABLES

Number of strands*	Total number of wires — Wires per strand*				
	7	19	37	61	91
1	7	19	37	61	91
7	49	133	259	427	637
19	133	361	703	1159	1,729
37	259	703	1369	2257	3,367
61	427	1159	2257	3721	5,551
91	637	1729	3367	5551	8,281
127	889	2413	4699	7747	11,557
$3(n^2+n)+1$	$21(n^2+n)+7$	$57(n^2+n)+19$	$111(n^2+n)+37$	$183(n^2+n)+61$	$273(n^2+n)+91$

ly "strand" is here meant the stranded wires of which the rope is built up.
e number of wires in a rope-lay cable is frequently designated by a product; 7 X 19 indicates a conductor made up of 7 strands, each strand containing 19

mp-core Cables. — Cables with **hemp** cores have caused serious le and are not being recommended. (D. B. Rushmore, *G. E. Review*, 1912.)

ameters of Component Wires in Commercial Stranded Conductors. e table on p. 1875 gives the diameters of the component wires in the types anded conductors ordinarily used.

fect of Lay on Resistance and Weight. — In the tables given on pp. 1969, and 1978, for stranded cables, the values given for "ohms per unit length" 'weight per unit length" are 2 per cent greater than for a solid rod of section equal to the total cross-section of the wires of the cable. This ment of 2 per cent means that the values are correct for cables having a lay n 15.7. For any other lay, equal to 1 in n, resistance or mass may be calcu- by increasing the above tabulated values by

$$\left(\frac{484}{n^2} - 2\right) \text{ per cent.}$$

neral Formulas for Properties of Cables in Terms of the Properties e Constituent Wires. — The following table gives the principal formulas ncentric-lay cable having a core of one wire.

= total area in circular mils of the component wires measured at right angles to their axes, when laid out straight.
= diameter of cable over-all, in inches.
= diameter of each of the component wires, in inches.
= diameter of core, in inches.

Digitized by Google

d_p = pitch diameter, in inches, of any layer (= mean diameter of the made by any layer).
e = elongation, per cent, at which the wires (other than the core) brea
l = number of wires in any layer having pitch diameter d_p.
N = total number of wires except where the core is of special size, in case N is the number of wires exclusive of the core.
n = number of layers of wire over the core.
P = pitch of any layer of wires = distance in inches measured alo axis of the cable for one complete turn of the helix formed by a of this layer.
p = pitch-factor of any layer of wires = ratio of the actual length of to the corresponding axial length of the cable.
R = ratio of wire area to the total area of the circle circumscribing th side of the conductor.
s = stress in pounds per square inch in the core when the elongation
t = tensile strength of each outer wire, in pounds per square inch.
T = tensile strength of conductor, in pounds.
W = weight of conductor, in pounds per foot.
w = weight of each wire of the cable, in pounds per foot.
w_c = weight of the core of the cable, in pounds per foot.

ENGTH, ELASTICITY AND EXPANSION COEFFICIENT OF

. — The strength and elasticity of a wire of any material depends to erable extent upon the method of manufacture, heat treatment, etc. ile strength of soft copper is between 25,000 and 35,000 pounds per ch, as against 60,000 pounds per square inch for hard-drawn copper. ue to the greater relative thickness of the hard "skin" and com- y soft "core" of small hard-drawn copper wires as compared with es, the tensile strength, in pounds per square inch, of a small hard- pper wire is greater than the tensile strength of a large hard-drawn r example, a No. 0000 B. & S. hard-drawn copper wire has a tensile of about 50,000 pounds per square inch as against approximately unds per square inch for a No. 18. A similar but smaller variation soft-drawn wires. The tensile strength of steel wire depends to a very nt upon the composition of the steel.

llowing table gives, for a No. 0 A. W. G. wire, representative values rious quantities stated. These values do not hold, except to a rough ation, for other sizes of wire. For further information see articles on *Aluminum*, etc., and the section on *Specifications* below.

NGTH, ELASTICITY AND COEFFICIENT OF EXPANSION
Of a No. 0 A. W. G. or B. & S. Wire

Kind of wire	Tensile strength, lb. per sq. in.	Elastic limit, lb. per sq. in.*	Modulus of elasticity, lb.-in. units	Coefficient of linear expansion per °F.	Coefficient of linear expansion per °C.
oft-drawn	36,000	.....	.....	9.6×10^{-6}	17×10^{-6}
ard-drawn	54,500	30,000	16×10^{6}	9.6×10^{-6}	17×10^{-6}
n, soft-drawn	16,000	.....	.....	12.8×10^{-6}	23×10^{-6}
n, hard-drawn	25,000	25,000	9×10^{6}	12.8×10^{-6}	23×10^{-6}
nd steel, 40% grade	60,000	51,000	22×10^{6}	6.7×10^{-6}	12×10^{-6}
ctric	75,800	55,000	18×10^{6}	8.3×10^{-6}	14.9×10^{-6}
linary	68,000	40,000	24×10^{6} to 30×10^{6}	7.0×10^{-6}	12.6×10^{-6}
rmens-Martin	90,000	45,000		7.0×10^{-6}	12.6×10^{-6}
h strength	150,000	82,000		7.0×10^{-6}	12.6×10^{-6}
ra high strength	225,000	135,000		7.0×10^{-6}	12.6×10^{-6}

is no elastic limit for soft annealed copper and the elastic limits of hard- er and aluminum are doubtful.

* Tensile strength in pounds per square inch ranging from 49,000 for No. 0000 66,200 for No. 14; see below.

† For wires having a tensile strength of S pounds per square inch, multiply $S/100{,}000$. The tensile strength of steel varies from 60,000 to 225,000 pounds square inch.

Strength, Elasticity and Expansion Coefficient of Cables.—The following is a summary of the results of tests made on stranded copper wires at the Massachusetts Institute of Technology in 1912. Each figure is the average of a number of individual tests. In determining the modulus of elasticity each cable was given a preliminary stretch before readings were taken.

COMPARISON OF COPPER AND ALUMINUM FOR EQUAL LENGTH AND EQUAL RESISTANCE. — (*See Aluminum.*)

ALUMINUM-STEEL CABLES. — Cables made of a central core of steel, solid or stranded, surrounded by one or more layers of aluminum wire are now finding great favor for aerial lines. Their great advantage is that they may be erected not only with less sag than aluminum but with from 60 to 70 per cent of that of hard-drawn copper.

The modulus of elasticity and temperature coefficient of expansion depend upon the relative cross-section of aluminum and steel. The anchor clamps hold both the aluminum and steel, so that at low temperatures the load is divided between the two metals. As the temperature rises, the aluminum expands faster than the steel and the load gradually shifts over to the steel which in turn stretches more to keep pace with the expanded length of aluminum so that there is no relative motion between the two metals. Eventually the steel carries the total load, and the expansion follows the coefficient for steel only.

Let H_a = fraction of area covered by aluminum,
H_s = fraction of area covered by steel,
M_a = modulus of elasticity of aluminum (9,000,000),
M_s = modulus of elasticity of steel (30,000,000),
M = modulus of elasticity of aluminum-steel cable,
G_a = coefficient of expansion of aluminum (0.0000128),
G_s = coefficient of expansion of steel (0.0000064),
G = coefficient of expansion of cable.

Digitized by Google

$$M = M_a H_a + M_s H_s = (9 \times H_a + 30 H_s) 10^6,$$

$$G = \left\{ \frac{1}{1 + \frac{M_a H_a}{M_s H_s}} \right\} G_s - \left\{ \frac{1}{1 + \frac{M_a H_a}{M_s H_s}} - 1 \right\} G_a$$

$$= 0.0000064 \left\{ \frac{1}{1 + 0.3 \frac{H_a}{H_s}} \right\} - 0.0000128 \left\{ \frac{1}{1 + 0.3 \frac{H_a}{H_s}} - 1 \right\}.$$

RENT-CARRYING CAPACITY OF BARE WIRES. — (*See also* * *Rheostats; Wires, Resistance.*) Let d = diameter of conductor in inches, nissible temperature rise in ° C. above surrounding medium (air, earth, or r = resistance of conductor in ohms per mil-foot at final temperature, ent per conductor in amperes. Assuming that the rate of heat radia- unit length of wire is proportional to the difference of temperature the conductor and the surrounding medium and also proportional to ıce of the conductor, then for solid conductors

$$I = K \sqrt{\frac{T d^3}{r}},$$

tranded conductors

$$1.2\, K \sqrt{\frac{T d^3}{r}},$$

is a constant, which depends upon the condition of the surface of the upon the amount of heat convection due to air currents. Values of ant K for air given by different authorities vary from 800 to 1000, r referring to still air and the latter to open air.

S OF BARE WIRES AND CABLES. — The usual tests on bare gaging diameter, measuring tensile strength, elongation, modulus, ıit and electrical conductivity.

; **Diameter.** — (*See also section on Specifications, below.*) The best ge for measuring wire diameters is that shown

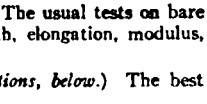

Fig. 4.

The wire is placed between the measuring ınd the screw adjusted until a click occurs. ber of large divisions exposed on the axis is l by 100; the number of small divisions ex- the axis is multiplied by 25; and the sum of items added to the number indicated on the revolving scale. The ıe the diameter of the wire in mils.

Strength, Elongation, Modulus and Elastic Limit. — The essen- es of a wire-testing machine are a means of applying a measurable ce to the wire, and a means of taking up the elongation. Accordingly, testing machine consists of two pairs of jaws for gripping the wire, one connected to a balance lever and the other pair to a power-driven n which draws it in the direction of the axis of the wire. A typical s shown diagrammatically in Fig. 5, where A the two pairs of jaws between which the wire ed. The machine is operated by setting in e mechanism which makes the jaw A move the direction indicated. The operator then counterpoise C by hand, in the direction in-

so as to keep the beam balanced. This operation is continued until : breaks, when the elongation of the sample is measured by the travel jaw *A* and its breaking strength by the weight indicated on the beam at the counterpoise *C*.

leasurement of Strain. — The amount by which the wire is stretched ired by means of an extensometer which consists of a pair of clamps to wire at points a definite distance apart, and a magnifying scale for ng the increase of distance between amps as the wire stretches. The rain curve obtained by plotting igations thus measured against sses measured by the machine de- bove is not a true one, as there is an abnormal elongation due to the ning of the wire, as shown by *OA* in Fig. 6. The standard of overcoming this, is described n 8 of the A.S.T.M. *Specification -drawn Copper Wire.*

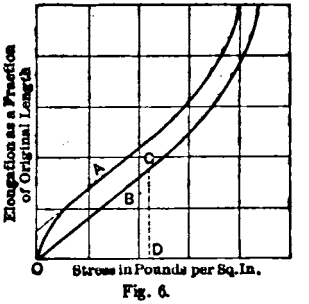

Fig. 6.

lodulus of Elasticity. — The of elasticity is obtained from e of the straight part of the cor- urve. In Fig. 6 the modulus of elasticity is OD/CD pound-inch

lastic Limit. — The true elastic limit can be obtained only by applying of increasing loads, releasing the load (leaving, however, a sufficient eep the wire straight) and measuring the elongation between successive The load at which a permanent elongation begins is the elastic limit.

ictivity. — In order to maintain a wire at a uniform and known tem- it must be short. Unless the wire is very small the test sample will have a very low resistance, and an ordinary Wheatstone bridge will fficiently accurate to measure it. This difficulty is avoided by using a either the Kelvin, Hoop, Willyoung or Reeves type (*see Bridges for Measurements; Resistance and Conductance*).

IFICATIONS FOR COPPER WIRE AND CABLE. — The fol- ecifications for bare copper wire and cable are those prepared by the Society for Testing Materials, 1915 (hard-drawn copper), and 1915 annealed copper), and 1916 (copper cable). See also the article on *ions and Contracts*, and the section on *Specifications* in the article on *l Cables, Insulated*.

IFICATION FOR SOFT OR ANNEALED COPPER WIRE.

General. — The copper shall be of such quality and purity that, awn and annealed, it shall have the properties and characteristics quired.

This specification covers untinned, drawn and annealed round wire.

(*a*) The wire must be free from all imperfections not consistent with commercial practice.

(*b*) Necessary brazes in soft or annealed wire must be made in e with the best commercial practice.

Shipment; Coils, Spools and Reels. — (*a*) Wire may be shipped in reels as agreed upon by the purchaser and manufacturer. In Table I ere are stated the maximum and minimum weights of wire of the stated

sizes which may be shipped in any one package, whether coil, reel or spool. In the case of wire larger than 0.010 inch in diameter, the maximum and minimum package weights are net, and in the case of wire 0.010 inch and less in diameter the maximum package weights are gross, and the minimum package weights are net. The table also states the limiting dimensions of the coils, reels or spools on which wire may be shipped. The length and diameter stated for reels and spools are to be measured over-all and are maximum sizes; reels or spools smaller than these may be used provided the minimum weights called for are carried by the reel or spool. In the table, there are also stated the diameters of the draw-block on which the final drawing of the wire is to be made, when the wire is shipped in coils; it being understood that the wire is not to be reeled after final drawing. This provision is made to insure that coils of wire of any given gage, when supplied by different manufacturers, will be of the same general dimensions.

Wire 0.204 inch in diameter and larger may be shipped in larger packages when agreed upon.

(*b*) The wire shall be protected against damage in ordinary handling and shipping.

TABLE I

Diameters, inches	Package weights, pounds		Diam. of draw-block, inches	Dimensions of reels and spools, inches		
	Max.	Min.		Max. diam.	Max. length	Diam. of barrel for wire
0.460 to 0.360	520	290	24	32	21	1½ to 2
0.359 to 0.258	430	290	24	32	21	1½ to 2
0.257 to 0.129	290	140	22	24	12	1½ to 2
0.128 to 0.102	230	95	22	24	12	⅝ to 1
0.101 to 0.083	230	75	22	24	12	⅝ to 1
0.082 to 0.081	200	75	16	24	12	⅝ to 1
0.080 to 0.064	200	50	16	24	12	⅝ to 1
0.063 to 0.051	120	50	16	24	10	⅝ to 1
0.050 to 0.041	100	50	16	24	10	⅝ to 1
0.040 to 0.032	50	20	8	24	8	⅝ to 1
0.031 to 0.020	25	15	8	10	6½	⅝ to 1
0.019 to 0.011	10	5	8	5½	4	⅝ to 1
0.010 to 0.008	5	2½	8	4	4	⅝ to 1
0.007 to 0.0056	2½	1	6	2½	4	⅝ to 1
0.005	1½	⅝	6	2½	4	⅝ to 1
0.004	1½	⅝	6	2½	4	⅝ to 1
0.003	1	¼	6	2½	4	⅝ to 1

5. **Specific Gravity.** — For the purpose of calculating weights, cross sections, etc., the specific gravity of copper shall be taken as 8.89.

6. **Size and Gaging.** — (*a*) Size shall be expressed as the diameter of the wire in decimal fractions of an inch.

(*b*) Wire shall be accurate in diameter; permissible variations from nominal diameter shall be:

Digitized by Google

r wire 0.010 inch in diameter and larger, 1 per cent over or under.
r wire less than 0.010 inch in diameter, 0.1 mil (0.0001 inch) over or under.

Each coil shall be gaged at three places, one near each end and one approxi-ly at the middle; from spools, approximately twelve feet shall be reeled he wire shall be gaged in six places between the second and twelfth foot the end. The coils or spools will be rejected if the average of the measure-s obtained is not within the limits specified in (*b*).

7. **Tensile Strength and Elongation.** — Wire shall be so drawn and aled that its tensile strength shall not be greater and its elongation not than the values stated in Table II. Tensile tests shall be made upon samples, and the elongation shall be determined as the permanent increase ngth, due to the breaking of the wire in tension, measured between bench cs placed upon the wire originally 10 inches apart. The fracture shall be een the bench marks and not closer than 1 inch to either bench mark. If, testing a sample from any coil, reel or spool of wire, the results are found e below the stated value in elongation or above the stated value in tensile ngth, tests upon two additional samples shall be made, and the average of three tests shall determine acceptance or rejection of the coil. For wire se nominal diameter is between listed sizes, the requirements shall be those ie next larger size included in the table.

TABLE II. — ANNEALED COPPER WIRE

Diameter, inches	Tensile strength, lb. per sq. in.	Elongation in 10 in., per cent
0.460–0.290	36,000	35
0.289–0.103	37,000	30
0.102–0.021	38,500	25
0.020–0.003	40,000	20

8. **Resistivity.** — Electric resistivity shall be determined upon fair mples by resistance measurements at a temperature of 20° C. (68° F.) and it ll not exceed 891.58 pounds per mile-ohm (0.15614 ohm per meter-gram).

9. **Testing and Inspection.** — All testing and inspection shall be made the place of manufacture. The manufacturer shall afford the inspector resenting the purchaser all reasonable facilities to satisfy him that the material forms to the requirements of these specifications.

SPECIFICATION FOR HARD-DRAWN COPPER WIRE

1. **General.** — The material shall be copper of such quality and purity that, en drawn hard, it shall have the properties and characteristics herein required.

2. These specifications cover hard-drawn round wire, grooved trolley wire, l figure-eight trolley wire, as hereinafter described.

3. (*a*) The wire, in all shapes, must be free from all imperfections not sistent with the best commercial practice.

(*b*) Necessary brazes in hard-drawn wire must be made in accordance with st commercial practice, and tests upon a section of wire containing a braze ist show at least 95 per cent of the tensile strength of the unbrazed wire. ongation tests are not to be made upon test sections including brazes.

4. **Shipment.** — (*a*) Package sizes for round wire and for cable shall

be agreed upon in the placing of individual orders; standard packages of grooved trolley wire shall be shipped upon reels holding about 2500 pounds each.

(*b*) The wire shall be protected against damage in ordinary handling and shipping.

5. **Specific Gravity.** — For the purpose of calculating weights, cross-sections, etc., the specific gravity of copper shall be taken as 8.89 at 20° C.

6. **Testing and Inspection.** — All testing and inspection shall be made at the place of manufacture. The manufacturer shall afford the inspector representing the purchaser all reasonable facilities to enable him to satisfy himself that the material conforms to the requirements of these specifications.

Hard Drawn Round Wire

7. **Dimensions and Permissible Variations.** — (*a*) Size shall be expressed as the diameter of the wire in decimal fractions of an inch, using not more than three places of decimals; i.e., in mils.

(*b*) Wire is expected to be accurate in diameter; permissible variations from nominal diameter shall be:

For wire 0.100 inch in diameter and larger, one per cent over or under;
For wire less than 0.100 inch in diameter, one mil over or under.

(*c*) Each coil is to be gaged at three places, one near each end, and one approximately at the middle; the coil may be rejected if, two points being within the accepted limits, the third point is off gage more than 2 per cent in the case of wire 0.064 inch in diameter and larger, or more than 3 per cent in the case of wire less than 0.064 inch in diameter.

8. **Physical Test.** — Wire shall be so drawn that its tensile strength and elongation shall be at least equal to the value stated in Table I. Tensile tests shall be made upon fair samples, and the elongation of wire larger in diameter than 0.204 inch shall be determined as the permanent increase in length due to the breaking of the wire in tension, measured between bench marks placed upon the wire originally 10 inches apart. The elongation of wire 0.204 inch in diameter and smaller shall be determined by measurements made between the jaws of the testing machine. The zero length shall be the distance between the jaws when a load equal to 10 per cent of the required ultimate breaking strength shall have been applied, and the final length shall be the distance between the jaws at the time of rupture. The zero length shall be as near 60 inches as possible. The fracture shall be between the bench marks in the case of wire larger than 0.204 inch in diameter and between the jaws in the case of smaller wire, and not closer than 1 inch to either bench mark or jaw. If, upon testing a sample from any coil of wire, the results are found to be below the values stated in the table, tests upon two additional samples shall be made and the average of the three tests shall determine acceptance or rejection of the coil. For wire whose nominal diameter is between listed sizes, the requirements shall be those of the next larger size included in Table I.

9. **Electric Resistivity.** — Electric resistivity shall be determined upon fair samples by resistance measurements at a temperature of 20° C. (68° F.

The wire shall not exceed the following limits:

For diameters 0.460 inch to 0.325 inch, 900.77 pounds per mile-ohm at 20° C.
For diameters 0.324 inch to 0.040 inch, 910.15 pounds per mile-ohm at 20° C.

Grooved Trolley Wire

10. **Sections.** — Standard sections shall be known as the "American Standard" grooved trolley-wire sections, the shape and dimensions of which are as shown in Fig. 1, above.

	0.065	4,225	66,200	0.91
14	0.064	4,096	66,200	0.90
15	0.057	3,249	66,400	0.89
	0.051	2,601	66,600	0.87
16	0.045	2,025	66,800	0.86
18	0.040	1,600	67,000	0.85

11. **Dimensions and Permissible Variations.** — (*a*) Size shall l
ressed as the area of cross-section in circular mils, the standard sizes beir
follows:

211,600 circular mils, weighing 3386 pounds per mile.
168,100 circular mils, weighing 2690 pounds per mile.
133,200 circular mils, weighing 2132 pounds per mile.

(*b*) Grooved trolley wire may vary 4 per cent over or under in weight p
it length from standard, as determined from the nominal cross-section.

12. **Physical Tests.** — The physical tests shall be made in the san
anner as those upon round wire. The tensile strength of grooved wi
all be at least 95 per cent of that required for round wire of the same sc
onal area; the elongation shall be the same as that required for round wire
e same sectional area.

13. **Electric Resistivity.** — The requirements for electric resistivit
hall be the same as those for round wire of the same sectional area.

Figure-eight Trolley Wire

14. **Sections.** — Standard sections of figure-eight trolley wire shall be shown in Fig. 2, above.

15. **Requirements.** — The requirements for weight, physical properties and electric resistivity of figure-eight trolley wire shall be the same as for the same sizes of grooved trolley wire.

SPECIFICATION FOR BARE CONCENTRIC-LAY COPPER CABLE: HARD, MEDIUM-HARD, OR SOFT

1. (*a*) **Products Covered.** — These specifications cover bare concentric-lay cables made from round copper wires laid helically around a central core in one or more layers. The central core shall be made of wire having the same quality and temper as the concentric layers, unless otherwise especially provided for in separate specifications governing the individual case.

(*b*) **Classes.** — The purpose for which the several classes of concentric-lay cables are generally used are as follows:

Class *A*, for bare, weatherproof, slow-burning, and slow-burning weatherproof cable for aerial use;

Class *B*, for various insulated cable, such as rubber, paper, varnished cloth, etc.

Class *C*, for cable where greater flexibility is required than in Class *B*.

2. **Requirements of Wires.** — The copper wires entering into the construction of standard concentric-lay cable shall, before stranding, meet all the requirements of that one of the Standard Specifications of the American Society for Testing Materials for Hard-Drawn, Medium Hard-Drawn, or Soft or Annealed Copper Wire (Serial Designations: *B* 1, *B* 2, or *B* 3), which apply.

3. **Brazes.** — Brazes may be made in the wire when finished and ready for cabling. Such brazes shall be made in accordance with the best commercial practice. No brazes in cable made from hard, or medium hard-drawn copper wire may be closer together than 50 feet.

4. **Pitch and Lay.** — The pitch of standard cable shall not be less than 12 nor more than 16 diameters of the cable, and the lay may be right or left handed, unless one direction of lay is specified by the purchaser.

5. **Testing.** — Tests for the physical and electrical properties of the wire composing the cables may be made before, but not after stranding. Experience indicates that the tensile strength of concentric-lay copper cable of standard pitch is at least 90 per cent of the total strength required of the wires forming the cable.

6. **Weights and Area.** — For the purpose of calculating weights, cross-sections, etc., the specific gravity of copper shall be taken as 8.89 at 20° C. The resistance and mass of a stranded conductor are greater than in a solid conductor of the same cross-sectional area, depending on the lay (that is, the pitch of the twist of the wires). Two per cent shall be taken as the standard increment of resistance and of mass. In cases where the lay is definitely known, the increment shall be calculated and not assumed.

7. **Variation in Area.** — The area of cross-section of the completed cable shall not be more than 2 per cent below the area specified, as determined by weight.

8. **Construction.** — The area of cross-section, number and diameter of wires, in standard cable Classes *A*, *B* and *C*, shall be as specified in Table 1.

TABLE I

Area of Cross-section Circular mils.	Approximate A. W. G. or B. & S. gage sizes	Class A		Class B		Class C

Note. — Class A cable, sizes 4/0 and 3/0, is usually 7-strand when b and 19-strand when weatherproof, etc.

Digitized by Google

9. (*a*) **Packing and Shipping.** — Packing sizes for cable shall be agreed upon in the placing of individual orders.

(*b*) The cable shall be protected against damage in ordinary handling and transportation.

10. (*a*) **Inspection.** — All testing and inspection, both of individual wires entering into the construction of the cable, and of the completed cable, shall be made at the place of manufacture. Tests on individual wires shall be made on samples taken before cabling, and not on wires removed from the completed cable.

(*b*) The manufacturer shall afford the inspector representing the purchaser all reasonable facilities to satisfy him that the material conforms to the requirements of these specifications.

INSTALLATION OF BARE WIRES AND CABLES. — For the installation of wires and cables in buildings see article on *Wiring of Buildings for Light and Power*. Below is given a brief description of modern practice in erecting bare wires and cables on pole or tower lines. For the construction of the latter see articles on *Distribution Lines; Transmission Lines*. Catenary construction is described in the article on *Trolley Systems, Overhead*.

Simple Span Construction with Pin Insulators. — Starting at an anchored pole, a rope about twice the length of the span is put over the cross arm and the wire pulled up by means of it. The rope is then put over the cross arm of the next pole and the wire drawn up in the same way. This is repeated from pole to pole until the reel, which remains at the starting point, is exhausted. The pulling may be done by men, horses, automobile, or locomotive. Care should be taken to prevent the wire unwinding too rapidly from the reel and the end of the wire must be prevented from slipping away.

The wire is placed on the insulators by means of a block and tackle attached either to the arm above or to a temporary boom. The next step is to draw the wires to the proper tension. Commencing at the first pole after the anchor, the wire is gripped by a clamp attached to a rope which is pulled until the wire is drawn to the sag indicated by a table or curve showing the proper sag for different temperatures and spans (*Spans, Wire*). The sag is gauged by sighting from pole to pole, using a gauge or sight on each pole, and drawing the wire until the bottom of the span is tangential to the sight line.

Tying to Insulator. — (*See also Insulators for Overhead Lines.*) The wires are tied to their insulators by small wires, usually of the same metal, as shown in Fig. 7. The two ends of the tie wire (not visible in Fig. 7) are twisted together for three or four turns. The tie wire must be held quite taut while it is being installed.

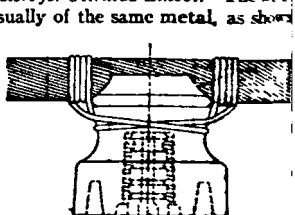

Fig. 7.

Simple Span Construction with Suspension Insulators. — Where suspension insulators are used, the wire, instead of being initially placed over the cross arms, is temporarily suspended therefrom on snatch blocks provided with wooden rollers. Prior to running the cables, linemen are sent ahead to attach the snatch blocks to the arms of the towers. The cables are then strung loosely through the snatch blocks, in much the same way as they are strung over the cross arms in the construction described above. The cables are anchored to the first pole and the necessary tension applied to the cable between the first and second towers, a dynamometer being used to indicate when the required stress point has been reached. The cable is then anchored

Digitized by Google

second tower and the operation repeated for the different spans until ble length is exhausted. The cable is then transferred to the insulator , and the anchorages removed except at the ends.

Clamping to Insulator. — The usual type of insulator clamp (Fig. 8) s of a curved, malleable-iron wire seat nine inches long, a saddle which fits over e and a pair of hook bolts to hold the wire between the saddle and wire seat. The at is supported from the insulator through el joint. Copper wire or cable is laid in e seat, the saddle placed on it and the hook laced in position. In the case of alumi- ire a 1/16-inch aluminum sleeve should be around the wire in the clamp. The lamp is then attached to the insulator by a bolt and socket or pin joint.

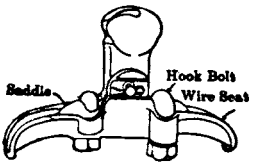

Fig. 8.

ting Conductors. — The following methods are used:

Western Union Joint. — The two ends of the wire are brought to- o that they lap from 3 to 8 inches, depending upon the size. Then ig half-way between the two ends, each wire is wound around the other a tight helix. With hard-drawn copper, excessive stress is avoided by he helix a long pitch for the first turn or two and then gradually reducing h until a tight helix is obtained.

uld appear from tests on galvanized-iron wire by C. T. Rashman (*E. W., l. 56, p. 1187*), that in order to make the joint as strong as the wire, l have the form shown in Fig. 9 which may be described as consisting k of five turns and five end turns at each end.

orm of splice shown in Fig. 10 should be

Dovetailing Strands. — The cables are l for say three or four feet, dovetailed or d, and the strands individually wound ie unopened part of the cable. The joint soldered or not, as desired.

Aluminum Tube Joint. — Aluminum con- of sizes up to about one-half inch diam- usually jointed by inserting the two e by side into a flat aluminum tube, which given 3 or 4 twists as shown in Fig. 11 by means of a special kind of led connectors.

Pressed Aluminum Joint. — Aluminum conductors larger than one- in diameter are more often jointed by dovetailing the strands, or by cal clamps such as the Dossert connector (*see below*), or by inserting the to a cast aluminum sleeve which is squeezed hydraulically until the ors and sleeve flow into a solid homogeneous mass.

Digitized by Google

Dossert Joint and Connector. — The Dossert joint, shown in Fig. 1 consists of a compression sleeve which is slipped over the conductor, a screw

Fig. 12.

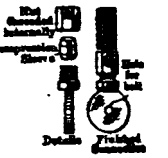

Fig. 13.

the lug proper and a nut threaded with a taper thread. The sleeve contains the conductor is thrust into the lug, with the nut over it. The nut is the tightened until the reaction of the tapered surface and the sleeve gives rise a pressure of several thousand pounds per square inch, thereby making go electrical contact.

The Dossert connector or terminal is similar in construction, and is shown Fig. 13.

MINOLOGY. — The terminology employed in referring to wires and as been in a very confused state, the same term being used with several t meanings. The following terminology is quoted from the *Standards .I.E.E.*

. — A slender rod or filament of drawn metal.

efinition restricts the term to what would ordinarily be understood by the term ire." In the definition the word "slender" is used in the sense that the length in comparison with the diameter. If a wire is covered with insulation, it is called an insulated wire. While primarily the term "wire" refers to the metal, less when the context shows that the wire is insulated the term "wire" will stood to include the insulation.

uctor. —A wire, or combination of wires not insulated from one another, for carrying a single electric current.

rm "conductor" is not to include a combination of conductors insulated from her, which would be suitable for carrying several different electric currents. conductors (such as bus-bars) are, of course, conductors, but are not considered e terminology here given.

ded Conductor. — A conductor composed of a group of wires or any tion of groups of wires.

ires in a stranded conductor are usually twisted or braided together.

d. — One of the wires or groups of wires of any stranded conductor.

ajority of American copper wire manufacturers have used the word "strand" ate a group of bare wires twisted together.

. — (1) A stranded conductor (single-conductor cable; or (2) a combi- f conductors insulated from one another (multiple-conductor cable).

mponent conductors of the second kind of cable may be either solid or stranded, kind of cable may or may not have a common insulating covering. The first able is a single conductor, while the second kind is a group of several conductors. "cable" is applied by some manufacturers to a solid wire heavily insulated covered; this usage arises from the manner of the insulation, but such a con- not included under this definition of "cable." The term "cable" is a general

one and in practice it is usually applied only to the larger sizes. A small cable is call "stranded wire" or a "cord," both of which are defined below. Cables may be bar insulated, and the latter may be armored with lead or steel wires or bands.

Stranded Wire. — A group of small wires, used as a single wire.

A wire has been defined as a slender rod or filament of drawn metal. If such a fila is subdivided into several smaller filaments or strands and is used as a single wire, called a "stranded wire." There is no sharp dividing line of size between a "stran wire" and a "cable." If used as a wire, for example, in winding inductance coi magnets, it is called a stranded wire and not a cable. If it is substantially insulated, called a "cord," defined below.

Cord. — A small cable, very flexible and substantially insulated to withst wear.

There is no sharp dividing line in respect to size between a "cord" and a "cable." likewise no sharp dividing line in respect to the character of insulation between a "co and a "stranded wire."

Concentric Strand. — A strand composed of a central core surrounded one or more layers of helically laid wires or groups of wires.

Concentric-lay Cable. — A single-conductor cable composed of a con core surrounded by one or more layers of helically laid wires.

Rope-lay Cable. — A single-conductor cable composed of a central c surrounded by one or more layers of helically laid groups of wires.

This kind of cable differs from the preceding in that the main strands are the selves stranded.

N-Conductor Cable. — A combination of N conductors insulated from another.

It is not intended that the name as here given be actually used. One would speak of a "3-conductor cable" and a "12-conductor cable," etc. In referring to general case, one may speak of a "multiple-conductor cable" (as in definition gi above.)

N-Conductor Concentric Cable. — A cable composed of an insula central conducting core with (N-1) tubular stranded conductors laid over concentrically and separated by layers of insulation.

This kind of cable usually has only 2 or 3 conductors. Such cables are used in con ing alternating currents. The remarks on the expression "N-Conductor" given in preceding definition apply here also.

Duplex Cable. — Two insulated single-conductor cables twisted together

They may or may not have a common insulating covering.

Twin Cable. — Two insulated single-conductor cables laid parallel, having common covering.

Twin Wire. — Two small insulated conductors laid parallel, having a com mon covering.

Triplex Cable. — Three insulated single-conductor cables twisted together.

They may or may not have a common insulating covering.

Twisted Pair. — Two small insulated conductors twisted together without common covering.

The two conductors of a "twisted pair" are usually substantially insulated, so th the combination is a special case of a "cord."

Sector Cable. — A sector cable is a multiple-conductor cable in which th

Google

section of each conductor is substantially a sector, an ellipse, or a figure ediate between them.

or cables are used in order to obtain decreased overall diameter and thus permit e of larger conductors in a cable of given diameter.

und Conductor. — A round conductor is either a solid or stranded con- r of which the cross-section is substantially circular.

it Conductor. — A split conductor is a conductor which is divided into ır more parts, separated from one another by insulation which is thin ared with the insulation around the conductor.

term split conductor usually designates a conductor in two parts or splits, which e either concentric or external to one another.

:tor of Assurance. — The factor of assurance of wire or cable insulation ratio of the voltage at which it is tested to that at which it is used.

ulation Resistance. — The insulation resistance of an insulated conductor electrical resistance offered by its insulation, to an impressed voltage ıg to produce a leakage of current through it.

tular Mil. — A circular mil is a unit of area equal to $\frac{\pi}{4}$ (=0.7854 . . .)

quare mil. The cross-sectional area of a circle in circular mils is there- equal to the square of its diameter in mils. A circular inch is equal to a ın circular mils.

y. — The lay of any helical element of a cable is the axial length of a turn : helix of that element.

ong the helical elements of a cable may be each strand in a concentric-lay cable, or nsulated conductor in a multiple conductor cable.

rection of Lay. — The direction of lay is the lateral direction in which rands of a cable run over the top of the cable as they recede from an observer ng along the axis of the cable.

)NSTRUCTION OF INSULATED WIRES AND CABLES. — on the manufacture and properties of insulating materials will be found e articles on *Cambric, Varnished; Gutta-percha; Paper, Impregnated; Rub- Insulating Materials, Miscellaneous.* Data on the conductor itself will be l in the articles on *Copper; Aluminum; Wires and Cables, Bare.*

nductors. — Round copper wire, solid or stranded, is almost invariably for insulated wires and cables. Aluminum, requiring a larger cross-section ie same conductance per unit length, requires more insulating material for ame thickness of insulation. Aluminum cables, however, are sometimes ided with a weatherproof covering.

Stranding. — Conductors are stranded in order to make them more ıle. The cable can then be drawn into a conduit more readily, following ends of the conduit without injury during installation. In the case of cables, flexibility is required first in order to permit them to be put on ; second, to permit easy installation, and third to permit them to be bent ıd the walls of splicing chambers. Cords, elevator cables, mining machine r, etc., must have considerable flexibility in order to permit them to be ily shifted from place to place in service.

ır conduit work it is found unnecessary to strand conductors smaller than 6 A. W. G., although some contractors use stranded conductors as small as 12.

Sector-shaped Conductors. — Two, three and four conductor cables,

Digitized by Google

with sector-shaped conductors are in successful use, the three-conductor ty being most common. It has been shown experimentally that if the conduct are properly shaped there will be lower dielectric stresses than in a round ductor cable of the same cross-section. The principal advantage of thi of cable, however, is the greater carrying capacity for a given outside diamet

Preparation of Conductors for Insulation. — Where rubber insula is used it is necessary to cover the conductor with a thin film of tin or with layer of soft cotton threads.

Tinning. — Copper and rubber when brought into contact react on one another chemically. It was formerly thought that this action was due the sulphur in the rubber compound combining with the copper and in t old days, it was common practice to place a layer of pure rubber next to t copper and the regular vulcanized compound over that. It was found, howev that pure rubber reacted with the copper even more vigorously than vulcani rubber containing free sulphur. The pure rubber broke down into a gl sticky mass. It was later found that tinning the copper afforded the neces protection as tin does not react with rubber.

Separators. — Small stranded conductors are usually covered with winding of soft cotton threads for the following purposes:

1. To protect the copper and rubber from mutual chemical action where coating of tin on the copper cannot be used.
2. To hold together a group of fine wires so that individual wires will stand up and penetrate the insulation during the manufacturing process.
3. To prevent adhesion between the rubber and copper in order that the cop may be easily bared for making connections.

A separator composed of a wind of soft cotton is used on cords of various ty for the first and second reasons. A similar cotton wind on small conductors, paper or dry muslin tape on large conductors is used on cables for car wiring the third reason given above.

Insulation. — The materials used for insulation are vulcanized rubber, gut percha, varnished cloth, impregnated paper, asbestos, cotton and silk thre enamel, etc.

Rubber Insulation. — There are two processes by which rubb compound is put on wire, the strip and the tube or seamless processes. By t former, the compound is first made into long narrow strips and then pres around the wire; by the latter, the wire is run through a die through which t compound is pressed on to the wire. Insulation made by the former proc shows a seam or ridge where the sides of the strip have united, unless a tape applied before vulcanization, while that made by the tube process is seamles

Rubber insulating compounds are prepared by mixing rubber gum with s phur, wax and fillers which may be mineral substances or rubber substitut Experience has shown that from 25 per cent to 30 per cent of rubber must used in order to obtain compounds which will resist oxidation when expose the air.

The various grades of rubber insulation on the market may be divided in three classes, known respectively as 30 per cent Hevea, Intermediate and C compounds. The majority of commercial 30 per cent Hevea compounds pro ably fall within the following limits of composition:

Ingredient	Percentage by weight
Rubber	30 to 32
Whiting	0 to 30
Zinc oxide	28 to 67

Ingredient	Percentage by weight
Litharge	1 to 12
Ozokerate	2 to 4
Sulphur	2 to 4

npounds of intermediate grade usually contain less than 30 per cent of . rubber mixed with reclaimed rubber, to make a total of at least 30 per cent ber gum. The other ingredients are similar to those used in 30 per cent . compounds.

e compounds contain a mixture of new and reclaimed rubber, mineral · or black hydrocarbon, sulphur and mineral fillers.

Gutta-Percha is applied to the wire in the same manner as rubber. It l only for deep-sea submarine cables.

Varnished Cloth. — The prepared cloth is applied to the conductor in m of tape wound on helically and reversed every two layers, with over- g joints staggered in successive layers. A thin layer of a non-hardening ; filler is applied between layers.

Impregnated Paper. — Strips of Manila paper are applied helically, ioroughly dried and impregnated with an oily compound.

Asbestos. — Asbestos is used for low-voltage wires to be used in very hot It is applied in the form of threads or tape, usually in several layers. more layers of varnished cloth are sometimes used to separate the groups stos tapes, and the whole is covered with a protecting braid.

Cotton and Silk. — Cotton or silk insulation consists of one to three of threads spun on to the wire.

Enamel. — This type of insulation is suitable only for wires under 10 diameter. Cellulose acetate is a common form of enamel. A solution lose acetate is applied to revolving coating rolls, which, in turn, deposit he moving wire. The quantity of solution placed on the wire must be d to a nicety. After receiving its coating of solution, the wire passes h an oven at the rate of several hundred feet per minute. The volatile is here driven off and the coating hardened, after which the process is d until the required number of coatings have been applied. This method an even distribution of the film over the whole surface of the wire (*R. g*).

rs. — Dry jute or paper is used as a filler between the insulated conductors iple-conductor cables, being placed directly in contact with the insulation. or asphalted jute is used as a filler between the sheath and armor of d cables.

ective Coverings. — Coverings of treated cotton, hemp, paper, rein- rubber, and lead are used to protect cables from mechanical injury and

Cotton Braid. — The most common covering for rubber-insulated tors is a cotton braid saturated with a compound consisting of asphaltic ls and waxy hydrocarbons (principally paraffine wax). The hydrocarbon ic is used to carry the asphaltic material into the fibers.

purpose of this saturation is to protect the cotton against natural deter- n.

melting point of saturating compound is from 118 to 124° F.

saturated cotton is covered with a finishing wax, the purpose of which is he interstices between threads and to afford a smooth surface which will : moisture and permit the wire to be drawn into a conduit with the least

friction. Finishing wax is usually composed of asphaltic material and high grade waxes, such as Carnauba and Montan wax, which are used to give it or lustre.

There are two important grades of finishing wax, one of which has a melting point between 156 and 166° F. and a higher grade which has a melting point between 180 and 190° F.

Weatherproofing. — Treated cotton braid is also put on uninsulated hard-drawn copper wire for overhead service, in order to protect the wire from destructive arcing due to accidental contact with tree branches and other foreign bodies.

Lead Sheath. — The only thoroughly waterproof cable covering yet devised is a lead sheath. It is put over the insulation by passing the cable through a die while hot lead is pressed hydraulically around it through an annular die, forming a continuous and close-fitting pipe. Were it not for electrolytic corrosion, it would be practically permanent. Unfortunately lead is very subject to electrolytic and even chemical corrosion. It is also rendered brittle and eventually breaks into pieces when exposed to vibration, this effect being due to crystallization. Pure lead is suitable for cables which are hard and compact. Other cables require a small quantity of tin to harden the lead. For a given thickness pure lead is cheaper, but for a given tensile strength a 3 per cent tin alloy is cheaper.

Antimony has been used instead of tin with very satisfactory results and material saving in cost, especially with telephone cable.

Armor Wire and Tape. — Submarine cables are usually covered with steel wire armor and cables to be buried direct in the ground are usually covered with galvanized steel tape armor. In either case the armor is covered with asphalted jute.

APPLICATIONS OF VARIOUS TYPES OF CABLES. — The type of insulation and protection to employ in any instance depends upon the purpose for which the conductor is to be used and the place in which it is to be installed.

Power Cables, that is, cables for the transmission or distribution of electric energy, may be installed in buildings, in cars, in underground conduits, on pole lines, or under water.

Wires and cables for buildings are usually rubber insulated and covered with a saturated braid. Varnished cambric is often used for the larger sizes.

Wires and cables for power houses are usually varnished cambric insulated with either a saturated or a flame-proof braid.

Wires and cables for underground conduit lines are almost invariably paper insulated, but rubber or varnished cambric are sometimes used.

Wires for mining machinery and for railway signals are invariably rubber insulated.

Submarine Power Cables are usually insulated with rubber, sometimes sheathed in lead and armored with wire or steel bands. In recent years, however, paper-insulated lead-sheathed and armored submarines have come into extensive use.

Communication Wires and Cables, that is, wires and cables for telephone and telegraph service, are rubber insulated where only two or three conductors are required. Cables composed of many pairs are generally insulated with dry paper and are known as dry-core cables.

Submarine telegraph cables are insulated either with gutta-percha or vulcanized rubber, the former if for deep-sea use. Such cables are protected by jute and steel wire armor.

Digitized by Google

ulated Conductors for Instrument and Machine Windings. — Enam- ire or wire insulated with cotton or silk is used for the former, while hed cambric, mica and asbestos compounds are used for the latter.

ULATION THICKNESS. — The thickness of insulation required for ltage cables is merely that necessitated by inevitable irregularities of acture and roughness in handling. At voltages between 500 and 1000, lectric stress begins to have an influence and when 2000 volts are reached, lectric stress becomes the dominant factor. If certain assumptions are the thickness of insulation corresponding to a given dielectric stress e calculated, but these assumptions are only partially realized in e. These assumptions are:

hat the radial depth of the insulation or dielectric is the same at all i.e., that the cross-section of the cable is a perfect circle with the con- section (also a perfect circle) exactly in the center of the insulation. Due, r, to the crinkling of tape, the pressure of the braid, or other accidents ufacture, this is never the case. The eccentricity of the conductor with to the insulation may, however, be allowed for by adding to the theoreti- kness of insulation an additional thickness, known as the "error thick- r excess thickness.

hat the dielectric is perfectly homogeneous throughout. This is never l in practice. It is probable that even in the most carefully made on there is a minute amount of air and moisture, but sufficient to considerably any conclusions based on absolute homogeneity of the ic. In the case of impregnated paper, the lack of homogeneity results rtant departures from the following law.

hat when the electric stress, or potential gradient at any part of the dielec- eeds a certain value F_s known as its dielectric strength, that part of the ic becomes a partial conductor even though there is no actual rupture turing.

assumption is made only in the case of rubber insulation, and then en the electric stress is applied for a considerable time. The internal wn of the rubber appears to be due to the ionization of the air between ber and conductor, the rubber being oxidized, split internally, and show- er signs of disintegration. (See C. A. Adams, Trans. A.I.E.E., 1917, . pp. 514–517.)

retical Thickness of Insulation. — Let

otential gradient, in kilovolts per centimeter, at any point P in the dielectric at a distance x centimeters from the center of the wire, Fig. 1,

ilovolts between wire and sheath (or outside surface of insulation).

adius of wire, in centimeters,

utside radius of insulation, in centimeters,

ielectric strength of the insulation, in kilovolts per centimeter.

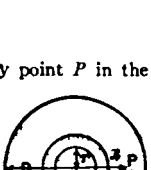

Fig. 1.

on the assumption of a perfectly homogeneous dielectric and perfect try between conductor and insulation,

$$F = \frac{E}{x \log_e \left(\frac{R}{r}\right)}.$$

, the potential gradient is the greatest at the surface of the conductor

Google

and decreases toward the outer surface of the insulation as shown in Fig. The potential gradient at the surface of the conductor is

$$F_{max} = \frac{E}{r \log_e \left(\frac{R}{r}\right)}.$$

For the same outside diameter of the insulation this stress at the surface va with the radius of the conductor as shown in Fig. 3, and has a minimum va theoretically when $r = R/2.72$, but actually when R/r is somewhat gre than 2.72.

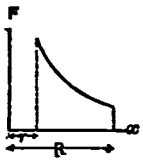

Fig. 2.

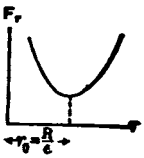

Fig. 3.

Consequently, if the breakdown of a cable is a progressive action, i.e., if insulation breaks down close to the wire and then the breakdown spreads through the insulation, it is evident, from Fig. 3, that if r is greater than R and the impressed voltage E is such as to produce a stress F_r at the sur of the conductor in excess of F_s, then as successive layers of the insulation br down, F_r at each new conducting surface thus formed will be greater than and the breakdown will rapidly extend to the sheath. If, however, r is than $R/2.72$, then a value of F_r in excess of F_s will break down only a suf layer of insulation to render the value of F_r at the new conducting surface formed just equal to F_s.

Therefore, on the basis of the assumptions noted in the preceding sec the maximum voltage which a cable can withstand is equal to

$$E_m = F_s r \log_e \left(\frac{R}{r}\right),$$

provided R/r is less than 2.72, but when R/r is greater than 2.72 the maxim voltage is

$$E_m = F_s r_0 \log_e \left(\frac{R}{r_0}\right) = \frac{RF_s}{2.72},$$

and is *independent of the radius of the conductor.*

If there are films or globules of air in the insulation the dielectric stress in th will be greater than in the surrounding insulation in the ratio of the dielectr constant of the insulation to that of the air. As the dielectric constants common insulating materials are between twice and five times that of air, th air will be stressed between two and five times as much as the insulation. air ionizes at a much lower stress than the dielectric strength of the insulatio the limiting working voltage of a cable may depend upon the effects of i ionization. In the case of rubber insulation the principal effect is oxidation ozone, but in the case of paper or varnished cambric the energy loss due ionization is the most serious matter.

Practical Determination of Insulation Thickness. — On account of th numerous assumptions which must be made in determining the necessa thickness of insulation from any simple theory, such as outlined above, a theor

little value in the generality of cases and reliance must be placed upon ence, as embodied in the standards of various associations.

* The rubber to comply with the rubber specification of the National Board of e Underwriters, which assumes the use of 20 per cent of rubber gum.

† The A.I.E.E. Standards for 600 to 7000 volts are identical with the code xpt that they cover only 30 to 40 per cent hevea insulation and that for ltiple conductor cables of any voltage the thickness of insulation on each nductor shall be based on the highest r.m.s. voltage between the conductor d the outside of the insulation.

‡ The rubber insulation to comply with the specifications of the R.S.A., which lls for a very high-grade 30 per cent Para compound.

* Above working voltages are based on all conductors of the circuit being insulated. For d-c 600-volt railway single-conductor, leaded cables, use 1,000-volt class. For three-phase "Y"-connected circuits with grounded neutral and three-conductor cables, thickness of insulation between conductors and ground may only be 1/10 of that between conductors.

† For three-conductor cables only, use 1,000-volt class for single-conductors from 0 to 1,000 volts.

‡ For three-conductor cables use 5/64 in. for No. 6 to No. 0000, 6/64 in. for 250,000 to 500,000 cir. mils and 7/64 in. for larger sizes.

n, Silk and Enamel. — The thicknesses rated by various manufa
s "single," "double," and "triple" covered differ by several mils; s
on *Electromagnet Windings*. Enamel insulation will stand a workir
l of about 500 volts alternating per mil of thickness. Silk or cott
d about one-quarter as much.

WEIGHT OF INSULATED WIRES AND CABLES. — So many ables enter into the weight of an insulated wire or cable, and there are so forms in use, that it is impossible to give comprehensive tables here reader is referred to the catalogues and circulars of the manufacturing com When such sources of data are not available the weight may be calculated the dimensions of the cable by finding the sum of the weights of the cond and the weights of the insulation, braid, tape, sheath, etc. The weight conductor may be found in the wire tables under *Wires and Cables, Bare.* weight of the insulation, braid, tape or sheath, may be found by calcu the cross-section of each of these materials and multiplying by the leng the cable and a factor proportional to the density of the material; see accompanying.

The cross-section of a tube having an internal diameter d and thick is $\pi t(d+t)$. When the diameter and thickness are in inches and the spe gravity of the material forming the tube is δ, then the weight in pounds per feet of tube is

$$W = 1362\,\delta(d+t).$$

The values of the specific gravity δ, the product $1362\,\delta$, and the weight per in., for the various materials used in the construction of cables are given in accompanying table. From this relation the weight per 1000 feet of any tub (circular cross-section) layer of insulation, braid tape or sheath may be read calculated. The formula is, therefore, directly applicable to single-con cables.

The weight of duplex or triplex cables is calculated as for a group of conductor cables, except with regard to the fillers. The cross-section filling material is most readily calculated by subtracting from the cross of the entire cable the cross-sections of the individual conductors and the insulation, sheath, etc. The weight of twin cables can also be readily f calculating the cross-section of the various parts in inches and multip the length and the proper density factor.

The weight of separators in pounds per 1000 feet is usually between

WEIGHTS OF CABLE INSULATION

Material	Specific gravity, δ	Pounds per cubic inch, $0.03613\,\delta$	$1362\,\delta$

es the mean diameter, expressed in inches, of the conductor and sepa-

weight of saturated braids per 1000 feet is from 12 to 30 times the diameter e insulation expressed in inches.
corresponding multiplier for 12 mil tape with ½ lap, is 24.

ULATION RESISTANCE. — The insulation resistance of a cable is r expressed in megohm-miles, sometimes erroneously called megohms ile. The total insulation resistance of a cable varies inversely as its e.g., a cable two miles long has half the resistance between conductor eath of a length of one mile of this cable. The formulas for insulation ce of various types of cables are given below.

le-conductor Cable. — In absolute units the insulation resistance of a of l centimeters of such a cable is

$$R' = \frac{\rho}{2\pi l} \log_e \frac{D}{d},$$

d = diameter of conductor, D = outside diameter of insulation, R = insula- istance, l = axial length, ρ = specific resistance. From the above formula ohm-miles are

$$R = k \log_{10} \frac{D}{d},$$

k = 0.43 × (specific resistance in millions of megohms per centimeter cube)

two diameters are d either in inches centimeters. The k for various types ation at 60° F., n electrification of nately one minute constant d-c. volt- iven in the accom- table. k varies ith the time of ation and with the ture.

Insulation	k at 60° F.	
	Limits	Usual values
Vulcanized rubber.	780 to 23,000	3000 to 6000
Gutta-percha.....	500 to 4,000	2500
Varnished cloth....	400 to 1,200	700
Impregnated paper.	1000 to 3,000	1500

ables on the following pages give the value of $\log_{10} \frac{D}{d}$ for various sizes of l thicknesses of insulation.

insulation resistance be measured with alternating current, it will o be much less than with direct current because of the dielectric loss.

and Three-conductor Cable in Lead Sheath. — The insulation e between the two conductors of a two-conductor cable is practically hat between each conductor separately and the sheath.
nsulation resistance of a three-conductor cable between any one con- nd the other two conductors and the sheath is approximately one-half between each conductor separately and the sheath. Simple formulas e resistances in terms of the dimensions of the cable are not available, arious parts of the coverings (insulation, fillers and braids) have differ- tivities.

CAPACITY AND CHARGING CURRENT. — See article on *Capa and Charging Current.*

INDUCTANCE, REACTANCE AND IMPEDANCE. — The formu for bare wires and cables (*see Inductance and Inductive Reactance*) are also plicable to lead-sheathed insulated cables, the insulation and sheath produc practically no effect on the self inductance.

Resistance and Impedance of Three-conductor Cables. — The follo ing table, published by the G. E. Co., is based upon 100 per cent conductiv copper at 75° F., with an allowance of 3 per cent for spiral path of the compos wires, 60 cycles per second, and standard thicknesses of varnished cam insulation.

e is $x = \sqrt{z^2 - r^2}$; the inductance is $L = x \div 2\pi f$ where f is the cles per second.

and Reactance of a Pair of Armored Single-conductor J. B. Whitehead (*Trans. A.I.E.E., 1909, Vol. 28, p. 737*), gives rmula for the self inductance of each of two parallel armored cables:

$$L = 0.161 \left\{ 2 \log_e \frac{D}{r} + \frac{1}{2} \right\} + 0.078\,(k - 1),$$

nrys per mile of each conductor,
ce between centers of conductors, any unit,
of each conductor, in same unit as D,
6, depending upon the permeability of the armor wires.

l paper concludes as follows: 1. Theoretically the reactance of single-conductor, iron-armored power cable may be from of unarmored cable, depending on the distance to return or increases with decreasing distance. 2. In cables as manuance is about 0.7 of the maximum theoretical value as calcue formula. 3. The effective resistance at 25 and 60 cycles times respectively the d-c. resistance for a current density 00 circular mils, and varies little with the distance between ie impedance for distances under 12 inches is about 3 times t 60 cycles and 1.7 to 2 times the d-c. resistance at 25 cycles. and the armor grounded at both ends the impedance is nd is largely of the nature of resistance. 5. The impedance or iron-armored cable with conductors located 0.873 inch ers and at the current density given above is about 5 per cles and 3 per cent greater at 25 cycles than the calculated is in effective resistance, due to eddy currents in the lead

Digitized by Google

H. W. Fisher (*Trans. A.I.E.E., 1909, Vol. 28, p. 747*) says that the impedance of armored cables cannot be calculated with any degree of certainty owing to the effect of slight differences in the air gaps between armor wires. He finds that a single-conductor No. 0 B. & S. cable armored with two flat bands of steel (0.39×1.) may have a maximum effective resistance 8 times the direct resistance when the lead and armor are disconnected, and that under practical conditions of operation the ratio is about 3.5. With larger cables the ratio will be greater.

Unless the armor and lead of single-conductor cables are bonded together arcs may occur between them and under water they would be injured by alternating-current electrolysis. Single-conductor steel armored cables cannot be used with 60-cycle currents greater than 8 or 10 amperes because of the inductance and losses due to hysteresis and eddy currents.

CURRENT-CARRYING CAPACITY OF WIRES AND CABLES. The maximum permissible temperature rise of insulated conductors is limited by the effect of heat upon the insulation. The highest temperatures which may be safely attained continuously are given in the table below.

Insulation	Maximum permissible temperature centigrade	
	Low voltage	At E kv. between conductors
Impregnated paper...	85	$85-E$
Varnished cambric...	75	$75-E$
Rubber insulation....	60	$60-0.25E$

When rubber is heated, the usual order of events is as follows: Oxidation is accelerated if air is present, "devulcanization" commences, i.e., the rubber molecule breaks up without, however, liberating any sulphur; vulcanization proceeds until all the free sulphur has combined with the rubber or mineral matter. In the case of varnished cambric, both the insulation resistance and dielectric strength fall quite rapidly after the limiting temperature is attained. The same applies to impregnated paper in a less degree. Furthermore, at high voltages, the dielectric loss is often considerable, and if neglected in calculating carrying capacity, is likely to make one overlook possibilities of temperatures far in excess of those to be expected on the basis of I^2R losses alone. The A.I.E.E. rule for high voltage cables may be assumed to refer to temperatures calculated on the assumption that the only losses are ohmic losses in the conductor. Hence, if the A.I.E.E. temperatures are used, dielectric losses may be neglected and the carrying capacities derived from these temperatures may be used with safety. The A.I.E.E. rule is equivalent to assuming that the dielectric loss in watts per foot are equal to $12\frac{E}{R}$ (see below).

Where, however, cables of either very low or very high dielectric loss are used it may be advisable to calculate the carrying capacity, taking the dielectric loss into account, as in the former case a higher, and in the latter case, a lower carrying capacity will be obtained than when the A.I.E.E. rule is followed.

ormula for Carrying Capacity, Using A.I.E.E. Rule. — Where the cable truction or operating conditions are unusual, the carrying capacity may be ulated from the following formula.

$$I = 110\sqrt{\frac{T}{rR}},$$

re I = amperes,
T = permissible temperature rise, degrees centigrade,
r = electrical resistance per 1000 feet of each conductor in ohms (the factor 110 would become unity if r were expressed in ohms per inch),
R = heat resistance, from conductor to air, in degrees, centigrade rise per watt lost in each inch of conductor (see below).

ormula for Carrying Capacity, Using Actual Dielectric Loss. — When desired to take into account the dielectric loss, an approximation may be e by assuming the entire dielectric loss to occur at the surfaces of the con- ors. Then:

$$I = 110\sqrt{\frac{1}{r}\left(\frac{T}{R} - W\right)}.$$

re W = dielectric loss per inch of cable for each phase at the ultimate temp- ure. This is 1/6 of the dielectric loss in watts per foot of cable.

ample. — In the case of a No. 0000 paper insulated cable for 12,000 volt ice, with a dielectric loss of one watt per foot at 85° C., the carrying capacity be about 5 per cent less than if the dielectric loss were zero.

ormulas for Heat Resistance of Cables. — The heat resistance of single luctor cables may be calculated from the formula given below.

t D = overall diameter of cable, inches,
Q = ratio of the outer to the inner diameter of each layer of heat insulation,
K = heat resistivity of the material of each layer of heat insulation in degrees centigrade rise per watt per inch cube,
= 285 for rubber,
= 300 for varnished cambric,
= 300 for impregnated cotton,
= 465–485 for impregnated paper,
= 100 for asphalted jute,
= 300 for impregnated cotton braid.
H = heat resistivity from cable surface to room, in degrees centigrade per watt dissipated from each square inch of surface.
= 120 for impregnated braid,
= 120 for painted steel braid,
= 180 for lead bright,
= 155 for lead dull.

hen,

$$R = 0.318\frac{H}{D} + 0.367\,\Sigma K \log_{10} Q.$$

corresponding formula for multiple conductor cables has been developed by and is quoted by Powell, *Trans. A.I.E.E., 1916, Vol. 35-2, p. 1035.* The ; resistances of triplex paper, lead cables are given below, based upon Mie's ula and the following heat resistivities,

$$K = 475 \quad \text{and} \quad H = 155.$$

hese tables give the heat resistance from each conductor to air and are used h values of r for one conductor to get the carrying capacity of each conductor.

ıe cable is in a duct, the heat resistance of the duct should be taken into it. For a single duct, this is usually from 1 to 20 degrees C. per watt lost h inch of duct. Clark and Shanklin, *Trans. A.I.E.E., 1920*, give the e heat resistance from the conductors in a cable, to the earth, as 69° C. tt lost in each inch of duct, or 207° C. per watt lost in each inch of each ıtor of a triplex cable. R.W. Atkinson, *Jour. A.I.E.E., Sept., 1920*, gives per watt-inch as a safe average figure for a conduit containing up to 16 surrounded by earth with a normal amount of moisture.

Cables Buried Underground, Under Water, etc. — A cable buried in earth will carry 25 per cent more current with a given rise in temperature than it will when run in a dry duct, depending upon the character of the soil. If immersed in water it will carry about 50 per cent more.

Current-carrying Capacity of Lead Sheath. — The carrying capacity of a lead sheath is given approximately by the following formula:

$$C = 128 \sqrt{dp\,(d-p)T},$$

where

d = outside diameter of sheath in inches,
p = thickness of sheath in inches,
T = temperature rise, ° C.

Rise of Temperature with Time. — Fig. 5 shows the rise of temperature with time for a single conductor, 0.5 square inch in cross-section, carrying 750 amperes. Curves I to VI are from a paper by C. Beaver (*Jour. I.E.E., 1911*) and curve VII from Del Mar's *Electric Power Conductors*.

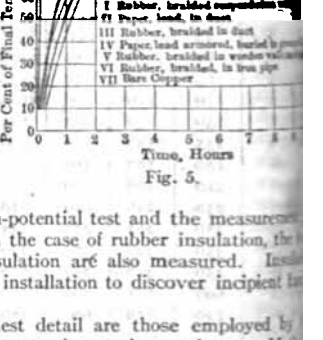

Fig. 5.

TESTS AND INSPECTION OF INSULATED WIRES AND CABLES. — (*See also section on Specifications, below.*) Wires and cables are submitted to factory tests to ascertain whether they meet specified requirements. For the tests on the conductors themselves, see the article on *Wires and Cables, Bare*. The usual factory tests of insulation are the high-potential test and the measurement of insulation resistance and capacity. In the case of rubber insulation, the tensile strength and elasticity of the insulation are also measured. Insulated wires and cables are also tested after installation to discover incipient faults and to locate existing faults.

The tests described below in greatest detail are those employed by the majority of American cable manufacturers and operating engineers. Methods of measuring insulation resistance are described in the article on *Resistance and Conductance*, and methods of measuring capacity and inductance in the articles on *Capacity* and *Inductance*.

A.I.E.E. Rules for Tests. — Electrical tests of insulation on wires and cables shall be made on the entire lengths to be shipped.

The outer surface of the insulation of complete insulated wires and cables shall be grounded while being electrically tested. If the insulation is not provided with a conducting covering and if the covering is not liable to injury by water, the ground shall be obtained by immersing the insulated wire or cable for at least twelve hours and testing at the end of that period while immersed. If the outer covering is susceptible to injury by immersion, the insulated conductor shall be tested before the application of such covering.

Dry core paper-insulated lead-covered cables, such as telephone and telegraph cables, for use in water, shall be tested after at least twelve hours' immersion.

In the case of multiple-conductor cables, without waterproof overall jacket of insulation, no immersion test should be made on finished cables, but only on the individual conductors before assembling.

High-voltage Tests. — High-voltage tests are intended to detect weak spots in the insulation and to determine whether its dielectric strength is such

r enabling it to withstand the voltage to which it is likely to be subjected ice, with a suitable factor of assurance.

-voltage tests shall be made at the factory by applying an alternating between the conductor and sheath or water. The initially applied must not be greater than the working and the rate of increase shall be ap- ely uniform and not over 100 per cent nds.

in the case of communication cables s insulated with code rubber com- e duration of the test voltage shall onsecutive minutes. Code wires are one minute.

ultiple-conductor cable is designed ne operating voltage between con- d sheath or water as between con- h conductor shall be tested against onductors connected together and h or water. If the cable is designed ating voltage between conductors different from that between con- test between conductors and the ter shall be made separately and l on the normal operating voltage ductors and sheath or water as the accompanying table.

s based upon the minimum thick- ition specified by engineers and panies. The following tables d where the insulation thickness

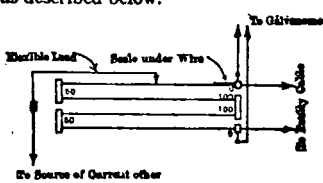
(b) A.I.E.E. Standards, Five Minutes Test



One kilovolt per 64th inch insulation thickness up to 19/64 in. Above 19/64 10 kilovolts plus 1.5 kv. per 64th inch up to 29/64. Where thickness is 29/64 or over, rule applies only to conductors as big as No. 6 A.W.G. The A.I.E.E. allows lower test voltage for working voltages up to 600 v. a-c. In this case the rule is as follows:

14-8 A.W.G.	3.0 kv.
7-0000	3.5
250,000 and larger	4.0

stripped from stranded conductors are neglected in computing the cross-section area.

In order to measure its tensile strength the sample of rubber is held in a sort of grip and stretched in a machine similar to that used for wire (*see Bureau of Standards Bulletin No. 37*). It is usual to reduce the results thus obtained to pounds per square inch.

Tests after Installation. — A high-potential-test with the voltages given above in the tables is usually applied to the full length of cable immediately after installation and at regular intervals to detect incipient faults. Double line voltage is frequently used for the periodic tests. Grounds or crosses of relatively low resistance may be detected by bridge methods or by exploration as described below.

Arrangement of Bridge

Fig. 6.

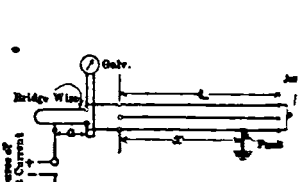


Fig. 7.

Some engineers make periodic insulation-resistance tests and plot the results as a curve. If the curve manifests any decided downward tendencies the cause is immediately sought for. The methods of making these tests are given below.

Testing for Faults by Murray Bridge Methods. — The bridge used in the Murray loop tests is shown diagrammatically in Fig. 6. It consists essentially of a resistance wire graduated into two equal scales each reading from 0 to 100, the zero points being at the ends of the wire. A galvanometer

onnected across the zero points and a flexible lead connected to the positerminal of a source of direct current is put in sliding contact with the . The negative terminal of the direct-current source is grounded.

ne Conductor Grounded. — When one conductor of a multiple-conductor e is grounded, the bridge is connected as shown in Fig. 7, a jumper being ed between the faulty conductor and one of the others. The sliding con- is moved along the bridge wire until the galvanometer deflection becomes . Let a = distance of sliding contact, on bridge scale, to the terminal of br dge connected to faulty wire, as a percentage of the length of half the ge wire, and L = length of cable; then if x is the distance from the bridge to fault,

$$x = \frac{aL}{100}.$$

wo Conductors Crossed. — When one conductor of a three-conductor cable ossed with another, the bridge is connected as shown in Fig. 8, a jumper

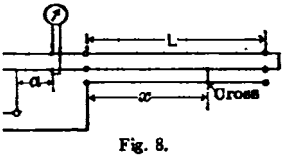

Fig. 8.

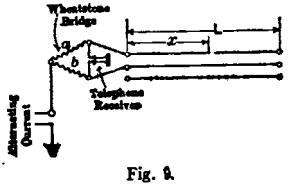

Fig. 9.

g again used, although connected differently. Zero reading is obtained on galvanometer as before, and, using the same notation,

$$x = \frac{aL}{100}.$$

ne Conductor Open. — When one conductor is open, the bridge is connected hown in Fig. 9, a telephone receiver being substituted for the galvanometer, alternating current for the direct current. The sliding contact is moved g the bridge until silence is obtained in the telephone.

et a = distance from sliding contact to the terminal of bridge connected to n conductor,

= distance from sliding contact to the terminal of bridge connected to whole ductor: then,

$$x = \frac{b}{a} L.$$

Ayrton's Method to Detect Crosses. — In Fig. 10, a, b and r repre- three arms of a Wheatstone bridge, the fourth arm being the conductor N, ch is in contact with a second conductor M of the same cable at the point Ground the conductor N at the far end and let x and y be the resistances

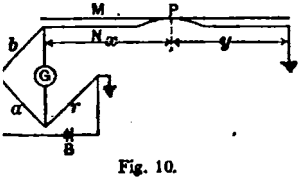

Fig. 10.

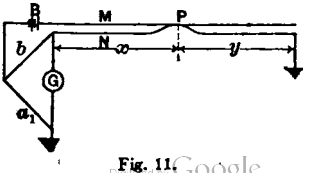

Fig. 11.

Digitized by Google

of the grounded conductor from the bridge to P and from P to the ground respectively. Let a, b and r be the resistances of the other three arms of the bridge. Make $a = b$, and adjust the variable resistance r until the galvanometer shows no deflection; then

$$x + y = r,$$

neglecting the resistance of the ground.

Then connect battery to M instead of to earth as shown in Fig. 11, and adjust a to a value a_1 such that the galvanometer shows no deflection. Then $a_1 = b$, or

$$\frac{x}{x+y} = \frac{b}{b+a_1}.$$

But from first arrangement $x + y = r$, whence

$$x = \frac{br}{b+a_1}.$$

From the resistance of the conductor per foot, the distance to the point P is then immediately determined.

Varley Loop Test for Grounds. — Grounds may be located by the arrangement shown in Fig. 12. Loop the bad wire at the distant end with a good one of equal resistance. Call the resistance of the good wire c and the resistance to the fault on the bad wire x. Adjust the rheostat until the galvanometer balances. Then

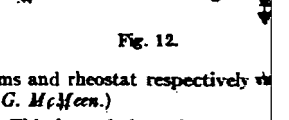

Fig. 12.

$$x = \frac{2bc - ar}{a+b},$$

a, b and r being the values of the bridge arms and rheostat respectively when the galvanometer shows no deflection. (*S. G. McMeen.*)

Varley Loop Test for Crosses. — This is made by substituting the crossed wires for the earth path of Fig. 12, using one good wire as before.

Cable Tests by Exploring Coil. — Grounds on wires in cables may be located by the use of a telephone receiver connected to an exploring coil. To do this, connect a source of interrupted current to one end of the wire in trouble, the other terminal of the source being grounded. Remove from the wire in trouble all the grounds other than the fault. Then move along the cable a coil such as one spool of an 80-ohm telephone ringer (*see Telephony*) across whose terminals a receiver is connected. Hold the exploring coil with its iron core at right angles to the cable. A tone from the interrupter should be heard when the exploring coil is between the fault and the source of sound, but not when it is beyond the fault. (*S. G. McMeen.*)

Listening Tests on Telephone Lines. — A long telephone line will be noisy if one of its wires is grounded, open or crossed with a third wire, whether the latter be grounded or clear. To determine where the fault is, listen on the line while assistants short-circuit it at different places. The fault is beyond the short-circuit if the short-circuit makes the line quiet (*S. G. McMeen.*)

SPECIFICATIONS. — (*See also article on Wires and Cables, Bare.*) The following forms are recommended for insulated wire and cable specifications. The general idea is for the purchaser to have printed or mimeographed forms and to fill them in according to specific requirements. These tabular specifications are supplemented by general specifications for workmanship and material which should be included when bids are sought or orders given. This arrange

t minimizes the chance of accidental omission on the part of the purchaser manufacturer and saves the bidder time in reading long specifications.

NERAL WIRE AND CABLE SPECIFICATIONS. — Purchasers re desirous of obtaining wires or cables of adequate design and good con-ion, use specifications which describe the major details of construction to lowed and tests to be applied.

merly every customer who purchased on specification wrote his own ications, but this led to endless difficulty with the manufacturers who had ke special compounds or follow special rules for each customer. In recent

years various engineering societies have adopted standard specifications wh are now largely used.

American Institute of Electrical Engineers. — (*a*) *Standards of the A.I.E.E.* which cover definitions of terms, methods of test, insulation thickness for va grade rubber insulation, test voltages, etc.

(*b*) Marine Code, which covers merchant ship wiring.

American Railway Association. — Signal wire specifications.

American Railway Engineering Association. — General wire specifications

American Society for Testing Materials. — Specifications for bare copper wi and cables. Tentative specifications for rubber-insulated conductors.

Association of Railway Electrical Engineers. — Specifications for practica all types of wires and cables used by railways. (Now becoming obsolete)

Joint Rubber Insulation Committee (superseded in 1921 by A.S.T.M.). — Spe fication for 30 per cent hevea rubber insulation.

National Board of Fire Underwriters. — Specification for wires and cables to used in buildings.

National Electric Light Association. — Specifications for paper-insulat lead-covered underground cable.

Rubber-insulated Wire and Cable. — Most of the characteristics of ru ber compounds are so good from the point of view of electrical insulati that the efforts of purchasers are mostly concentrated on obtaining life, or p manency.

There are three recognized standard specifications for rubber insulation, t National Electrical Code specification which is the least severe, the Joint Rub Insulation Committee specification which has severe chemical requirem and the American Railway Engineering Association (Signal Division), specifi tion which specifies a formula and requires rigid inspection during manufact The idea of chemical clauses is that by specifying close limits upon the follo analytical results (obtained by a standard method of analysis), the use of permanent substances will be prevented.

Analytical results upon which limits are placed	Deleterious substances whose use is prevented by limits upon analytical results
Total sulphur	Reclaimed rubber
Alcoholic potash extract	Rubber substitutes
Chloroform extract	Tars
Mineral matter	Carbon, cellulose, etc.
Saponifiable acetone extract	Unextracted high resin rubbers
Unsaponifiable acetone extract	Deresinated rubber

The chemical requirements are supplemented by mechanical and electri requirements, the former for the purpose of checking vulcanization and th latter to ensure proper insulating qualities.

Paper Cable. — The principal characteristic which is insisted upon for l voltage paper insulated cables is good condition of the paper in regard to mechan cal strength, in order that the cable may not be injured during installatio When cables are installed they often have to be bent to a very short radius, an unless the paper is in very good condition, it will crack, usually on the outsi of the bend. If the paper is wrinkled, scorched or improperly lapped, it wi break open when it is installed.

Digitized by Google

rchasers, therefore, require that a high grade of manila rope paper be used hat it be free from wrinkles, tears and scorches.

the case of high-voltage cables, in addition to the requirements for low- ge cable, it is usual to put a limit upon the dielectric losses in order to e the cable having ample carrying capacity.

'ere bending tests, followed by high voltage tests, are often specified to up defects in the paper, and lack of uniformity in drying or impregnating ealed by the megohms test.

rnished Cambric Cable. — Most of the specifications for varnished ric cables are not very severe, except in requiring a smooth application of ipe and proper overlap.

lectric loss requirements are not applied to varnished cambric cables, ome recent specifications call for certain characteristics of the varnished itself, which make it necessary to use only the highest grade of cloth. specifications call for soaking the cambric in petroleum at a high tempera- o make sure that it does not become tacky as a result of reaction with the ler" compound.

STALLATION OF INSULATED WIRES AND CABLES. — For stallation of wires and cables in buildings see articles on *Wiring of Buildings ght and Power; Wiring of Buildings for Miscellaneous Devices*. Below is a brief description of modern practice in installing insulated wires and on messenger wires and in underground conduit systems. For the con- ion of the pole lines carrying the messenger wire see articles on *Poles rhead Lines; Towers, Transmission*. For the construction of conduit sys- ee article on *Conduits and Conduit Lines*. See also the articles on *Distri- Lines* and *Transmission Lines*.

ssenger Construction. — The messenger wire is erected in the same man- an ordinary line wire; see article on *Transmission Lines*. A "leading- ire is stretched from the bottom of one pole to the messenger wire on the g pole, forming an incline on which to pull up the cable. A pulling rope fastened to the end of the cable by means of a cable grip and carried ide of the messenger to the point where the cable is to reach, thence through ch-block down to the terminal pole to a second block at the bottom and to a capstan, winch, locomotive or whatever is to be used for pulling. temporary rollers should be provided on the poles over which the rope r the rope should be suspended from the messenger by wire hooks. The s then slowly drawn up the inclined wire and along the messenger, attach- nporary carriers to the cable as it is paid out and hooking them over the ger to carry the weight of the cable. Linemen must be stationed on each pass these carriers around the messenger clamp or insulator. The final sion of the cable may be accomplished in either of the following ways: nen the end of the cable arrives at the beginning of the last span, the n on each pole replaces the temporary carriers by permanent hangers, g them regularly along the cable, so that when the last span is pulled, all ngers will be in place. (2) When the cable has been pulled all the way, an rides along the messenger wire in a carriage replacing each temporary by a hanger. This plan is preferable as the hangers may be attached ightly to the messenger wire, and are less likely to slip on the cable.

allation of Cables in Ducts. — The conduit system having been con- d, it must be prepared for the reception of the cable by being cleaned rodded as described in the article on *Conduits and Conduit Lines*.

nere are several ducts available, the choice of the particular duct to be hould be governed by the following considerations: 1. Avoiding un-

necessary crossings of cable in the splicing chambers, substations, etc.; 3. Avoiding the obstructing of empty ducts; 3. Keeping the cables cool; and 4. Keeping d-c. cables away from others. The following statement in the catalogue of the A. S. & W. Co. is pertinent with regard to keeping the cables cool. "Usually the coolest and best heat-radiating ducts are those located at the lower corners of the system, next are those nearest to the outside of the system and lastly the middle and top ducts which not only take up heat from the lower cables, but must dissipate heat through adjoining ducts. Attention to these points when planning a new system may prove very profitable in the end."

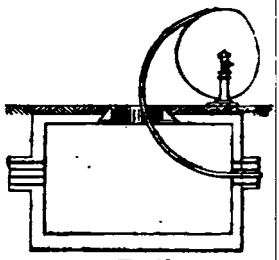

Fig. 13.

The next step is to set the cable reel on the shaft of a pair of wheels of slightly greater diameter than the reel itself or on jacks and raise it slightly above the ground, taking care to locate it as shown in Fig. 13, so that the cable will unreel into the manhole without making a reverse bend.

Fig. 14.

The pulling rope having been left in the duct after rodding, the cable is unreeled sufficiently to bring its end close to the mouth of the latter and a wire pulling grip (Fig. 14) is drawn over its end. The end of the grip is hooked to the rope and the rope pulled from the other end. Fig. 15 shows an arrangement of pulleys for guiding the pulling rope. The pulling may be done by capstan, winch, motor truck, horse or by hand, depending upon the size and amount of cable to be pulled, and upon local conditions. The cable should be carefully guided into the duct so as to avoid sharp bends and abrasions, and a small quantity of grease may with advantage be spread over the cable as it enters the duct. R. J. Robb (*Journ. I.E.E., 1911, Vol. 47, p. 350*) says that 112 pounds of petroleum jelly is required per mile of cable. It is also necessary to cover the edges of the duct with pieces of lead to prevent abrasion of the cable as it passes into the mouth of the duct.

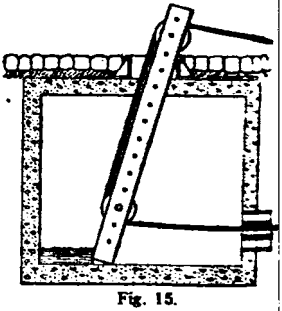

Fig. 15.

Protection of Cables in Splicing Chambers. — (*See also article on Conduits and Conduit Lines.*) Wherever there are several large cables in a splicing chamber, there is always danger that a burn-out of one cable will involve some or all of the remainder. Hence it is usual to protect such cables by means of one or more of the following methods:

1. Concrete shelves,
2. Open-face conduits,
3. Cement coating with ⅛-inch rope bond,
4. Asbestos tape saturated with silicate of soda,
5. Asbestos tape covered with soft steel-tape armor,
6. Asbestos rope,
7. Split tile duct.

Methods Nos. 1 and 2 are applicable only to chambers containing few cables

3 has given good results in many cases, but the cement is liable to crack fall away from the cable unless carefully bonded. On the other hand, the ion of a burn-out is plainly indicated by the cement covering being blown No. 4 combined with No. 5 is very generally used and gives very satis- ry results. No. 6 is but little used. No. 7 is very satisfactory, but is dumsy, and cannot be used where there are many cables in the chambers. ie necessity for such protection (according to the Committee on Under- nd Construction of the N. E. L. A., 1911) is equally great with low-tension s as with high-tension cables, for, while a breakdown of the insulation of h-tension cable is often attended with a violent explosion and the genera- of a very high temperature, the duration of the trouble is limited to one ro seconds; whereas in the case of a short circuit on a low-tension cable, it continue to burn with a considerable flame for several minutes, which d be quite long enough to damage adjacent unprotected cables.

the case of direct-current feeders for electric railways, where the return ounded, the danger of burn-outs spreading is much greater than with the ated lighting systems referred to in the N. E. L. A. report. This sub- is treated at greater length in the author's *Electric Power Conductors*, which the following is quoted: "If it is necessary to put direct- and alter- g-current cables in the same duct line, it is well to isolate the direct-current s as much as possible in the splicing chambers. The racks on which direct- nt cables are supported should not be in metallic contact with other racks. owever, this is unavoidable, the cables should not lay directly on the racks, n insulating pads or blocks."

isting Insulated Conductors. — (*See also article on Wires and Cables,*) Having selected the corresponding cable ends, they should be inspected echanical defects along the entire exposed length and bushings placed them at the ducts so that the sheath will not be cut by the edges of the uits. The cables should then be bent until the ends overlap, the bends g of ample radius throughout, and the position of the cable such that the , when completed, will not have to bear any elastic stress or weight.

Drying Out Cable Ends. — In the case of paper- or cambric-insulated s, the ends should be examined for moisture before they are finally cut t and if any exists or is suspected, heat should be applied to the sheath, aning at the duct end and slowly working to the open end. This is lly done with a gasoline torch but sometimes by pouring on hot insulating pound.

Overlap. — This operation having been completed, the cable ends are o as to leave an overlap, depending upon the method of joining the conduc- (*see below*) and upon the number of separately insulated conductors in the e. If the cable has but a single conductor, and a butt joint is to be used, overlap should be merely sufficient to allow for cutting off the ends, whereas interlaced joint is contemplated, the overlap should be greater by about 4 times the diameter of the conductor.

Removal of Sheath. — The next operation is to cut off a sufficient th of lead sheath to permit the joint to be made. This length may be ed from the size of the sleeve to be used (*see below*). The operation is ormed with a chipping knife and hammer, or with a special tool designed the purpose, and the greatest care should be exercised to avoid cutting the lation to the slightest degree. It is usual to make a cut around the sheath gradually increase its depth until the lead is cut through. The lead must be cut lengthwise from the circular cut to the end, injury to the insulation g avoided by holding the knife tangent thereto. The lead may then be ed off with a pair of pliers and loose particles carefully removed. In the

case of high-tension cables the ends of the lead should then be turned up slightly to a bell-mouth shape by means of a fibre wedge.

Putting on Lead Sheath. — Before jointing the conductors, the lead sleeve should be slipped over one of the cable ends and pushed out of the way. The ends of the sleeve and the corresponding surfaces of the sheath should have been previously scraped for a length of about a couple of inches along the outside and the cleaned surfaces smeared with stearine.

Removal of Insulation. — The next step is to cut back the insulation for a length between ¼ and ½ inch greater than half the length of the connector to be used, and taper the remainder uniformly for a distance of 1 to 1½ inches using a small sharp knife. In the case of multiple-conductor cables having a belt, the belt must be cut back sufficiently to expose all the joints, the greatest care being exercised to avoid cutting the inner insulation in doing so. The paper tapes should be tied with string to prevent unwrapping. The surface of each taper should be covered temporarily with a strip of dry cloth.

Jointing the Conductors. — The next process is to prepare the conductor or conductors for jointing. The most usual type of joint is made by butting the ends of the conductors and enclosing them in a cylindrical copper connector. The conductors are first cleaned with gasoline and then tinned by pouring molten solder over them, using stearine for flux. All burrs should be removed with a file and the ends smoothed so that they will butt together perfectly. The connector is then put over one conductor end and the other end slipped in until the two ends butt. Solder is then poured over the joint until it is thoroughly saturated, when the surplus is wiped off so as to leave no sharp projections.

Connectors. — The connector should have a cross-section not less than that of the conductor and a length about four times the diameter of the conductor. From points ¼ inch back from each end, it should be pencilled down to the rounded edges at the ends, and it should be split the entire length. It should be finished so as to eliminate all sharp points and edges. The opening should not be over 3/64 inch in width.

Jointing Stranded Conductors. — While the connector joint is by far the most common, stranded conductors may be joined by cutting the wires alternately long and short, and fitting the two conductor ends into one another. The joint is then bound with small wire. Stranded conductors are sometimes joined by cutting the wires of successive layers alternately long and short, and telescoping the ends into one another.

Insulation of Joint. — The next step is to insulate the joint. The depression at each end of the copper sleeve should be filled flush with impregnated 4-strand cotton twine, which should be thoroughly impregnated with compound. The usual process is to cover the joint with a tape of similar material to the remainder of the cable insulation, although this method is not universal. If oiled paper or varnished cambric, the tape should be cut on the bias. Narrow strips of impregnated tape should first be wrapped back and forth in the space between the two ends of the original paper insulation until it is built up to the level of this insulation. Compound should be applied on each layer. Wider tape is then wound on until a thickness about 40 per cent greater than that of the cable insulation is reached.

In the case of three-conductor high-tension cables the wrapping should commence at a point on the covered conductor 3 inches from the outer belt and extend to a corresponding point at the other end. The wrapping is then continued back and forth, stopping each successive layer ¼ inch short of the end of the preceding layer. In applying the tape, each turn should be drawn tight

ould overlap the preceding turn by two-thirds of its width. the tape should be applied tightly and evenly. In the case nsion should be such as to stretch it to about half its width. nust be taken to have everything perfectly clean and dry.

t." — Where cotton or linen tape is used, each layer must ouring hot compound over it until all the moisture is expelled oing is thoroughly saturated. Before applying the com- nould assure himself that it is *not* hot enough to ignite a d in it; otherwise the tape is likely to be charred. This e entering the splicing chamber, as the accidental ignition l is dangerous in such a confined space.

— Where rubber tape containing sulphur is used, it should ed by the application of heat from a spirit lamp, care being heat evenly and to avoid burning the insulation. This mplete in about one minute with conductors up to one-half

or Three-conductor Cables. — In the case of three-con- all the conductors are joined and insulated as described, a liameter is inserted between them at the center of the joint er. A band of tape is then wrapped around all three con- ameter that the whole will slide nicely into the lead sleeve, . Instead of this, a band of tape may be built around each nter of the splice.

ting Tubes. f insulating n insulating nductors be- oring it over atter is com- to get the y during sol- large enough

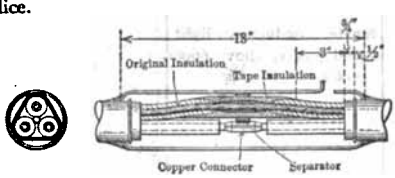

Fig. 16.

the insulation. Such tubes are made of prepared paper, micanite. The jointed conductor should first be wound to the level of the original insulation, "boiled out" as de- then the sleeve slipped on. A further "boiling out" with mpletes the job. In the case of belted multiple-conductor to the insulating tube over each conductor a large tube er the belt before splicing the conductors.

Baffles. — Baffles of micanite, bakelite, etc., are now com- en conductors of triplex cables. They replace part of the n around each conductor and the whole of the belt. The mmonwealth Edison Co. splices are of this type.

ves. — The joint having been insulated, the lead sleeve t symmetrically over it, and the ends beaten down into sheath, taking care to make the sleeve concentric with the

sheath are then joined by pouring solder over the ends from g the joint with a cloth. This process should be continued tight joints are obtained, the under side being examined for of a hand mirror.

is well wiped on, two small holes should be made in the top pound poured in one hole until it appears at the other. If ars the compound should be poured in one hole and allowed

to escape from the other until this defect ceases. The joint should be allowed to cool for about an hour, and if then the compound has settled should be added until the sleeve is full. The sleeve is then closed by small patches of lead over the holes. When the joint has thoroughly and solidified, it may be pushed gently into its permanent place.

The following data on lead sleeves are given by the Standard Underground Cable Co.

DATA ON LEAD SLEEVES

	Outside diam. of cable, mils	Inside diam. of sleeve, inches	Length of sleeve, inches	Gals. of compound per joint
Single-conductor, light and power, up to 6600 volts.	Up to 550	1	8	0.05
	551–950	1½	10	0.1
	951–1350	2	12	0.2
	1351–1750	2½	12	0.3
	1751–2150	3	14	0.5
	2151–2550	3½	14	0.6
Single conductor, light and power, above 6600 volts.	Up to 550	1	10	0.05
	551–950	1½	12	0.1
	951–1350	2	14	0.2
	1351–1750	2½	16	0.4
	1751–2150	3	18	0.6
	2151–2550	3½	18	0.8
Multi-conductor, light and power, all voltages.	Up to 800	1½	14	0.2
	801–1200	2	16	0.25
	1201–1600	2½	16	0.35
	1601–2000	3	18	0.6
	2001–2400	3½	18	0.8
	2401–2800	4	18	1.0
	2801–3200	4½	20	1.4

Compounds for Filling Lead Sleeves. — Various compounds have been used for filling the sleeves, such as conduline, G. E. No. 227 compound, E. P. Trotter's "B–7," ozite, etc. The Commonwealth Edison Co. of Chicago uses a compound developed by the engineers of the company. It is poured at a temperature of 150° C.

A good compound should have a high melting point, adhesiveness, high dielectric strength, low coefficient of contraction and should not be brittle at ordinary temperatures.

Stamping the Joint. — After the joint is completed the jointer should stamp his initials at each end of the sleeve.

Taped Joints. — Where the cable has no lead sheath, but is merely braided, it is usual to finish the joint with friction tape.

Shielded Splice. — A joint used for 25,000-volt cables is described by Torchio, Elec. W., 1916, Vol. 67, p. 873. The conductors are wrapped with oil-saturated paper-tape, and over the three conductors is provided an outer jacket pierced with holes to allow a free circulation of oil. Over the jacket is

gauze sleeve and around it a heavy lamp wick. The gauze protects t sharp potential gradients and the wick retains the insulating oil within lice. When the joint is completed, it is subjected to a vacuum of 27–29 and then filled with liquid petrolatum.

minals. — Conductors may be soldered to lugs or terminals or they may mped mechanically by means of a Dossert or similar connector.
he former case the insulation is cut from the end of the conductor, which n brightened by scraping or sandpapering and smeared with soldering The conductor is then tinned by plunging into molten solder. The lug also be tinned internally and heated so that it will hold some solder in olten state. The conductor, also heated above the melting point of solder, i pushed into the lug and the latter cooled by the application of wet waste. cool the shreds and globules of solder are filed off and the surfaces ened with sandpaper. Some jointers prefer to hold the lug in the molten until it attains the same temperature as the latter. In this case, if the s been previously treated with flux, its outside as well as its inside surface e tinned and it will make better contact with its accompanying lug or al. If, however, the copper or brass surface is desired for appearances, r be preserved by coating the outside of the lug in a light oil of high flash. before dipping it into the solder.
either case it is advisable to wrap the end insulation in a rag previously ; out in cold water to prevent it being melted or charred.

nding Sheaths. — The conductors of high-tension cables induce electro-charges on the sheaths, often raising the latter to dangerously high poten- It is, therefore, customary to ground the sheaths of cables at suitable in order to carry off the "static," as these induced charges are called. heaths of low-tension cables do not have to be grounded to drain off static icity. The sheaths of direct-current railway feeders which are used in nction with a grounded return system should, however, be grounded to gative return system, except when the tracks have insulated sections for atic block signals, in order to afford a low-resistance path for a short- t current. Unless this is done, the escaping current will return through es paths, inflicting damage without attaining sufficient strength to trip ation circuit breakers.

RN-OUTS OR PUNCTURING OF INSULATION. — Cable burn- may be caused by mechanical injury, exposure to excessive heat or cold, mulative heating, by chemical deterioration, or by transient high-voltage omena.

rn-outs Due to Mechanical Injury. — Paper insulation differs from r and varnished cambric in depending upon the integrity of the lead sheath i incloses it. Hence in the case of paper-insulated conductors, a puncture e lead sheath will sooner or later result in a burn-out even though it may a week or longer for the moisture to penetrate the insulation sufficiently complish this. (*Burch, Trans. A.I.E.E., 1903, Vol. 22, p. 433.*)
chanical injury often occurs in the process of installing underground cables. ght projection in a duct will cut a groove in the lead sheath, thereby reduc- s effective thickness and rendering it liable to crack open. The bending ble in splicing chambers may crack the insulation, especially if tightly d paper insulation is used A loosely insulated cable is also liable to injury use bending will flatten the cable, compress the insulation in one direction flare it out in the other, causing voids or air spaces between the layers, h under the influence of high voltages will cause electric discharges, heating e and consequent chemical action. Mechanical injury after installation

may be due to settlement of the conduit line, to careless stepping upon the cable to vibration setting up crystallization of the lead sheath, etc.

Exposure to alternate heat and cold leads to expansion and contraction which may introduce mechanical stresses into the insulation and thereby injure it. Excessive heat (120 to 150° F.), such as would result from direct exposure to summer sunlight, is likely to dangerously reduce the insulating qualities of varnished cambric and to a less extent that of impregnated paper. A higher degree of heat (200° F.), such as would occur in the proximity of steam pipes has the effect of making rubber insulation become brittle.

Chemical deterioration may be due to electrolysis (q.v.) or merely to ordinary chemical reaction between the sheath and the material in contact with it, the former cause being the more common.

Burn-outs Due to Static Discharges. — Failure of high-tension rubber insulated conductors is sometimes due to electrostatic discharges from the charged conductor to its supports, the irregular potential gradient giving rise to local static discharges with consequent formation of ozone and oxidation of the rubber.

Burn-outs Due to Imperfect Manufacture or Splicing. — Insulated conductors also burn out because of defects of manufacture or of splicing. The former class of defects is happily rare, but dirt, moisture and jagged edges of metal are frequently responsible for the failure of joints, especially on high-tension cables.

Transient High Voltage and Currents. — "Surges," i.e., transient high voltages and heavy currents, are sometimes responsible for very serious cable failures, such as described in *Trans. A.I.E.E., Vol. 24, p. 297*. To determine the origin and cause of high-voltage disturbances, so as to be able to guard against their recurrence, the most important thing seems to be to very carefully observe and record all the details of the phenomena, even those which appear unessential. The existence of static (i.e., high-voltage discharges of small currents) on switchboards, lines, etc., and the existence of voltages and currents different from those which may be expected require special attention. Either of these is sufficient to raise the suspicion of some dangerous fault in the system or some dangerous arrangement of apparatus, which requires considerable. The severity of the phenomena depends almost entirely upon the power momentarily available in the system and very rapidly increases with the size of the generating stations (*C. P. Steinmetz*).

After considering the likelihood and severity of such potential disturbances P. Junkersfeld and E. Schweitzer reached the following conclusions with respect to their influence upon the use of high-tension cables.

1. Where local and commercial conditions justify, pressures as high as 25 000 volts can be satisfactorily used even for systems aggregating as much as a hundred miles of cable. No single line of such a system would be much longer than twenty miles. If higher voltages are needed to meet operating requirements and can be justified commercially, special construction will be necessary to overcome limitations in paper, rubber or varnished-cabric insulation, and also in the standard forms of underground conduit or subways used in this country.

2. On comparatively short lengths, underground or under water, as a part of a long overhead transmission line, cables operating at 40,000 volts can be used.

3. Potential rises of 50 per cent and 100 per cent are not uncommon in large underground cable systems, although this fact may not always be manifested due to the high factor of safety in the insulation.

Occurrence of Cable Burn-outs. — The following table gives the number of cable burn-outs reported to the Underground Systems Committee of the N.E.L.A. in 1921.

— The life of cables depends so much upon the type, excellence of manu- and conditions of service, that specific figures are of little use. Further- any of the earliest cables made are yet in satisfactory operation. For , there are at Buffalo, rubber-covered 11,000-volt cables that were in 1897, and in 1921 they were in perfect condition.

TS. — There are so many types of wires and cables and the prices e so greatly that it is impossible to give adequate cost data. The g examples will give a general idea of the cost of a few common types s:

Kind of wire or cable	Cost per 1000 ft.
14 code wire.....	$6.00 to $ 12.00
e conductor, 2500 volt, rubber ins., Park cable.	$85.00 to $115.00
e conductor, 1 circ. inch, 3/32" paper and 1/8" lead.....	$725.00 to $1350.00
e conductor, 0.35 circ. inch, 9/32 by 9/32, 1/8" lead	$1070.00 to $1710.00

WIRES, RESISTANCE. — (*See also Electromagnet Windings; Resistance and Conductance, Electric; Rheostats and Resistors; Wires and Cables, Bare; Wires and Cables, Insulated.*) Metals and alloys having high specific resistance or low temperature coefficient of resistance are largely used for resistors. Some of the principal metals used for this purpose are listed below. They are usually be obtained in the form of wires, ribbon or sheets. The data given Nichrome, Climax, Advance, Therlo, Yankee Silver, Ferro-nickel, Monel Metal, Kromore, No. 193 Alloy, and Nickel Silver were supplied by the Driver-Harris Co., those on Calido, Ideal, Akbar, Comet, Karma, Lucero, Nickel, Phenix and Rayo were supplied by the Electrical Alloys Co., those on Excello, Ia Ia, and Superior resistance metals were taken from the catalogue of H. Boker & Co., those on Acme, Electris, Excelsior, Eureka, Peerless, Premier Nickel Chrome, Sichrome, Superior Nickel Chrome and Tarnac were supplied by the Alloy Metal Wire Co., those on Chromel were supplied by the Hoskins Manufacturing Co., and those on Manganin by Baker & Co.

Acme is a nickel-steel-chromium alloy and is used in heat radiating elements. It is similar to No. 193 Alloy and Comet.

Advance is a copper-nickel alloy, containing no zinc. It is uniform in composition and constant in its resistance under all conditions of service. Because of its high thermal e.m.f. against copper, it cannot be used in electrical apparatus in which the generation of an electromotive force would cause errors, as for example, in a wheatstone bridge where a few microvolts would cause an error in the galvanometer deflection. It is used in switchboard voltmeters, street car heaters, and other forms of heating devices provided its operating temperature is not exceeded. For ordinary temperature measurements a commercial grade may be used as a thermo-couple element. For accurate temperature measurements, it should be purchased on specification.

It is similar to Excelsior and Ideal.

Akbar is an alloy of copper, nickel and manganese. It is used for heating purposes.

Calido is a high percentage nickel-chromium alloy. The melting point is about 1530° C. It is recommended for electrically heated devices at temperatures up to 1000° C.

Chromel is furnished in three grades: Chromel "A" is an alloy containing about 80 per cent nickel and 20 per cent chromium. It is used in heating devices such as hot plates at temperatures from 875° C. to 1100° C. Chromel "B" contains about 85 per cent nickel and 15 per cent chromium. It is more durable than Chromel "A" but is suitable for the same class of work where conditions are less severe. Chromel "C" is a nickel-chromium-iron alloy containing about 25 per cent iron and 11 per cent chromium. Its iron content somewhat lowers its durability at high temperatures. It is used extensively in flatirons where it is enclosed and thus protected to a certain degree against oxidation.

Climax is a high-resistance nickel-steel alloy. It is especially well suited for use in rheostats. It is one of the cheapest resistance metals, but has a tendency to rust and scale and should therefore not be used in smaller sizes than No. 20 A.W.G. It is similar to Electris and Phenix.

Comet is an alloy of nickel, chromium and steel. It is low in cost and is used extensively in heating devices at temperatures below red heat. This alloy with Ideal wire produces a thermocouple of high e.m.f. and as such is more durable than iron or copper. It is similar to Acme and No. 193 Alloy.

Constantan is a copper-nickel alloy. It is used primarily as an element

ɔcouples. Constantan, Advance and Ideal are very similar and used for
· purposes. When thermocouples are to be made up for use with cali-
: apparatus, the thermoelements should be purchased on specification
urities in very small quantities affect the thermal e.m.f. (see article on
ters).

:tris is used as resistance element at medium low temperatures in such
: as controlling devices and rheostats. It can be soldered with any stand-
x and is similar to Climax and Phenix.

eka is a nickel-copper alloy and is claimed to be superior to German
because it is free of zinc, which produces brittleness when the alloy is
ated. It is used for general heating purposes such as car heating. In
l it is similar to Lucero.

elsior is an alloy of nickel and copper. It has characteristics similar to
ce, Ideal and Constantan and is used for similar purposes. The manu-
r recommends it for use in heating pads and other light duty service.

ello is adapted for use in electric heating devices.

o-nickel has a high current-carrying capacity, on account of its low
: resistance. As it will rust, it can only be used where it is not attacked
isture.

man Silver is an alloy of copper, nickel and zinc. The "grade" of
e designates the percentage of nickel. The 18 per cent grade is the
ɔmmon. The resistance of any particular grade depends upon the
of annealing; hard wire is slightly higher in resistance than soft. Ger-
lver was for many years the only resistance alloy obtainable, but it is
ing generally displaced by materials of the same specific resistance but
rior qualities. (See article on *Alloys*.)

a is recommended for use in instruments and electrical devices where a
ıperature coefficient is desired.

l is an alloy of nickel and copper, and contains no zinc. The manu-
rs state that its temperature coefficient is "nil." It may be used
ɔcipient red heat of 520° C. Its use in general is the same as that of
e. When used with Comet wire it forms a very durable and desirable
couple. In general it is similar to Advance and Excelsior.

ne is a nickel-chromium alloy used for heating purposes at temperatures
100° C.

nore is a nickel-chromium alloy. It is used at temperatures up to
in heat radiating elements. It is similar to Peerless and Rayo.

ro is a nickel-copper alloy and is intended for use in place of German
It is used in car heaters and other similar heating devices. In general
ilar to Eureka.

ganin is a material developed by the Reichsanstalt, for use in
ents and standards. The alloy which was shown to be the best for
· purposes is one containing 85 per cent of copper, 12 per cent of man-
ınd 3 per cent of nickel. Prior to 1918 it was imported but now it is
ıanufactured in the United States and is known as Baker manganin.
ıer manganin contains a small amount of iron and is claimed to be an
ment over that formerly obtainable.

anin should be used with a double silk covering saturated with shellac
ı baked in an oven at 140° C. for at least 24 hours. The baking process
the wire and sets the shellac so as to exclude air from the wire which
ɔtherwise become slightly oxidized in use. Oxidation increases the
ture coefficient of resistance. When used in resistance standards and

precision apparatus the shellacked coils of wire should be sealed to exclud from the shellac, otherwise the shellac will absorb varying amounts of mo from the air under a variation of humidity. When the shellac absorbs mo it expands and changes the tension of the wire and thus changes its resis The resistance element should be adjusted to its desired value after the an ing process, as the resistance of the wire decreases by a few tenths of one cent upon annealing.

The change of resistance with temperature is not a straight line but a cu represented by the formula:

$$R_t = R_{20}[1 + \alpha(t - 20) - \beta(t - 20)^2],$$

in which R_{20} is the resistance at 20° C., R_t is the desired resistance at the t perature t in degrees centigrade, α is a constant given in Table I, β is a cons usually equal to 4×10^{-7}.

Monel Metal contains approximately three parts nickel to one of co In smelting and refining the ore from which monel metal is mad nickel and copper are not separated, and, therefore, appear in the fi alloy in the same relative proportions. The treatment of this ore co merely in eliminating the impurities, excepting a small percentage duced iron. As a result the metal is tough, strong, as non-corrosive a nickel, and is the same in appearance; whereas nickel, as a pure metal, tively expensive, owing to the difficulty of isolating it. This alloy is pro at a cost which permits favorable competition with German silver, etc. resistance varies somewhat in different lots, and according to temper variation is, however, no greater than that of 18 per cent German silver.

Nichrome is practically *non-corrosive*, has an extremely high melting (about 1550° C.) and is far superior to nickel in its ability to wi high temperatures. It is especially recommended for use in elec heated appliances and resistance elements generally where extreme co are encountered.

Nichrome II is strongly resistant to oxidation. It has been es developed for use in carbon combustion furnaces, and other labo furnaces where the more extreme temperatures are to be met.

Nickel, due to its high temperature coefficient, is very efficient for resistance thermometers and owing to its non-corrosive qualities it employed for rheostats where acid fumes are to be met with.

Nickel Silver, as commonly known, contains 18 per cent of nickel resistance varies somewhat in different lots and according to temper.

Peerless is an alloy of nickel and chromium used in such service as ovens and furnaces. It does not deteriorate when operating continuo 1100° C. with exposure to air. It is similar to Kromore and Rayo.

Phenix is a nickel-steel material suitable for resistances at compara low temperatures. It is readily soldered with any standard flux. It is extensively in arc lamps, rheostats, resistors for controllers and other heavy duty apparatus. It is similar to Electris and Climax.

Premier Nickel Chrome has a high resistivity and used in heating ances at temperatures up to 1000° C. It is similar to Nichrome and Cabl

Rayo is an alloy of nickel and chromium in such proportions that it withstand high temperatures and mechanical rubbing. It can be used con ously at temperatures up to 1100° C. without deterioration. It is used in elec ranges and ovens. It is similar to Kromore and Peerless.

Sichrome is a new alloy consisting of silicon, chromium and iron. It

o per cent German silver has substantially the same properties as Advance metal.

Google

claimed to have a less tendency to corrode than the nickel chromium al It is intended for use in heating elements at temperatures up to 1100° C. rather severe conditions. Its specific gravity is lower than that of an resistance wire.

Superior is a nickel-steel alloy recommended for use in rheostats, ar resistances, etc.

Superior Nickel Chrome is an alloy containing approximately 80 per nickel and 20 per cent chromium. It is used in heating devices at temperat up to 1100° C.

Tarnac is an English product which is very similar to manganin and is for the same purposes. For precision purposes it should be treated in the manner as manganin. The variation of its resistance with temperatu similar to that of manganin. The value of β in this case is usually 2.5 × It has a maximum resistance at 70° C.

Therio is an alloy of copper, manganese and aluminum for work w low thermo-electric effect against copper is demanded. Compared with ganin, this alloy gives a higher specific resistance, does not oxidize so fast, is more stable in its electrical and mechanical behavior. This material is cially suitable for shunts. Temperature coefficient is +0.0000031 per It cannot be soldered but has to be brazed. This characteristic is favorabl its proper use. It should be treated in the same way as manganin to pr accurate resistance coils.

Yankee Silver. — This is a new alloy with most of the qualities of "s cent German Silver." It will withstand repeated heating and cooling and gives satisfactory service where German silver fails.

No. 193 Alloy consists of nickel, iron and chromium. It serves as resi elements for elevator controllers and rheostats at temperature up to 640° is similar to Acme and Comet.

TABLE II. — RESISTANCE, WEIGHT AND CURRENT-CARRYI CAPACITY OF WIRES

$$\text{Resistance, ohms per foot at } 20^\circ \text{ C.} = \frac{K\rho}{1000},$$

where ρ is the resistivity of the metal in microhms per centimeter cube, taken Table I, and K is given in the table below.

$$\text{Weight, pounds per foot} = \frac{H\delta}{1000},$$

where δ is the specific gravity of the metal, taken from Table I, and H is given in table below.

$$\text{Current for given temperature rise, amperes} = \frac{10\, I_\theta}{\sqrt{\rho}},$$

where ρ is the resistivity of the metal in ohms per centimeter cube, taken from Ta and I_θ is given in the table below. This formula is based upon the following multi to convert the resistivity at 20° C. to that at the temperatures stated.

100° C.....	1.031
200° C.....	1.052
500° C.....	1.081
1000° C.....	1.118

These are correct for Calido wire. For any other wire, the current derived from formula must be multiplied by the factor $\sqrt{\frac{m_c}{m_x}}$, where m_c is a multiplier from the al table and m_x the corresponding multiplier for the wire in question.

General Requirements. — Wires and fittings designed to conduct el tricity in a building should be selected as to size and insulation and instal in such a manner that: (1) the attending fire risk and the possibility of electric shock to the inhabitants shall be a minimum; (2) the elec power efficiency of the system shall be reasonable; (3) the voltage at t receiver shall approximate the rated voltage of the receivers and shall rem sensibly constant; (4) the mechanical arrangement of the system shall simple and convenient for inspection and use; (5) the conductors shall mechanically protected from external injury; (6) the service shall not be in rupted under normal load; (7) the cost of the materials, labor of installa and replacement due to depreciation shall not be excessive, and (8) the ent wiring system shall conform to the rules and regulations of any author having jurisdiction over the building in question.

SYSTEMS OF WIRING. — For direct-current and single-phase dis bution the two-wire system (Fig. 1) and the three-wire system (Fig. 2

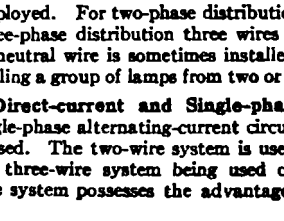

Fig. 1.

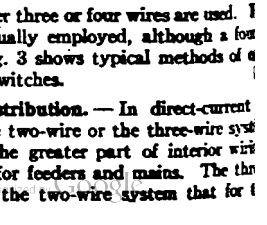

Fig. 2.

employed. For two-phase distribution either three or four wires are used. I three-phase distribution three wires are usually employed, although a fou or neutral wire is sometimes installed. Fig. 3 shows typical methods of c trolling a group of lamps from two or more switches.

Direct-current and Single-phase Distribution. — In direct-current single-phase alternating-current circuits, the two-wire or the three-wire syst is used. The two-wire system is used for the greater part of interior wirin the three-wire system being used chiefly for feeders and mains. The thr wire system possesses the advantage over the two-wire system that for t

e power transmitted at the same efficiency to receivers of the same voltage, three-wire system requires less weight of conductor. The neutral wire of a e-wire system is usually of the same size as either outside wire, the saving opper over the two-wire system then g 5/8 or 62.5 per cent (*see Distribution of tric Energy*). In some cases, buildings wired with the three-wire system in ch the neutral wire is made twice the of either outside wire so that if neces-, the system may be operated either as o-wire or a three-wire system; in the ier case the two outside wires are con-ed in parallel. Power may then be plied to the building from a local two-source of supply (isolated plant in the ding) or from an emergency three-wire t service.

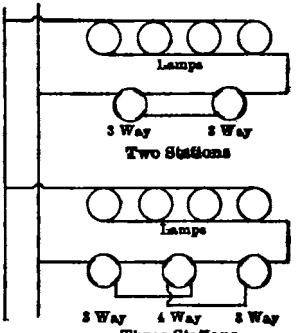

Fig. 3.

i this case wires of such size would be as would give normal efficiency and lation when used as a two-wire system; loss when used as a three-wire system ld then be only half as great.

he first cost of a three-wire system may not be less than that of a two-wire em because of the increased cost of the fittings, insulation and the labor of llation. The three-wire system is not as simple as the two-wire system, is subject to more disturbances unless the load is kept balanced. Some ric power companies limit the power which they will supply to a two-wire m and in such cases in new installations buildings taking power above the wire limit must be wired with the three-wire system. The two-wire system ed for either lighting or power loads while the three-wire system is used ither lighting or mixed lighting and power loads, motors in the latter case g connected between the outside wires.

wo-phase and Three-phase Distribution. — For distributing two-phase nating currents, either three or four wires are employed. A four-wire phase system may be treated as two separate two-wire systems, which ot in any case be connected in parallel. A single wire 41 per cent larger i either of the wires it displaces may be substituted for any two of the wires e four-wire two-phase system thus making a three-wire two-phase system. er three or four wires may be used for two-phase lighting or power loads. hree wires are usually employed on three-phase alternating-current circuits lying power to lighting or power loads. If the neutral is accessible, a neutral may also be used, making a four-wire three-phase system for lighting s, the lamps being connected between any outside wire and the neutral

TANDARD VOLTAGES FOR LIGHTING AND POWER LOADS. — all standard lighting loads the voltage across the lamps ranges from 100 25 volts in accordance with the rating of the lamps. In a few cases, lamps d between 200 and 250 volts are used with the corresponding voltages. voltage between the service wires of a constant-current series-arc or series-ndescent lamp system must not be greater than 5000 volts, the maximum tge for inside work allowed by the National Electrical Code (see p. 2063). stant-current systems are used chiefly in lighting large areas as in mills, ories, armories, etc. On power loads standard voltages of approximately 220 or 550 volts are used depending on the magnitude of the load supplied.

Digitized by Google

STANDARD FREQUENCIES ON ALTERNATING-CURRENT CIRCUITS. — Alternating currents are usually supplied to lighting loads at a frequency of 60 cycles and to power loads at 25 cycles. In some cases a frequency of 40 cycles is used when the lighting and power loads are of about the same magnitude.

PRELIMINARY LAYOUT OF THE WIRING SYSTEM. — If power is to be supplied to the building from some outside source, the service entrance must first be located from plans or by an inspection of the building itself. In most cases, service entrances are made in the basement, although first-floor entrances may be substituted when basement entrances are impracticable. In overhead-service connections, the service wires are usually run in conduit on the outside of the building from the point where the wires are attached to the building to the service panel-board. In underground-service connections, the service wires are run in conduit from the street mains through the basement walls. In the latter case, the conduit should be tightly closed at the outlet to prevent gases from entering the building. Fig. 4 shows two types of service connections.

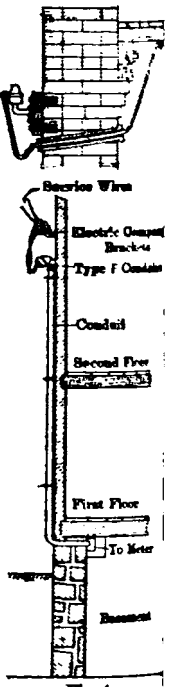

Fig. 4.

Location of Panel-Board. — The service panel-board should be placed securely in an accessible location and should contain space for the service cut-outs, service switch and meter. When power is supplied from within the building, the switchboard of the power plant must be located as a starting point in the design of the feeder system.

Location of Outlets, Switches, etc. — Outlets, control switches and cut-out cabinets should then be located throughout the building. Great care must be exercised in locating outlets and control switches in such positions as to accommodate the receiving devices planned for the building. Cut-out cabinets, which constitute the local distributing centers, should be located as near as possible to the dependent receiving devices and should at the same time be easily connected by feeders to the main switchboard. Fig. 5 shows a riser diagram and Fig. 6 a diagram of the wiring for one floor of an office building.

Number of Feeders. — Having located the outlets, control switches, distribution centers and the main switchboard, a feeder system must be planned to suit the conditions under which the system is to operate. The number of feeder sets required depends upon: (1) the power taken by the receiving devices; (2) the degree of control desired at the main switchboard; (3) the number of receiving devices which may rely upon one set of feeders; (4) the desired uniformity of voltage at the receiving devices, and (5) the character of the receiving devices. If the total current supplied to the building is roughly calculated and is found to exceed 650 amperes (the allowable carrying capacity of a 1,000,000 circular-mil rubber-insulated conductor), more than one set of feeders should be used, since it is impracticable to install feeders larger than one inch in diameter

† Upper numeral indicates number of

Unless controlled by remote control switches, separate feeders must be
illed from the switchboard to receiving devices which are controlled at the
switchboard.

a single set of feeders is used on a lighting load, the possible extinction of
lights in a building by an open circuit in the main feeders may cause a
; on a power load an interruption of all the machinery for any length of
may cause a considerable loss of money. To avoid such a discontinuance
e service, it is customary to connect separate feeders to sectionalized parts
e load, so that the entire load may not be interrupted at one time.

e voltage at receiving devices may be made more uniform by the use of
ate feeders than by the use of one set of feeders, except when a single set
ders may be run to a distributing panel to which branch feeders of nearly
l length are connected. When the power taken by certain receiving devices
s extensively and rapidly, the voltage at all other devices connected to the
feeder will vary accordingly, and in such cases lamps must be connected
parate feeders to avoid undesirable flickering.

iring Diagram. — After deciding upon the number of feeders to be used in
nstallation, a diagram should be made showing the location and length of
eders and branch circuits. When the wiring system is sectionalized, each
n should be treated by itself as a complete system. Figs. 5 and 6 are
al wiring diagrams for an office building.

RING CALCULATIONS. — The proper size of wire for any feeder is
mined by three factors: (1) mechanical strength; (2) current-carrying
ity, and (3) the allowable potential drop in the feeder.

nimum Size of Wire. — The National Electrical Code specifies No. 14
G. as the minimum allowable size for all classes of rubber-insulated
, except that in fixture work and for pendant cords wires as small as
8 A. W. G. may be used. The minimum allowable size of varnished cloth
ted wire is No. 6 A. W. G., except by special permission.

ıd of Insulation. — Rubber insulated wire protected with an outside
d covering and varnished-cloth insulated wire also with an outside braided
ing may be used where not exposed to moisture.

ıd Sheaths. — Lead-covered wire should be used when installed in tile
for mechanical protection against abrasion and in underground runs in
, etc., where condensed moisture may be present.

rrent-carrying Capacity. — The following table, from the National
ical Code, gives the allowable carrying capacity of copper wires and
of 98 per cent conductivity, and must be followed in placing interior
ctors. See also *Wires and Cables, Insulated.*

made. From the table below * select the size of wire corresponding to the
culated area. Unless the calculated area in circular mils agrees very clo
with the area of one of the conductors given in the table, the next larger
of wire should be selected.

600-VOLT RUBBER-INSULATED COPPER WIRE

* More extended wire tables will be found in the article on *Wires and Ca*

† Two insulated wires side by side, the insulation of the two wires in cont

‡ Measured from insulation to insulation, equals distance between centers

Check on Calculation of Size of Wire. — Calculation of Actual Potential Drop. — (*See also Alternating Currents.*) From the table, corresponding to the size of wire selected, take

r = the resistance per 1000 feet of conductor,
x = the reactance per 1000 feet of conductor,

put

l = length of each conductor in feet,
I = amperes per conductor,
V = volts to neutral at receiver,*
$\cos\phi$ = power factor of receiver,

$$R = \frac{rl}{1000} = \text{total resistance per conductor},$$

$$X = \frac{xl}{1000} = \text{total reactance per conductor}.$$

Then the actual volts drop *per conductor* is

$$v = \sqrt{(V\cos\phi + RI)^2 + (V\sin\phi + XI)^2} - V. \qquad (2)$$

With a very close approximation in all ordinary cases this is equal to

$$v = RI\cos\phi\left(1 + \frac{X}{R}\tan\phi\right). \qquad (3)$$

If the drop as calculated does not check within a reasonable value with the drop assumed in calculating the size of the wire, select another size of wire and recalculate, etc. This refinement will be found necessary, only in the case of very low power factors and when the size of wire as calculated is either exceptionally large or exceptionally small, in which case the values given for the factor K in the formula for A, equation (1), may be in error by a large amount (in limiting cases 50 per cent or more).

In addition to making sure that the drop will be within a reasonable amount, one should also note whether the conductor selected is large enough mechanically and has the proper current-carrying capacity (*see above*), remembering also that the National Electrical Code requires that conductors through which power is supplied to a motor shall have a current-carrying capacity equal to at least 25 per cent of the full-load current taken by the motor.

Example of Calculation for a D-C. or Single-phase System. — Incandescent lamps taking 0.5 ampere each are supplied with power from a 115-volt two-wire service through a set of feeders 200 feet in length which terminate at a distributing cut-out cabinet as shown in Fig. 7. The lamps are grouped in sets of 10 lamps each (only one set is shown) and each set is connected to the cut-out cabinet by a branch circuit conductors averaging 25 feet in length. Assuming a total allowable tential drop of 3 volts, the drop per conductor will be 1.5 volts. The drop per conductor in the branch circuit should then be one-third of 1.5 or 0.5 volt and the drop per conductor in the feeder circuit should be two-thirds of 1.5 or

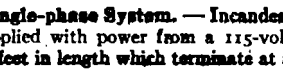

Fig. 7.

* For d-c. or a-c. single-phase or a-c. 2-phase, 2-wire systems $V = \frac{1}{2} \times$ (volts between wires); for a 3-phase system $V = \frac{1}{\sqrt{3}} \times$ (volts between wires); for a 2-phase 3-wire system $V = \frac{1}{2} \times$ (volts between either outside wire and middle wire). In calculating the normal drop in a single-phase 3-wire system pay no attention to the middle wire, i.e. assume a balanced load.

Digitized by Google

1 volt. The respective calculations of the areas of the conductors in the feede and branch circuits may then be carried on independently. In the branch circuit, referring to equation (1), $I = 10 \times 0.5 = 5$, $l = 25$ and $v = 0.5$, when for copper wire

$$A = \frac{11 \times 5 \times 25}{0.5} = 2750 \text{ circular mils.}$$

From the wire table it is found that the next larger commercial size is No 1 A. W. G., which has a resistance of 2.58 ohms per 1000 feet, and a reactance (assuming a 2.5-inch spacing) of 0.106 ohms per 1000 feet.

Referring to equation (3), $V = 57.5$, $\cos\phi = 1$, $\tan\phi = 0$, $R = 2.58 \times 25/1000 = 0.0645$, $X = 0.106 \times 25/1000 = 0.00265$, whence

$$v = 0.0645 \times 5 = 0.323.$$

Equation (2) gives the same value. This voltage is 35.4 per cent less than the assumed voltage of 0.5 volt, but since No. 13 wire is not a commercial size a closer realization of the assumed voltage is impracticable.

In the same manner, the required area of the conductors used in the feeder circuit is determined by snbstituting the following values in equation (1): $I = 100 \times 0.5 = 50$ amperes, $l = 200$ feet, and $v = 1$ volt. Hence

$$A = \frac{11 \times 50 \times 200}{1} = 110{,}000 \text{ circular mils.}$$

From the wire table it is found that a No. 00 A. W. G. wire must be used.

The above calculations although made for a lighting load apply equally well to a motor load, except that in the final selection a wire must be chosen which will carry 125 per cent of the full-load current of the motor.

Example of Calculation for a Three-phase System. — Power is to be supplied by three feeders each 400 feet in length to a three-phase, 60-cycle, alternating-current motor (power factor 80 per cent), the voltage between any two line wires at the service entrance being 550 volts. At full load the current taken by the motor is 50 amperes. The voltage to neutral at the service entrance is $\frac{550}{\sqrt{3}}$ or 318 volts. The wires are to be spaced 6 inches apart.

Allowing a drop in each conductor of 3 per cent of the voltage to neutral, the drop will be 3 per cent of 318 or 10 volts approximately. The following values should then be substituted in equation (1): $K = 17$, $I = 50$ amperes, $l = 400$ feet and $v = 10$ volts, giving

$$A = \frac{17 \times 50 \times 400}{10} = 34{,}000 \text{ circular mils.}$$

From the wire table it is found that a No. 5 A. W. G. wire might be used considering the potential drop alone but since the carrying capacity of the conductor must be 1.25×50 or 62.5 amperes, it would be necessary to use a No. 4 wire.

Adopting a No. 4 wire and referring to equation (3), $V = 318$, $\cos\phi = 0.8$, $\tan\phi = 0.75$, $R = 0.253 \times 400/1000 = 0.101$, $X = 0.101 \times 400/1000 = 0.040$, whence

$$v = 0.101 \times 50 \times 0.8\left(1 + \frac{0.04 \times 0.75}{0.101}\right) = 5.3 \text{ volts,}$$

Digitized by Google

ich is a little more than half the allowable drop of 10 volts. Equation (2) also es 5.3 volts.

AUTHORITIES GOVERNING THE INSTALLATION OF WIRING BUILDINGS. — As noted at the beginning of this article all interior ing must be installed in accordance with the regulations of the authorities ring jurisdiction over the building in question. In general, these authorities : (1) the fire underwriters; (2) the municipal authorities; and (3) the power pany supplying the current.

National Electrical Code. — This code is a set of instructions published in n years by the National Board of Fire Underwriters. A List of Electrical tings approved by the Underwriters' Laboratories, Inc. is published by the tional Board in April and October of each year. In order that fire insurance any building wired for electric light or power may be obtained from an urance company, the wiring must be installed in accordance with the rules of : National Electrical Code or such modifications of it as are required by law certain municipalities (*see Municipal Regulation, below*). Permission must o be obtained to use any fitting not included in the list of approved fittings. Both the Code and the List of Approved Fittings may be obtained gratis applying to the National Board of Fire Underwriters, 135 William St., New rk City. In view of this fact, and the frequent revisions of the rules and t it is not deemed advisable to give them in detail here. The general require- nts, however, are covered in the section below on *Methods of Installing iring.*

Municipal Inspection. — Many state legislatures have passed laws regu- ing the installation of electric wiring and empowering the appointment of micipal inspectors of wiring. In some states fines are imposed by legislative actment upon those who violate the inspector's rules. Although free to decide on the proper installation of electric wires, municipal inspectors have gener- y adopted the National Electrical Code as a standard with modifications ited to their desires. A copy of these modified rules can usually be obtained ntis from the municipal authorities.

Regulations of the Light and Power Companies. — The National Elec- cal Code is usually adopted by electric power companies with the addition of ecific requirements pertaining to service connections, placing of meters, type system, etc.

METHODS OF INSTALLING WIRING. — The National Electrical ode approves the use of the following methods of wiring: open work, moulding ooden moulding and metallic raceways), concealed knob and tube work, id conduit, flexible conduit, armored cable and flexible tubing (in short runs). hese methods are described in detail below, but first are given the more impor- nt general requirements regarding joints, protection, cut-outs, switches, etc., hich apply to all classes of wiring for voltages not exceeding 600.

General Requirements. — All joints must be mechanically and electrically cure without solder and unless made with some form of approved splicing rvice must be soldered and covered with an insulation equal to that on the nductor. Wires must be separated from contact with walls, floors, timbers partitions through which they may pass by non-combustible, non-absorptive sulating tubes, such as glass or porcelain, except at outlets where flexible tubing required. Unless inclosed in conduit or moulding, wires must be separated om any conducting material or from any other electric wire not more than wo inches away by some continuous and firmly fixed non-conductor creating permanent separation. In damp places wires must be separated from pipes y an air space and should be run over rather than under pipes upon which

Digitized by Google

moisture may gather. Wires must be protected from mechanical injury by running-boards or guard-strips on low ceilings and by wooden boxing or metal conduit on side walls. Protection on side walls must extend not less than 6 feet from the floor. No method other than open wiring may be used when the difference of potential between any two wires exceeds 550 volts.

Automatic Cut-outs (fuses or circuit breakers) must be placed in the service wires (i.e., the leading-in wires from the street circuit), and at every point where a change is made in the size of wire unless the cut-out in the larger wire will protect the smaller wire. The cut-out in the neutral of a three-wire system may be omitted if the neutral wire is grounded and is of the same size as the outside wires. No set of incandescent lamps requiring more than 660 watts, whether grouped on one fixture or on several fixtures must be dependent upon one cut-out. Cut-outs must in general be inclosed in an approved cabinet although circuit breakers and inclosed fuses may be placed in plain sight in dry places where there is no danger of igniting any combustible material.

Heating devices, which singly or in groups require more than 660 watts must be protected by a cut-out and the supply conductors should preferably be installed in rigid conduit. Such conductors should be insulated with rubber.

Switches which disconnect *all* wires (i.e., switches having 2, 3 or more poles) must be placed in the service wires as near as possible to the point where they enter the building and in all circuits supplying current to motors, heating devices or lamps; except that in the case of motors of one-fourth horse-power or less in circuits where the voltage does not exceed 300 volts, and in circuits supplying not more than 660 watts of power to heating devices or lamps, single-pole switches may be used in two-wire systems or branches. Switches must always be placed in dry, accessible places and must be grouped as far as possible. When used in rooms where combustible flyings are liable to exist, switches must be placed in dust-tight cabinets and when flush switches are used, they must be inclosed in an approved steel box.

Open Wiring. — When the appearance of the wiring is not important exposed surface wiring supported on cleats or insulators furnishes one of the safest and best methods of wiring. The wires must be insulated in dry places with rubber, varnished cloth, slow-burning weatherproof or slow-burning insulation, in damp places with rubber insulation, and in locations where the wires are exposed to corrosive vapors with weather-proof, varnished cloth or rubber insulation.

Voltage	Inches from surface to insulation on wire		Inches between wires* from insulation to insulation
	Dry	Damp	
0–300	0.5	1	2.5
301–600	1	1	4

* In the case of 3-wire d-c. or single-phase systems the neutral may be placed between the two outers, these latter being 2.5 inches apart.

Spacing of Wires and Supports. — Wires must be separated from each other and spaced from the surface wired over as given in the accompanying table.

Wires must be supported under ordinary conditions at least every 4.5 feet, except that in mill construction, wires of not less than No. 8 A. W. G. gage, if separated about six inches, may be run from timber to timber and be supported at each timber only. Open wiring cannot be used in elevator shafts.

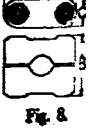

Fig. 8

Cleats. — Cleats are made in a variety of forms. The following are the dimensions of cleats of the form shown in Fig. 8, all dimensions being in inches.

DIMENSIONS AND COSTS OF CLEATS

te of wire, circular mils or A. W. G.	1-wire cleats			
	Dimensions, inches			Size of screw, inches
	A	B	C

	2- and 3-wire cleats			
14–12	3⅜	1⅜	⅝	3×8
10 6	3⅜	1⅜	⅝	3×8

Wooden Moulding. — When exposed wiring is not desired, and when it is practicable in old buildings or too expensive in new buildings to install concealed wiring, wooden moulding may be used, provided the difference of potential ween any two wires in the same moulding does not exceed 300 volts. Its is forbidden in elevator shafts and in concealed or damp places. Wooden ulding is manufactured in the following sizes. See table on next page. Moulding may be made inconspicuous by matching the wood of the moulding the finish of the room and by using a capping, which will conceal the purpose the moulding. In this manner, moulding may be made to simulate picture ulding, and on ceilings a panel effect can be obtained by the use of dead ulding. All wires used in wooden moulding must have a rubber insulation d must not be jointed or tapped in the moulding. Branch taps may be made th tap fittings designed for the purpose. Many other moulding fittings are nufactured, which, if used, reduce the labor of installation and improve the neral appearance of the work. Wooden moulding is fastened to walls by ans of thin screws or toggle-bolts and the capping is nailed on with brads. Kicking boxes" are usually placed around the end of moulding on floors to otect the wires and porcelain tubes from possible injury.

Metallic Moulding. — Metallic moulding may also be used to conceal and otect wires when the difference of potential between any two wires in the oulding is not more than 300 volts and the power transmitted through the ires contained in the moulding does not exceed 1320 watts. Metallic moulding manufactured in one width only, namely, 1 inch wide by ⅝ to ½ inch deep, e depth depending upon the type of moulding. The two types of metal

3	⅞	5 ⅛	1 ¾		0000–250,0
3	1	6 1 1/16	2 3/16		300,000–400,0

moulding in common use differ principally in the method of attaching capping. In the "Lutz" metal moulding the capping consists of a flat metal strip, which is slid into the two grooves that form the upper edge of moulding. In the "National" metal moulding the capping is snapped over base. "Lutz" moulding is made in 10-foot lengths while the National mould is made in 8-foot 4-inch lengths.

Metallic moulding cannot be used in concealed or damp places except t in passing through a floor, such moulding may be used if carried through iron pipe extending from the ceiling below up through the floor to a point feet above the floor or to a point at least 3 inches above the floor wi appearance is an essential feature. Such moulding may be carried thro walls and partitions provided it is in one continuous length and that the locat is dry. All parts of a metallic moulding system including outlet boxes, junct boxes and cabinets must be electrically connected and grounded. Fitti employed with metallic moulding must be so constructed as to protect the in lation of the wires from abrasion. Wires placed in metallic moulding must insulated and installed as in wooden moulding with the exception that in al nating-current systems two or more wires of the same circuit must be insta in the same moulding. It is suggested that this also be done for direct-curr systems when there is a possibility that an alternating-current system may used at some future time.

Concealed Knob and Tube Work. — This method of wiring is forbidd by the inspectors in many large cities, but when approved, it is employed buildings of frame construction when it is desired to install the wiring at

The wires when running parallel to beams or studding
os and when running through beams, studding or floors
lain tubes. When passing through floors at the bottom
; or through braces, the porcelain tubes insulating the
least four inches above the floor or brace. Split knobs
support of conductors smaller than No. 8 A. W G.
ins where a solid knob or strain insulator must be used.
than No. 8 A. W. G., solid knobs may be used. Wires
sulation and tie wires when used must have an insulation
nductors they confine.

een Wires. — Wires must be installed in such a manner
een *any* two wires is at least 5 inches and each wire must
surface wired over by a distance of at least 1 inch. If,
nch separation cannot be maintained, each wire must
l in a continuous length of approved flexible tubing.
ist be protected by flexible tubing extending in con-
the last porcelain support to at least 1 inch beyond the

'een Supports. — Wires must be supported under ordi-
y 4.5 feet and if the wires are liable to be disturbed the
supports must be shortened.

ıbes. — Two types of knobs are used, namely, the solid

Bushings, Bends, etc., in Rigid Conduit. — All parts of the c duit system including outlet or junction boxes must be mechanically se in place and must be electrically connected and grounded. At outlets or junct boxes rigid conduits must be provided with bushings or nipples to protect t wires from abrasion. The radius of curvature of the inner edge of an elbo bend must not be less than 3.5 inches and there must not be more than equivalent of 4 quarter bends from outlet to outlet, the bends at the outlet being counted. Bends should be used whenever possible in place of elbows the wires will pass more easily around a bend than an elbow. The various ki ing tools that are on the market consist of some form of lever, the end of wh may be slipped over the conduit while it is in position. When the number bends between outlets becomes excessive or when a large number of condu placed side by side must be deflected, pull boxes are installed so that the di tion of the conduit may be changed and the wires may be drawn in more easi In fireproof buildings conduit is frequently installed just after the steel wo has been erected and is then covered up by concrete or tiling.

Insulation of Wires Used in Rigid Conduits. — Wires used in ri conduit must have an approved rubber insulation and must not be spliced tapped within the conduit. Varnished cloth insulation may be used in perm nently dry locations. In alternating-current systems the two or more wires o circuit must be drawn in the same conduit. It is suggested that this be do for direct-current systems also when there is a possibility that an alternati current system may be used at some future time. The same conduit must n contain more than four two-wire or three three-wire circuits of the same syst and circuits of different systems must be run in separate conduits.

Wires should not be drawn in until all mechanical work on the building ha been completed. For short runs wires may be pushed in at one opening unt they come out at the other opening, but on long runs or where there are many bends, a spring-steel "fish-wire" or "snake" is first pushed through the conduit and a piece of sash cord attached to the "fish-wire" is pulled through. Th

ched to the sash cord and pulled through. When the through a conduit easily, powdered soapstone is blown uce the friction of the conductors.

Wires. — In vertical runs conductors must be supported dance with the following table:

, W. G. to o,	every	100 feet
.. W. G. to oooo,	"	80 "
W. G. to 350,000 cir. mils,	"	60 "
ir. mils to 500,000 cir. mils,	"	50 "
ir. mils to 750,000 cir. mils,	"	40 "
ir. mils,	"	35 "

pported by a turn of 90 degrees in the conduit system esigned for the purpose.

above, varnished cambric insulated conductors must be r ends of vertical runs by securely attaching the copper, ion has been removed, to a strain insulator.

2073 for tables, covering number of wires in a conduit.

— In distinction to flexible tubing, a non-metallic tubing, *etallic* tubing built up of spiral, convex and concave steel : in such a manner as to form a fairly smooth surface, ually. "Flexible conduit," which is metallic, is usually lexible tubing" (*see below*), which is non-metallic tubing. esses the advantage over rigid conduit in that it can be and quickly from outlet to outlet and if necessary may be ons or floors. Its chief disadvantages are that it is neither re-proof. Flexible conduit is manufactured in the follow-

Armored Cable. — In place of flexible conduit in which wires must be drawn in after the conduit is installed, armored cable consisting of rubber-insulated conductors protected by interlocking spiral steel strips may be used. Where installed in damp places, leaded armored cable, which has a lead covering between the insulation and the steel armor, must be used. Armored cable is employed extensively in wiring old buildings where it would be impossible to install rigid conduit without cutting up the walls and floors. Armored cable for interior wiring is manufactured in the following sizes:

STANDARD ARMORED CONDUCTORS

Size of each conductor A. W. G.	Number of bunched conductors		Approximate outside diameter, inches	Weight per 100 feet, pounds	Approximate feet in coil
14	1	Steel armored	0.37	20	250
12	1		0.40	21.5	250
10	1		0.435	23	250

2*	1		0.900	120	150
1*	1		0.985	165	100

* Stranded.

All requirements as to mechanical and electrical connections to outlet boxes, grounding, splicing and tapping of wires, assembling of conductors in alternating-current systems, etc., applying to rigid conduit also pertain to armored cable. Bends in armored cable may be of smaller radius than in rigid conduit, however, the minimum allowable radius of a bend being 1.5 inches for armored cable.

Flexible Tubing. — In addition to its use in all places where it is necessary to add to the insulation of the conductors, if the difference of potential between the wires is not over 300 volts, continuous flexible tubing may be used to protect individual wires when fished for short distances in dry places. Although not allowed by some inspectors, flexible tubing is extensively used in this manner in conjunction with moulding or knob and tube work, especially in old buildings where it is necessary to fish the wires to avoid

GENERAL RULE FOR ANY NUMBER OF WIRES

size of conduit for a given combination of wires may also be estimated as : Find the total *circular inches** of area of insulated wire to be put in nduit and divide by the following factor:

1 conductor	0.56
2 conductors	0.32
3 conductors	0.42
4 conductors	0.40
Over 4 conductors	0.37

result will be the circular inches inside area of conduit required. The diameter of conduit will be the square root of this figure.

example, what size conduit is required for six No. 8 and four No. 2 wires? erall diameter of a No. 8 is 0.27 in. and of a No. 2 is 0.47 in. Their areas ular inches are $0.27 \times 0.27 = 0.073$ and $0.47 \times 0.47 = 0.22$, respectively. es 0.073 is 0.436 and four times 0.22 is 0.88. The total is $0.436 + 0.880 =$ ircular inches, which divided by 0.37 gives 3.56 circular inches. The root of this is 1.89 which is the diameter of pipe required The next rd size is 2 inches.

e area in circular inches of any circle is equal to the square of its diameter es.

COST OF WIRING. — The total cost of wiring a building is made up of three elements: materials, labor and engineering. The labor and engineering charge will depend upon local conditions, and these costs may be estimated accurately only by reference to similar costs in completed work of the same general character. In regard to labor, the local conditions must include the factor of wages paid in the vicinity and the amount of work completed in a given time by the class of labor available. In determining the engineering charge the contractor must estimate the amount for each contract which should be charged to office expense and solicitation of business.

Office Estimates. — The cost of the materials is usually determined from a supply catalogue. This may be accomplished by finding (1) the costs of the wiring materials between outlets and (2) the costs of the special devices such as outlet boxes, switches, cut-out cabinets, etc., and adding the two together.

Cost of Complete Installations. — According to 1920 prices of materials the cost of wiring various types of buildings per outlet (switches counting as outlets) is as follows:

Residences wired with armored cables	$5.50–$7.
Office buildings, hotels, lofts, factories, etc., with wires installed in rigid conduit	8.00– 9

Knob and tube and cleat wiring is not now much less in cost than conduit work on account of the high labor cost.

Field Estimates. — In order to enable its representative to make a rapid estimate of the cost of wiring a building while he is interviewing the owner or agent, the contract department of a lighting company usually provides its solicitors with a schedule of wiring costs, based (1) upon the number of lamp sockets and *switch* outlets to be provided, or (2) upon the *total* number of outlets (both lamp and switch), or (3) upon the number of lamp sockets and the number of *lamp* outlets required. Such wiring schedules are usually applicable only to finished buildings; the cost of wiring a building while it is being erected is usually much less than the cost of wiring the same building after it has been completed.

First Method. — The buildings to be wired are divided into classes and the cost of wiring a building in any class is based upon the number of lamp sockets, the number of *switch* outlets, and the type of switches and receptacles installed. The disadvantage of this method is that it does not take into account the number of lamp outlets. In two buildings in which the same number of lamp sockets are installed, the number of lamp outlets may differ widely and as a result the labor and material required for the work will differ in the two buildings although the cost of the wiring may be the same. In most instances however, this defect is not serious, because of the close relationship between the number of lamp sockets and the number of lamp outlets which are usually installed in the buildings for which the schedule is intended.

Second Method. — The various openings for switches, receptacles, drop cords and fixtures are considered as outlets and on the number of these is based the cost of work in houses of different classes of construction. An extra charge is made for hardware and for work installed under double or hardwood floors. With this method the number of lamp sockets installed in two houses for which the cost of wiring is the same may differ considerably. For schedules of cost see *Elec. World*, *1910*, *Vol. 56*, *p. 1134*.

Third Method. — The buildings to be wired are divided into classes and the cost of wiring a building in any class is based upon the number of lamp outlets and lamp sockets and the type of switches installed. This method

provement on Methods I and II as it does take into account the average ber of lamp sockets per lamp outlet, and while the cost of the wiring in two ings requiring the same labor and material may differ slightly, such differ- will not be as frequently encountered as in the other two methods. As an ple of this type of schedule see article in *Elec. World, 1912, Vol. 59, p. 548,* iptive of the method used by the Consolidated Gas, Electric Light and r Company of Baltimore, Md.

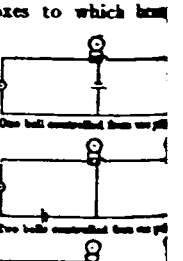
WIRING OF BUILDINGS FOR MISCELLANEOUS DEVICES

— (*See also Wiring of Buildings for Light and Power.*) In addition to the wi designed to conduct electrical energy to lamps, motors and heating devices building, wires may be installed in connection with telephone (q.v.), telegr (q.v.), district messenger and call-bell circuits, fire and burglar alarms, do opening devices, gas lighters, watchman's clocks and electric clocks. Since of these devices are operated at low voltage, it is unnecessary to use the same ca in selecting and installing the wires as in the higher voltage systems, except th in all low-voltage systems care must be exercised that the conductors shall n become crossed with light and power circuits.

Protection of Low-voltage Wiring. — When the conductors of any lo voltage system are brought into a building from the outside, an approved pr tective device must be located as near as possible to the entrance of the wi to the building. With the exception of instrument circuits of telegraph system where cut-outs only are required, protective devices must contain a lightni arrester with a ground connection and a cut-out or heat-coil (*see Telephone Instruments and Circuits*). The conductors beyond the protective device low-voltage systems need be insulated only sufficiently to prevent short-circui and the consequent interruption of service. When bunched together in vertic runs the wires must be inclosed in a fire-resisting covering to prevent the wi from carrying fire from floor to floor. Low-voltage circuits may be run in t same shaft with light and power circuits, provided the two classes of wires separated by at least two inches or one of the classes is run in a non-combusti tubing. Low-voltage wires may not be run in any case in the same tube w lighting or power wires.

Telephone Wiring. — (*See also Telephone Instruments and Circuits.*) In in large buildings, rubber-insulated twisted pairs of wire are used exten for telephone work. The twisted wires may be fished between partitions concealed in moulding and if open wiring is not objectionable, the wires carried along the finish of the room and fastened with insulating staples tacks. In new buildings the wires are frequently installed in conduit and th connections are made at connection boxes designed for the purpose. In lar buildings, when the number of telephones in use becomes very great, lead-cove insulated cable containing multiple pairs of conductors is installed in wire-wa provided for the purpose. Distributing connection boxes to which local circuits may be connected are then installed on each floor.

Bell Wiring. — In its simplest form a bell-wiring system consists of a battery (usually a Leclanché type or dry battery), a bell-push, a bell or buzzer and the connecting wire. Paraffine-impregnated double-cotton covered wires ranging in size from No. 16 to No. 22 A.W.G. gauge are usually employed, either singly or in the form of twin wires. The wires may be fished, concealed in moulding or run exposed along the finish of the room. When a large number of bell-wires must be run together through a building as in the case of a hotel annunciator system, the wires are frequently inclosed in a cotton braid or in a tube made of zinc or impregnated paper. In many buildings supplied with an alternating current source of power a small step-down transformer is used in place of the batteries, thus effecting a savi in the cost of the installation and eliminating the possibility of run-down ba



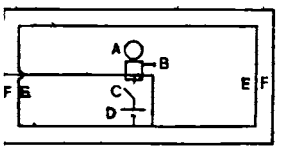


Fig. 1.

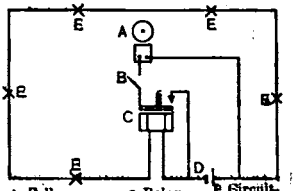

s. In Fig. 1 are shown several systems of bell wiring; these figures are explanatory.

urglar Alarms. — In place of the bell-push used in bell-wiring systems, the circuit may be closed by some circuit-closing device attached to windows, rs, etc., so that the opening of any window or door in the building will be le known by the ringing of a bell. As such a system has the objection that ill not operate if the battery is run down or if the wires are cut, a closed-circuit em is preferable, in which the opening of a window or door opens the circuit

A Bell B Constant Ringing Drop
C Day Switch D Battery

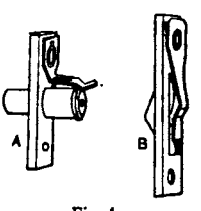
Fig. 2. Open-circuit Burglar Alarm

A Bell C Relay E Circuit-opening Springs
B Day Switch D Battery

Fig. 3. Closed-circuit Burglar Alarm

a relay in turn closes the bell circuit. In Fig. 2 is shown a typical open-uit and in Fig. 3 a typical closed-circuit system. In Fig. 4 are shown a spring *A* and a window spring *B*.

ire Alarms. — In the manually-operated system glass disks are placed at renient points throughout the building and with each disk is provided a mer, with which the disk may be broken in case ire. The breaking of the disk opens or closes an ric circuit by means of which electric gongs are throughout the building. In the automatic sys- the expansion or fusion by heat of elements in uit-closing or opening devices usually placed on ngs, causes gongs to ring throughout the building the watchman's office.



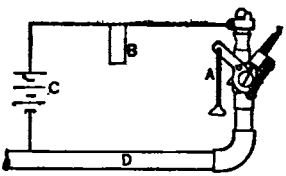


Fig. 4.

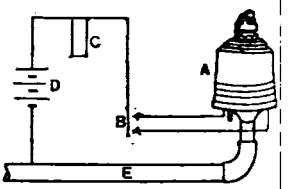
oor-opening Devices and Electric Clocks. — rs may be opened by pressing a button at some ant point and thereby closing a circuit, through ch current flows, energizing a magnet, which releases the nosing in the door ne. In the same manner, a moving disk on a master clock may periodically e a circuit, through which a magnet is energized which operates a pawl ched to the hands of another clock.

Watchman's Clock. — Circuit-closing devices are placed at different points ughout a building so that a watchman on his rounds may close the circuit means of a handle or special key. The closing of the circuit at any station es a record on a dial in the watchman's clock indicating the time at which circuit was closed at each particular station, the stations being designated numbers. To obviate the possibility of run-down batteries, magneto systems often installed, a small magneto being placed at each station.



Gas Lighters. — In the "pull-burner" and "automatic-burner" systems, en the gas is turned on, an electric circuit is made and broken by means of tacts placed at the tip of the burner. To intensify the spark at the burner, ark coil is always connected in series with the circuit. In the "pull-burner" tem (Fig. 5) the pulling of a chain or the turning of a key on the gas jet ns on the gas and at the same instant makes and breaks the circuit by contacts

placed near the burner. In this system one wire connects the battery in se with a spark coil to the contact device, the other terminal of the contact dev being grounded to the gas pipe through which connection is made to the ot terminal of the battery.

A Pull Burner C Battery
B Spark Coil D Gas Pipe

Fig. 5.

A Automatic Burner D Battery
B Two-Button Push E Gas Pipe
C Spark Coil

Fig. 6.

In the "automatic-burner" system (Fig. 6) three wires are run from a t button push to one pole of the battery and one terminal each of the two magn on the automatic burner, the other terminals of the battery and the two magn being grounded on the gas pipe. The two push buttons are usually made bl and white respectively, the white button being pushed to light the gas and t black one to extinguish it. When the white button is pushed, a circuit is cl connecting the battery, the magnet which turns on the gas, the vibrating c tactor and the spark coil in series. When the black button is pushed, a circ is closed connecting the battery and the magnet, which turns off the gas, series.

RAYS. — (*See also Generators, Static; Induction Coils.*) X-rays or Röntrays are generated when the cathode rays of a vacuum tube impinge a any solid substance. The form of X-ray tube commonly used, known as focus tube," is shown in Fig. 1. When a high unidirectional e.m.f. is imsed between the anode (*A*) the cathode (*C*), the cathode emitted from (*C*) strike upon anti-cathode (*B*) from which X-rays originate. The de and cathode are made of ninum because of its low of disintegration under ious discharge. The antiode is made of platinum to stand the intense heat of odic bombardment. The -cathode must be electrically nected to the anode to pre- the possible emanation of ode rays from its surface. The cathode is concaved spherically so that ays are focussed upon the anti-cathode, the rays falling within a spot not e than 0.08 inch in diameter. Owing to the repulsion between the particonstituting the cathode rays, the optical focus point of the cathode should just in front of the surface of the anti-cathode, so that the actual focus t will fall upon the surface of the anti-cathode. The vacuum tube, made in glass to reduce the absorption of the X-rays, is blown in spherical form ithstand the external pressure most effectively.

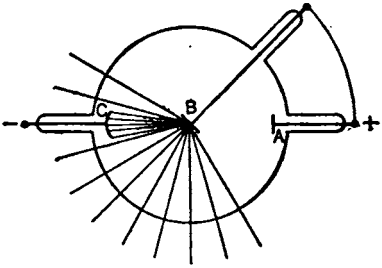

Fig. 1. X-ray Tube

haracter of X-Rays. — Numerous attempts made to prove that X-rays are adulatory form, similar to that of light, have been unsuccessful. It has been d that X-rays are neither reflected nor refracted and are not deflected like ode rays by a magnetic force. Barkla (*Phil. Trans., 1905, p. 467*) found such rays may be polarized and his conclusions have been confirmed other investigators. According to the existing information, it may only resumed that, when the negatively electrified particles constituting the ode rays strike any solid substance, they lose their charge and give rise to the emely high vibrations known as X-rays. It has been shown that such rays ot emanate from the impact spot on the anti-cathode but from a ring surding the spot, and travel in all directions from the surface of the antiode, the densest emanation being in a direction normal to the surface.

roperties of X-Rays. — All substances, many of which are opaque to nary light, transmit X-rays to a greater or less degree. In most cases the sparency of any substance to such rays is (roughly) inversely proportional s specific gravity. In the accompanying table are given the relative transncies of various substances and their specific gravities, the transparency of r being taken as unity.

hen X-rays are passed through gases, the gases become ionized and their rical conductivity is accordingly increased. This property has been used means of measuring the relative strengths of X-rays.

ertain substances fluoresce under the action of X-rays making the existence -rays visible to the eye. The fluorescent screens ordinarily used for anatomexaminations are coated with barium platino-cyanide, potassium platinoide or calcium tungstate.

-rays are to a considerable degree chemically active and photographs may nade of objects generally opaque to the eye but built up of substances of

different transparencies to the X-rays, so that the internal structure of the ject is revealed in the photograph. Such photographs made with highly sen tive plates are called radiographs or skiagraphs.

Considerable use is also made of X-rays in the electro-therapeutic treatm of certain diseases especially those of the skin.

Manipulation of the Tube. — It is important that the tube be connect in the proper polarity as a reverse current in the tube will cause it to blac The voltage used with the tube depends upon its size and the degree of vac attained. The ordinary tube requires a voltage of from 50,000 to 100,000 v or, as usually stated, a voltage which will puncture a needle gap of from 5 10 inches in air. The source of e.m.f. used with the tube is usually an in tion coil (q.v.) and in some cases a static generator (q.v.). The voltage quired to puncture a tube is materially reduced if a sheet of tinfoil electric connected to the cathode terminal is wrapped around the outside of the tube the cathode end and covering about one-third of its surface. The current tak by a tube is extremely small so that the connecting wires need only be lar enough to withstand breakage but must be heavily insulated. Under contin ous use the internal pressure of the gas in the tube decreases due to the occ sion of the gas content by the metals and glass of which the tube is constructed

Digitized by Google

the internal pressure in the tube decreases, it may become inoperative and uld then be heated in an oven to release the occluded gases and reëstablish proper pressure. Certain "regenerative" tubes contain palladium which ludes gas at ordinary temperatures and gives off gas under heat, thereby ntaining a constant pressure within the tube.

"Hard" and "Soft" Tubes; Condition of Tubes.—The penetrating er of an X-ray tube is proportional, within certain limits, to its vacuity. igh-vacuum tube, known as a "hard" tube, will emit a few rays of great pene- ing power, whereas a low vacuum tube, known as a "soft" tube will emit reater number of rays of less penetrability. In most cases better contrast btained upon the photographic plate or fluorescent screen when a "soft" e is used than when a "hard" tube is used, since the rays emitted by a rd" tube may penetrate all the constituent parts of the object examined nearly equal strength.

he condition of a tube under operation may be easily detected by observing color of the vacuous discharge. When running under normal conditions, tube will glow with a greenish-yellow light; the face of the anode will emit nary-yellow light, but in the space behind the anode, a violet glow will ap- . The question of correct polarity may then be checked by this appearance he anode. A pinkish light within the tube indicates that the vacuum is low, and the absence of any glow indicates too high a vacuum. A needle connected in parallel with the tube will show when the voltage is too high protects the tube from excessive voltages.

e Coolidge Tube.—In the ordinary X-ray tube, shown in Fig. 1, the ation from the cathode is due to the bombardment of the cathode by ive ions. The stability of tion of the tube is there- dependent upon the main- ce of a constant gas press- within the tube. In the dge tube (Fig. 2), use is : of the principle of emis- of electrons from hot s, the cathode being con- ted of an electrically d spiral of tungsten (*c*) unded by a focussing sur- (*S*) of tungsten or some other refractory material. The anti-cathode or t (*A*), which also serves as anode, consists of a piece of wrought tungsten. ressure within the tube is made as low as possible, usually not more than hundredths of a micron. The tungsten spiral is heated by current sup- from a storage battery, while the terminals of the tube are connected to -potential source of direct or alternating current. The operating tem- ure of the tube is lower with direct than with alternating current.

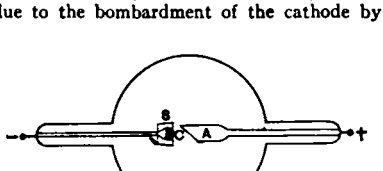

Fig. 2.

principal advantages of the Coolidge tube over the ordinary Röntgen ure (1) the use of either direct or alternating current, (2) the independent ol of the penetrating power and intensity of the X-rays by adjusting the ssed voltage or the temperature of the cathode, (3) the continuous stable tion of the tube under any adjustment for several hours, (4) the reduction perature and absence of the fluorescence of the glass and (5) the produc- f intense X-rays of any desired penetrating power.

TANDARDS OF THE A. I. E. E.

ted that permission to publish the Institute Standards be accorded to Messrs. raw-Hill Book Company and John Wiley & Sons, in their respective publications, ded that suitable explanatory notes be included substantially as follows:

"The Standards of the American Institute of Electrical Engineers, 1922 edition (issued in September, 1922), are reprinted with the permission of the Institute for the general information of patrons of the Handbook, but are not guaranteed to be the latest or correct edition of the standards themselves. In all cases where it is desired to consult or quote the standards for authoritative purposes, an official copy should be procured from the Institute. Apply to Secretary, American Institute of Electrical Engineers, 33 West 39th Street, New York City."

APPENDIX

STANDARDS OF THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

CHAPTER I

GENERAL PRINCIPLES UPON WHICH THE A. I. E. E. STANDARDS ARE BASED

temperatures in this and the following chapters are given in centigrade degrees.)

HEATING

30. General Principles.— The General Principles by reference to which atings of electrical machines are fixed, so far as their heating is concerned, it that the life of insulating materials depends upon the temperatures to h these materials are subjected. Taking, as a basis, the results of experi- with machinery in practical service and the results of laboratory tests of us insulating materials, limiting "hottest-spot" temperatures have been blished for various classes of insulation *for purposes of standardization.* ting "observable" temperatures are deduced from these limiting "hottest- " temperatures by subtracting therefrom a specified number of degrees h, *for purposes of standardization* represents the margin fixed between the ing hottest spot and the limiting observable temperatures.
is margin may be designated as the "*conventional allowance.*"

31. Methods of Temperature Measurement. — There are three funda- al methods of temperature measurement, namely:

1. The Thermometer Method.
2. The Resistance Method, and,
3. The Embedded-Detector Method.

Digitized by Google

The General Principles stated in Section 1000 permit of the use of whichever method is best suited to the class of machine, or part thereof, to be tested, by introducing appropriate values for the limiting observable temperature by each method. All the values of the observable temperatures are based upon the "hottest-spot" limitation adopted *for purposes of standardization* for the class of insulation employed.

1002. Methods of Temperature Measurement Defined. — These three fundamental methods of making temperature measurements are designated Methods 1, 2 and 3, and are defined as follows:

TABLE 109

Methods of Temperature Measurement

Method	Description of Method
1.	Thermometer Method This method consists in the measurement of the temperature, by mercury or alcohol thermometers, by resistance thermometers, or by thermocouples, any of these instruments being applied to the hottest accessible part of the completed machine. This method does not include the use of thermocouples or resistance coils embedded in the machine as described under Method No. 3.
2.	Resistance Method This method consists in the measurement of the temperature of windings by their increase in resistance. In the application of this method, *thermometer measurements shall also be made wherever practicable without disassembling the machine,** in order to increase the probability of obtaining the highest observable temperature. The measurement indicating the higher temperature shall be taken as the "observable" temperature.
3.	Embedded Temperature-Detector Method This method consists in the measurement of the temperature by thermocouple or resistance temperature detectors, located as nearly as possible at the estimated hottest spot. When Method No. 3 is used, it shall, when required, be checked by Method No. 2. The highest observable temperature obtained from the readings of the embedded detectors shall not exceed the values permitted by the Rules for Method 3, and the highest observable temperature obtained by Method 2 shall not exceed the values permitted by the Rules for Method 2.

* Note. As one of the few instances in which the thermometer check cannot be applied in Method II, the rotor of a turbo alternator may be cited.

1003. Conventional Allowances for the Three Methods of Temperature Measurement. — The specified differences by which the "observable" temperatures shall, *for purposes of standardization*, be assumed to be lower than the "hottest spot" temperatures, (which may be designated the "Conventional Allowances"), are as follows:

Method 1..... 15° C.
" 2..... 10° C.
" 3..... (See following table)

Digitized by Google

TABLE 101

Conventional Allowance for Method 8

Method 8	
windings with two coil-sides per slot ith detectors between top and bottom il-sides (and between coil-sides and ore).	5° C.
windings with one coil-side per slot for 000 volts or less, with detectors between il-side and core and between coil-side nd wedge.	10° C.
windings with one coil-side per slot for ore than 5000 volts, with detectors be- ween coil-side and core and between coil- de and wedge.	10° C. plus 1° C. for every kv. of terminal pressure of the machine above 5 kv.

M. **Classification of Insulating Materials.** — The insulations employed i rical Machinery are subdivided into four main classes, designated O, A, C and defined as follows:

TABLE 102

Classification of Insulating Materials

ss	Description of Material
	Cotton, silk, paper and similar materials when neither impregnated nor immersed in oil.
	Cotton, silk, paper and similar materials when so treated or impregnated as to increase the thermal limit, or when permanently immersed in oil; also enamelled wire.
	Mica, asbestos and other materials capable of resisting high temperatures, in which any Class A material or binder is used for structural purposes only, and may be destroyed without impairing the insulation or mechanical qualities of the insulation. (The word "impair" is used in the sense of causing any change which could disqualify the insulation for continuous service.)
	Materials capable of resisting higher temperatures than Class B, such as pure mica, porcelain, quartz, etc.

105.* **Limiting "Hottest Spot" Temperatures.** — The limiting "hotte " temperatures are, *for purposes of standardization*, taken at the followi s:

For Class O material.....	90° C.
For Class A material.....	105° C.
For Class B material.....	125° C. (See Note)
For Class C material.....	no limit yet specified

105) The Institute recognises the ability of manufacturers to employ Class ation successfully at maximum temperatures of 150° C. or even higher. Howev fficient data covering experience over a period of years at such temperatures esent unavailable, the Institute adopts 125° C. as a conservative limit for this cl sulation, and any increase above this figure should be the subject of special guaran e manufacturer.

Digitized by Google

If different insulating materials are used on various parts of one winding (for instance in the slot and for the end windings) the temperature of each material shall not exceed the limit set for that material.

When insulation consists of layers of materials having different temperature limits (for instance high-temperature limit material adjacent to the copper and lower-temperature limit material adjacent to the iron or to the air) the temperature of each material shall not exceed the limit set for that material.

1006. Limiting Observable Temperatures. — The limiting observable temperatures for use with Methods 1, 2 and 3, are arrived at by subtracting the "conventional allowances" from the limiting "hottest-spot" temperatures for insulating materials. They are set forth as follows:

TABLE 103

Limiting Observable Temperatures

		Class O Material	Class A Material	Class B Material
Method 1		75° C.	90° C.	110° C.
Method 2		80° C.	95° C.	115° C.
Method 3	For windings with two coil-sides per slot with detectors between top and bottom coil-sides and between coil-sides and core.	85° C.	100° C.	120° C.
	For windings with one coil-side per slot with detectors between coil-side and core and between coil-side and wedge.	80° C. (minus 1 degree for every 1000 volts of terminal pressure of the machine above 5000 volts.)	95° C. (minus 1 degree for every 1000 volts of terminal pressure of the machine above 5000 volts).	115° C. (minus 1 degree for every 1000 volts of terminal pressure of the machine above 5000 volts).

* See also Note, Section 1005.

1007. Limiting Observable Temperature of Oil. — The oil in which apparatus is permanently immersed shall, in no part, have a temperature, observable by thermometer, in excess of 90° C.

1008. Standard Ambient Temperatures of Reference. — The following values are adopted for the standard ambient temperatures of reference:

For Air..... 40° C.
For Water..... 25° C.

These values for the standard ambient temperatures of reference apply to conditions where the actual ambient temperature does not exceed them.

1009. Limiting Observable Temperature Rises. — The limiting observable temperature rises in the following Table 104 are obtained by subtracting the standard ambient temperatures of reference given in § 1008 from the limiting observable temperatures given in Table 103. The limiting observable temperature rises to be used in practice are given later in the Rules. They are in some cases greater and in other cases smaller than those given in Table 104. See § 1010.

For the purpose of rating, the limiting observable temperature rise must not be increased even when the ambient temperature is lower than the standard ambient temperature of reference.

:thod 3	For windings with two coil-sides per slot, with detectors between top and bottom coil-sides and between coil-sides and core.	45° C.	60° C.	80° C.
	For windings with one coil-side per slot with detectors between coil-side and core and between coil-side and wedge.	40° C. (minus 1 degree for every 1000 volts of terminal pressure of the machine above 5000 volts.)	55° C. (minus 1 degree for every 1000 volts of terminal pressure of the machine above 5000 volts).	75° C. (minus 1 degree for every 1000 volts of terminal pressure of the machine above 5000 volts).

ee also Note, Section 1005.

10. General Comments on Special and Specific Cases. — In the foregoing s been assumed for the purpose of presenting a comprehensive, logical and istent plan, that the Rules actually used in the industry are exactly in accord the General Principles. Practical experience indicates the necessity of blishing definite Rules to cover Special as well as Specific Cases. These s are set forth in later chapters. Any case not specifically dealt with may e under the General Principles.

11. Comments on the Method of Measurement to be Employed. — In the nce of definite Rules, the manufacturer may, on the occasion of the acceptt test, use any of the three methods for the temperature measurements. In cases, however, restrictions on the choice of method are imposed. These et forth in the Rules.

12. Comments on Temperature Limits in Special Cases. — Temperature s are prescribed in the Rules for special cases where conditions determined by tice, by experience, or by agreements, require departures (often arbitrary) the limits of temperature rise corresponding to the General Principles.

13. Hottest Spot Temperature the Primary Point of Reference. — The est spot temperature is the primary point of reference, or the "benchk" used as the basis for the foregoing scheme or temperature delimitation, not employed in commercial transactions or in the ordinary course of testing peration of electrical machinery.

14. Observable Temperature Rise the Working Standard. — The observtemperature rise is the working standard. A summary of working data explanatory notes, will be found in Table 200.

15. Duration of Temperature Test and Correction to Time of Shut Down. — ttever method of temperature measurement be employed, it is required that

(a) operation shall be continued until constant temperatures are determined if the machine has a continuous rating, or for the full period if the machine has a short time rating, and

(b) when measurements cannot be made while the machine is loaded, appropriate corrections to raise the temperature readings to the time of shut down shall be applied. See Chapter II.

Digitized by Google

MECHANICAL AND COMMUTATION LIMITATIONS

These limitations are set forth in subsequent Chapters dealing with spec kinds of machines.

WAVE SHAPE

1300. The sine wave shall be considered as standard except where the ture therefrom is inherent in the operation of the system of which the mac forms a part.

DIELECTRIC STRENGTH AND INSULATION RESISTANCE

(See §§ 2350 to 2380 incl.)

1300. The injury produced by dielectric stress applied to insulation is rela to the time during which the stress is applied. A stress up to a certain lim may be applied for an indefinite period without injury to the insulation somewhat greater stress will cause heating of the insulation and a progress deterioration, eventually resulting in breakdown. Higher values of str cause more rapid deterioration and a quicker breakdown. It is customary determine whether machinery will withstand the voltage stresses met in prac by a preliminary test for a definite period of time at a voltage considera higher than the normal voltage to which the machinery is to be subjected not high enough to produce injury to the insulation during the period of test

1301. The test voltage which shall be applied to determine the suitabili insulation for commercial operation is dependent upon the kind and size of machine, and its operating voltage, upon the nature of the service in which to be used, and upon the severity of the mechanical and electrical stresses which it may be subjected. The voltages and other conditions of test which recommended have been determined as reasonable and proper for the ex majority of cases, and are proposed for general adoption, except when spec reasons make a modification desirable.

1400. The insulation resistance of machinery is of doubtful significance compared with the dielectric strength. It is subject to wide variation w temperature, humidity and cleanliness of the parts. When the insula resistance falls below prescribed values it can, in most cases of good design where no defect exists, be brought up to the required standard by cleaning drying the machine. The insulation resistance therefore may afford a use indication as to whether the machine is in suitable condition for applicatio the dielectric test.

EFFICIENCY

(See §§ 2331 to 2333 incl.)

1500. The conditions under which efficiency is determined are those rel to the operation of the machine. These include voltage, current, power fact frequency, wave shape, speed, temperature, or such of them as may apply in ea particular case.

1501. The efficiency at all loads of all apparatus shall be corrected to a ref ence temperature of 75° C.

1502. In the case of machinery, two efficiencies are recognized, conventio efficiency (§ 3524) and directly measured efficiency. Unless otherwise specifi the conventional efficiency is to be employed. When the efficiency of a machi is stated without specific reference to the load conditions, rated load is always be understood, whether the efficiency be the conventional or directly measur efficiency.

RATING

(See §§ 2202 to 2232 incl.)

1600. Principle of Machine Rating. — (a) *Rating by Temperature Rise:* Th principle upon which machine rating is based, so far as relates to thermal cha acteristics, has been stated in earlier sections.

(b) *Rating by Limitations Other than Temperature Rise:* In some machine the rating is limited by other than thermal considerations. In such cases, th principle upon which machine rating is based is that the rated load applied co tinuously or for a stated period, shall not cause the various limitations specifie

later chapters; *e.g.*, §§ 4250–4252 inclusive, to be exceeded. The rating ll be based upon the capacity as limited by heating unless the capacity as ited by other characteristics, is less.

CHAPTER II

GENERAL RULES

he expressions "machinery" and "machines" are here employed in a eral sense, in order to obviate the constant repetition of the words "machin- or induction apparatus."

o ensure satisfactory results, electrical machinery should be specified to con- to the Institute Standards, in order that it shall comply in operation, with roved limitations in the following respects, so far as they are applicable.

Operating temperature	Efficiency
Mechanical strength	Power factor
Commutation	Wave shape
Dielectric strength	Regulation
Insulation resistance	

OPERATION

Temperature Limits

84. Permissible Temperatures with Insulations of More than One Class. (1) If different insulating materials are used on various parts of one winding instance in the slot and for the end windings) the temperature of each rial shall not exceed the limit set for that material.

(2) When insulation consists of layers of materials having different tempera- limits (for instance high-temperature limit material adjacent to the copper lower-temperature-limit material adjacent to the iron or to the air) the erature of each material shall not exceed the limit set for that material.

85. Temperatures of Metallic Parts of Machines. — (a) *Parts Adjacent to lating Material:* Metallic parts of machines in contact with or adjacent to kind of insulation, shall not attain a temperature in excess of that allowed e adjacent insulation.

Parts not Adjacent to Insulating Material: All parts of machines other those covered by § 2116 (a) may be operated at such temperatures as shall e injurious in any other respect.

90. Protection against Short Circuit. — The Institute recognizes the self- ctibility, both mechanical and thermal, of certain sizes and types of ines, when subjected to severe short-circuits, and recommends that ample ction be provided in such cases, external to the machine if necessary.

RATING

General

92. Expression of Rating. — Except where otherwise specified the machines be rated in terms of their available *output*. For exceptions see §§ 4223, 6204 and 6223.

94. Institute Rating. — The Institute Rating of a machine shall be its when operating with a cooling medium of the ambient temperature of nce specified in §§ 2211 and 2212 and with barometric conditions within nge given in § 2215. See §§ 2300, 2310, 2311, 4110 and 4300.

Ambient Temperature of Reference and Altitude Correction

91. Ambient Temperature of Reference for Air. — The standard ambient rature of reference, when the cooling medium is air, shall be 40° C.

93. Ambient Temperature of Reference for Water-Cooled Machinery. — ater-cooled machinery, the standard temperature of reference for incom-

2213. Machines Cooled by Other Means. — Machines cooled by means other than air or water shall receive special consideration.

2214. Outdoor Machinery Exposed to Sun's Rays. — Outdoor machinery not protected from the sun's rays at times of heavy load, shall receive special consideration.

2215. Altitude. — Increased altitude has the effect of increasing the temperature rise of some types of machinery. In the absence of information in regard to the height above sea level at which a machine is intended to work in ordinary service, this height is assumed not to exceed 1000 meters (3300 feet). For machinery operating at an altitude of 1000 meters or less, a test at any altitude less than 1000 meters is satisfactory, and no correction shall be applied to the observed temperatures. Machines intended for operation at higher altitudes shall be regarded as special. It is recommended that when a machine is intended for service at altitudes above 1000 meters (3300 feet) the permissible temperature rise at sea level, shall be reduced by 1 per cent for each 100 meters (330 feet) by which the altitude exceeds 1000 meters.

Kinds of Rating

There are various kinds of rating such as:

2220. Continuous Rating. — A machine rated for continuous service shall be able to operate continuously at its rated output, without exceeding any of the limitations established herein.

In the absence of any specification as to the kind of rating, the continuous rating shall be understood.

2221. Short-Time Rating. — A machine rated for discontinuous or short-time service (*i.e.*, service including runs alternating with stops of sufficient duration to ensure substantial cooling), shall be capable of operating at its rated output during a limited period, to be specified in each case, without exceeding any of the limitations established herein. Such a rating is a short-time rating.

2222. Duty-Cycle Operation. — Many machines are operated on a cycle duty which repeats itself with more or less regularity. For purposes of rating either a continuous or a short-time equivalent load may be selected, which shall simulate as nearly as possible the thermal conditions of the actual duty-cycle.

2223*. Standard Short-Time Ratings. — The following periods shall be used for short-time ratings: 5, 10, 15, 30, 60 and 120 minutes.

2224. A. I. E. E. and I. E. C. Ratings. — When the prescribed conditions of test are those of the A. I. E. E. Standards the rating of the machine is the Institute Rating. (See § 2401.) When the prescribed conditions of the test are those of the I. E. C. Rules, the rating of the machine is the I. E. C. rating. A machine so rated in either case may bear a distinctive sign upon its rating plate. I. E. C. stands for "International Electrotechnical Commission."

2225. Continuous Rating Implied. — Machines marked "A. I. E. E. Rating" or "I. E. C. Rating" shall be understood to have a continuous rating, unless otherwise marked in accordance with §§ 2223, 5201 or 5202.

Rating by Temperature Rise

2230. Limiting Observable Temperature Rises. — The following limiting observable temperature rises have been adopted.

(2223) When, for example, a short-time rating of 10 minutes duration is adopted for the thermally equivalent load is 25 kw. for that period, then such a machine shall be said to have a 10-minute rating of 25 kw.

In every case the equivalent short-time test shall commence only when the windings and other parts of the machine are within 5° C. of the ambient temperature at the time of starting the test.

Digitized by Google

TABLE 200

ing Observable Temperature Rises for Machines for Operation in Locations where the Ambient Temperature will not Exceed 40° C. for Air or 25° C. for Water.

Class A insulation use the values in the table.
Class O insulation use 15° C. lower values.
Class B insulation use 20° C. higher values (or 45° C. higher in the cases ed by the Note in § 1005).
Class C insulation no limits yet specified.

Items	Method 1	Method 2	Method 3	
			For windings with two coil-sides per slot with detectors between top and bottom coil-sides and between coil sides and core	For windings with one coil-side per slot with detectors against core and against wedge
1. Insulated windings other than 2.3 Note 1	50° C. Note 1	55° C. Note 1	60° C. Note 1	55° C. minus 1° for every 1000 volts by which the terminal pressure of the machine exceeds 5000 volts. Note 1
2. Single layer field windings with exposed surfaces uninsulated	60° C.	60° C.		
3. Short-circuited insulated windings	60° C.			
4. Field Windings (other than 5)		55° C.		
5. Single layer field windings with exposed surfaces uninsulated	60° C.	60° C.		
6. Windings in slots	50° C.	55° C.		
7. Short-circuited insulated windings	60° C.			
8. Transformers and Induction Regulators		55° C.		

1 — (a) The temperature of the windings of transformers and induction regulators is to be ascertained by Method 2.

off immediately at the end of the temperature run and air intake shall be closed to prev
further admission of cooling air. In checking the temperatures ascertained by resista
the readings of thermometers well distributed and in good contact with the coils shall
noted and the maximum temperature indicated by them, if higher than that determ
by resistance, shall be taken as the maximum observable temperature of the windi
With the above procedure, the observable temperature rise for air-blast transformers m
attain a value not in excess of 60° C. as determined by thermometer, although it ma
not exceed 55° C. as determined by resistance.

(c) Method 3 shall be applied to all stators of machines with cores having a width M
and over; it shall also be applied to all machines of 5000 volts and over M of over 500 k
regardless of core width.

(d) Method 2 shall not be used for circuits of low resistance (other than transfor
windings), such as interpole windings, where external joints and connections form a c
siderable part of the total resistance.

(e) For all other cases it is optional to employ either Method 1 or Method 2. Th
equivalent to authorizing Method 1 with a 5° C. lower limit of observable temperat
than is permitted for Method 2).

Note 2. — For enclosed machines (rotating) the limiting observable temperature
shall be taken as 5 degrees higher than the values set forth in the Table for Items 1 an

Note 3. — A further limitation to this Table relates to the restriction of its appli
to machinery for operation in locations whose altitude is not more than 1000 meters
sea level. Recommendations relating to the limiting temperature rise for machine
operation at higher altitudes are given in §§ 2215 and 2231.

Note 4. — If different insulating materials are used on various parts of one wi
(for instance in the slot and for the end windings) the temperature of each material
not exceed the limit set for that material.

When insulation consists of layers of materials having different temperature-limits
instance high-temperature-limit material adjacent to the copper and lower-temperat
limit material adjacent to the iron or the air) the temperature of each material sha
exceed the limit set for that material.

2231. Exceptions to Table 200. — (a) When the thermometers are app
directly to the surfaces of bare windings, such as an edgewise strip conduc
a cast copper winding, the limiting observable temperature rise shall be 10
higher than given for Method 1 in the table.

(b) For commutators, collector rings, or bare metallic surfaces not
part of a winding, the limiting observable temperature rise shall be 15° C. hig
than given for Method 1 in the table.

(c) Any machinery destined for use with higher ambient temperatures
cooling mediums, and also any machinery for operation at altitudes for w
no provision is made in § 2215, should be the subject of special guarantee be
manufacturer. The methods of test and performance set forth in these Ru
will, however, afford guidance in such cases.

2232. Limiting Observable Temperature of Oil. — The oil in which appara
is permanently immersed shall in no part have a temperature, observable
thermometer, in excess of 90° C.

TESTS

Ambient Temperature

**2300.* Measurement of the Ambient Temperature During Tests of Mach
ery.** — (a) *General:* The ambient temperature is to be measured by mean
several thermometers placed at different points around and half-way up
machine at a distance of 1 to 2 meters (3 to 6 feet), and protected from dra
and abnormal heat radiation, preferably as in § 2301.

(b) *Mean Temperature:* The value to be adopted for the ambient tempe
ture during a test, is the mean of the readings of the thermometers (placed
above), taken at equal intervals of time during the last quarter of the durati
of the test.

(c) *Use of Idle Units:* It is sometimes desirable to avoid errors due to th
lag in temperature changes, by employing an idle unit of the same size and st

(2300) The cooling fluid may either be led to the machine through ducts, or the a
pipes, or merely surround the machine freely. In the former case the ambient tempe
ture is to be measured at the intake of the machine itself.

ted to the same conditions of cooling as the unit under test, for obtaining the bient temperature.

1309. Oil Cup. — In order to avoid errors due to the time lag between the nperature of large machines and the variations in the ambient air, all reasonle precautions must be taken to reduce these variations and the errors arising erefrom. Thus, the thermometer for determining the ambient temperature all be immersed in a suitable liquid, such as oil, in a suitably heavy metal cup. is can be made to respond to various rates of change, by proportioning the ount of oil to the metal in the containing cup. A convenient form for such oil cup consists of a massive metal cylinder, with a hole drilled partly through This hole is filled with oil and the thermometer is placed therein with its lb well immersed. The larger the machine under test, the larger should be the tal cylinder employed as an oil cup in the determination of the ambient temperature. The smallest size of oil cup employed in any case shall consist of a tal cylinder 25 mm. in diameter and 50 mm. high (1 in. in diameter and 2 in. gh).

Machine Temperatures

1310. Temperature Rise for Any Ambient Temperature. — A machine may tested at any convenient ambient temperature, preferably not below 10° C., t whatever be the value of this ambient temperature, the permissible rises of nperature must not exceed those given in Table 200.

1311. Correction for the Deviation of the Ambient Temperature of the Cooling Medium, at the Time of the Heat Test, from the Standard Ambient Temperature of Reference. — Numerous experiments have shown that deviation of temperature of the cooling medium from that of the standard of reference, the time of the heat run, has a negligible effect upon the temperature rise of chines; therefore, no correction shall be applied for this deviation.

1312. Duration of Temperature Test of Machine for Continuous Service. — e temperature test shall be continued until sufficient evidence is available to w that the maximum temperature and temperature rise would not exceed requirements of the rules, should the test be prolonged until the attainment a steady final temperature.

1313. Duration of Temperature Test of Machine with a Short-Time Rating. The duration of the temperature test of a machine with a short-time rating ll be the time required by the rating. In every case the equivalent short- e test shall commence only when the windings and other parts of the machine within 5° C. of the ambient temperature at the time of starting the test. § 2235.

1314. Duration of Temperature Test for Machine Having More than One ting. — The duration of the temperature test for a machine with more than rating shall be the time required by that rating which produces the greatest nperature rise. In cases where this cannot be determined beforehand, the chine shall be tested separately under each rating.

1315. Temperature Measurements During Heat Run. — When possible, nperature measurements shall be taken during operation, as well as when the chine is stopped. The highest figures thus obtained shall be adopted. In ler to abridge the long heating period, in the case of large machines, reason- e overloads of current during the preliminary period are suggested for m.

1316. Rules for Correcting to Time of Shut-Down. — (a) Whenever a sufficnt time has elapsed between the instant of shut-down and the time of the al temperature measurement to permit the temperature to fall, suitable corctions shall be applied, so as to obtain as nearly as practicable the temperae at the instant of shut-down. This can sometimes be approximately effected plotting a curve with temperature readings as ordinates and time as abscissas, d extrapolating back to the instant of shut-down. In other instances, accept- e correction factors can be applied; *e.g.*, in the case of machines manu-

factured in large quantities, the correction obtained from tests made on representative machines may be used.

(b) Exception. In cases where successive measurements show increasing temperatures after shut-down, the highest value shall be taken.

Details of Testing Methods

2320. Covering of Thermometer. — Thermometers used for taking temperatures of machinery shall be covered by felt pads 4 cm. × 5 cm. (1½ in. × 2 in.) 3 mm. (⅛ in.) thick cemented on; oil putty may be used for stationary and small apparatus.

2321.* Temperature Coefficient of Copper. —The temperature coefficient of copper shall be deduced from the formula $1/(234.5+\theta)$. Thus, at an initial temperature $\theta = 40°$ C., the temperature coefficient of increase in resistance per degree centigrade rise is $1/(274.5 = 0.00364)$. The following table, deduced from the formula, is given for convenience of reference.

TABLE 201

Temperature Coefficients of Copper Resistance

Temperature of the winding, in degrees C. at which the initial resistance is measured	Increase in resistance of copper per °C., per ohm of initial resistance
0	0.00427

10	0.00409
15	0.00401
20	0.00393
25	0.00385
30	0.00378
35	0.00371
40	0.00364

2322. Temperature Measurement of Low Resistance Circuit. — In circuits of low resistance, where joints and connections form a considerable part of the total resistance, the measurement of temperature by the resistance method shall not be used. (Except transformers, for which see § 6320.)

2323.* Location of Embedded Temperature Detectors. — Embedded temperature detectors should be placed in at least two sets of locations. One of these should be between a coil-side and the core and one between the top and bottom coil-sides where two coil-sides per slot are used. Where only one coil-side per slot is used, one set of detectors shall be placed between coil-side and core, and one set between coil-side and wedge. A liberal number of detectors shall be employed, and all reasonable efforts, consistent with safety, shall be made to locate them at the various places where the highest temperatures are likely to occur. See § 1002.

(2321) Temperature by Resistance: The temperature by resistance may be calculated by the following formula:

Let R_θ = resistance at $\theta°$ C., R_{θ_2} = resistance at $\theta_2°$ C. Then

$$\theta_2 = \frac{R_{\theta_2}}{R_\theta}(234.5+\theta) - 234.5.$$

(2323) A coil side is one of the two active sides of the coil lying in a slot.

Efficiency

31.* Efficiencies Recognized. — Two efficiencies are recognized, conven-
al efficiency and directly measured efficiency. Unless otherwise specified,
conventional efficiency is to be employed. See §§ 3514 and 3524.
put and output determinations of efficiency may be made directly, measur-
he output by brake, or equivalent, where applicable. Within the limits of
tical application, the circulating power method, sometimes described as the
kinson or " loading-back " method, may be used.

32.* Normal Conditions for Efficiency Tests. — (a) *General:* The efficiency
correspond to, or be corrected to, the normal conditions herein set forth,
h shall be regarded as standard. These conditions include voltage, current,
er-factor, frequency, wave-shape, speed, temperature, or such of them as
apply in each particular case.
) *Load:* When the efficiency of a machine is stated without specific refer-
to the load conditions, rated load is always to be understood whether the
ency be the conventional or directly measured efficiency.
) *Wave Shape:* The sine wave shall be standard, unless a different wave
is inherent in the operation of the system. See § 2350.
d) *Temperature of Reference:* The efficiency of all apparatus at all loads
be corrected to a reference temperature of 75° C., but tests may be made
ny convenient ambient temperature, preferably not less than 15° C.
) *Power Factor:* The efficiency of alternators and transformers shall be
d at the rated power factor.

33. Direct Measurement of Efficiency. — (a) *General:* Electric power shall
easured at the terminals of the apparatus.
) *Polyphase Machines:* In polyphase machines, sufficient measurements
be made on all phases to avoid errors of unbalance.
) *Mechanical Power:* Mechanical power delivered by machines shall be
sured at the pulley, gearing or coupling, on the rotor shaft, thus excluding
loss of power in the belt or gear friction. See, however, an exception in
02.

Wave Shape

60. Standard Wave Shape. — The Sine Wave shall be considered as stand-
except where departure therefrom is inherent in the operation of the system
hich the electrical machine forms a part.

Tests of Dielectric Strength

350. Condition of Machine to be Tested. — Commercial tests shall, in
eral, be made with the completely assembled machine and not with indi-
ual parts. The machine shall be in good condition, and high-voltage tests,
ss otherwise specified, shall be applied before the machine is put into com-
cial service, and shall not be applied when the insulation resistance is low
to dirt or moisture. High-voltage tests to determine whether specifications
fulfilled are admissible on new machines only.

351. Where High-Voltage Tests are to be Made. — Unless otherwise agreed
n, high-voltage tests of machines shall be made at the factory.

352. Temperature at which High-voltage Tests are to be Made. — High-
tage tests shall be made at the temperature assumed under normal operation
it the temperature attained under the conditions of commercial testing.

2331) The need for assigning conventional values to certain losses arises from the
that some of the losses in electrical machinery are practically indeterminable, and
t, in many cases, either be approximated by an approved method of test, or else values
ommended by the Institute and designated "conventional" values shall be employed
them in arriving at the "conventional efficiency."
2332 d) In calculating plant or system efficiency it may be desirable to calculate the
es in each individual machine or part of the system at the actual temperature of that
nsformer or part during the specified interval. These losses may be appreciably
erent from the losses at 75° C., which latter shall be the standard temperature of refer-
e for all efficiency guarantees.

Digitized by Google

2358. Points of Application of Voltage. — (a) *General:* The test voltage s
be successively applied between each electric circuit and all other electric cir
and metal parts grounded.

(b) *Interconnected Polyphase Windings:* Interconnected polyphase wind
shall be considered as one circuit. All windings except that under test sha
connected to ground.

2354. Frequency and Wave Shape of Test Voltage. — The frequency of
testing voltage shall be not less than the rated frequency of the machine te
A sine wave shape is recommended (see §§2340 and 4351). The test sha
made with alternating voltage having a crest value equal to $\sqrt{2}$ times
specified test voltage.

2355. Duration of Application of Test Voltage. — (a) *General:* The te
voltage for machines shall be applied continuously for a period of 60 seco
See exception § 2355 (b).

(b) *Standard Machines and Devices produced in large quantities:* Stan
machines and devices produced in large quantities for which the standard
pressure is 2500 volts or less, may be tested for one second with a test pres
50 per cent higher than the one-minute test pressure.

2356.* Standard Test Voltage. — (a) *General:* The standard test voltage f
all machines, except as otherwise specified, shall be twice the normal voltage
the circuit to which the machine is connected plus 1000 volts. See exceptio
§§ 2357, 4361, 6361, 7323 (b).

2357. Assembled Apparatus. — Where a number of pieces of apparatus a
assembled together and tested as an electrical unit they shall be tested with
per cent lower voltage than the lowest required on any of the individual pie
of apparatus.

2358. Measurement of Voltage in Dielectric Strength Tests. — There a
two methods of measuring the voltage used in making dielectric strength tes
namely:

1. The voltmeter method.
2. The spark-gap method, using either the sphere spark-gap or the needl
spark-gap.

2359.* Use of Voltmeters and Spark-gaps in Dielectric Tests. — When mak
ing high-voltage tests on electrical machinery every precaution must be take
against the occurrence of spark-gap discharges in the circuits from which th
machine is being tested. A non-inductive resistance of about one ohm per vo
of test pressure shall be inserted in series with one terminal of the spark-gap.
the test is made with one electrode grounded, this resistance shall be inserte
directly in series with the non-grounded electrode; if neither terminal is ground
one-half shall be inserted directly in series with each electrode. In either ca
this resistance shall be as near the measuring gap as possible and not in seri
with the tested apparatus. A water tube is the most suitable form of resistor.

2360. Use of Spark-gap with Machines of Low Capacitance. — When th
machine under test does not require sufficient charging current to distort th
high-voltage wave shape, or change the ratio of transformation, the spark-gap
should be set for the required test voltage and the testing apparatus adjusted t
give a voltage at which this spark-gap just breaks down. This adjustmen
should be made with the machine under test disconnected. The machin
should then be connected, and with the spark-gap about 20 per cent longer, th
testing apparatus again adjusted to give the voltage of the former breakdown

---

(2358) All dielectric strength tests shall be based on the normal voltage of th
system, even if apparatus is applied on a part of the system which ordinarily operate
somewhat below the normal voltage.

(2359) The resistance will damp high-frequency oscillations at the time of breakdown
and limit the resulting current.

Carbon resistors should not be used because their resistance may become very low a
high voltages.

Digitized by Google

h is the assumed voltage of test. This voltage shall be maintained for the ired interval.

§1.[a] Use of Spark-gap with Machines of High Capacitance.— When the ging current of the machine under test may appreciably distort the voltage : or change the effective ratio of the testing transformer, the first adjustment ltage with the gap set for the test voltage shall be made with the machine r test connected to the circuit and in parallel with the spark-gap.

§2. Measurements with Voltmeter. — In measuring the voltage with a neter, the instrument should preferably derive its voltage from the high- sure circuit, either directly, or by means of a voltmeter coil placed in the ng transformer, or through an auxiliary *ratio transformer*. It is permissible easure the voltage at other places such as the transformer primary, pro- l corrections can be made for the variations in ratio caused by the charging nt of the machine under test, or provided there is no material variation in ratio. In any case when the capacitance of the machine to be tested is such cause wave distortion, the testing voltage must be checked by a spark-gap t forth in §§2364 and 2366 or by a crest-voltage meter. If the crest-voltage r is calibrated in crest volts, its readings must be reduced to the correspond- r.m.s. sinusoidal value by dividing by $\sqrt{2}$.

§3. Measurements with Spark-gaps. — (a) *General:* If proper precautions taken, spark-gaps may be used to advantage in checking the calibration of meters for high-voltage tests of machines.

(b) *Range of Voltages:* For the calibrating purposes set forth above, the re gap shall be used for voltages above 50 kv., and is preferred down to 30 kv. needle spark-gap may, however, be used for voltages from 10 to 50 kv.

§4. Needle Spark-gap. — The needle spark-gap shall be between new ng needles, supported axially at the ends of linear conductors, which are at : twice the length of the gap. There must be a clear space around the gap i radius at least twice the gap length.

§5. Needle-gap Sparking Distances. — The sparking distances in air be- a No. 00 double long sewing needle points for various root-mean-square soidal voltages shall be assumed to be as shown in Table 202.

TABLE 202

Needle-Gap Spark-Over Voltages

(At 25° C. and 760 mm. barometer)

R. M. S. Kilovolts	Millimeters	R. M. S. Kilovolts	Millimeters
10	11.9	35	51
15	18.4	40	62
20	25.4	45	75
25	33	50	90
30	41		

he values in Table 202 refer to a relative humidity of 80 per cent. Variations this humidity may involve appreciable variations in the sparking distance.

---

381) When making arc-over tests of large insulators, leads, etc., partial arc-over of tested apparatus may produce oscillations which will cause the measuring gap to dis- ge prematurely. The measured voltage will then appear too high. In such tests the uivalent ratio" of the testing transformer should be measured by gap to within 20 per of the arc-over voltage of the tested apparatus with the tested apparatus in circuit. measuring gap should then be greatly lengthened out and the voltage increased until tested apparatus also over. This arc-over voltage should then be determined by multi- ng the voltmeter reading by the equivalent ratio found above. Direct measurement he spark-over voltage over one gap by another gap should always be avoided.

2366.* Sphere Spark-gap. — The standard sphere spark-gap shall be betw two suitably mounted spheres. No extraneous body, or external part of circuit, shall be nearer the spheres than twice their diameter.

The shanks shall be not greater in diameter than ¼th the sphere diam Metal collars, etc., through which the shanks extend, shall be as small as pra able and shall not, during any measurement, come closer to the sphere tha maximum gap length used in the measurement.

The sphere diameter should not vary more than 0.1 per cent, and the cu ture, measured by a spherometer, should not vary more than 1 per cent fr that of a true sphere of the required diameter.

2367.* Use of Spherometer. — In using the spherometer to measure cu ture, the distance between the points of contact of the spherometer feet sha within the limits as indicated in Table 203.

TABLE 203

Spherometer Specifications

Diameter of sphere in mm.	Distance between contact points in mm.	
	Maximum	Minimum
62.5	35	25
125	45	35
250	65	45
500	100	65

2368. Sphere-gap Sparking Distances. — The sparking distance betwe spheres for various r.m.s. sinusoidal voltages shall be assumed to be as show Table 204.

2369.* Correction of Gap Spacing for Air-density. — The spacing at wh it is necessary to set a gap to spark over at some required voltage, is found a follows. Divide the required voltage by the correction factor given in Table 2 and use the new voltage thus obtained, to find the corresponding spacing fro Table 204, using a graph of the latter, if more convenient.

2370.* Correction of Voltage for Air-density. — The voltage at which a g sparks over is derived from the voltage corresponding to the spacing in Table 2 by multiplying by the correction factor.

(2366) When used as specified, the accuracy obtainable should be approximately 2 p cent.

(2367) In using sphere-gaps constructed as indicated in § 2366 and § 2367, it is assum that the apparatus will be set up for use in a space comparatively free from external dielec tric fields. Care should be taken that conducting bodies forming part of the circuit, or circuit potential, are not so located with reference to the gap that their dielectric fields a superposed on the gap, *e.g.*, the protecting resistance should not be arranged so as to pres large masses or surfaces near the gap, even at a distance of two sphere diameters.

In case the sphere is grounded, the spark point of the grounded sphere should be approx imately five diameters above the floor or ground.

(2369 and 2370) Effect of Air-density on Spark-over Voltage. The spark-o voltage, for a given gap, decreases with decreasing barometric pressure and increasi temperature. This variation may be considerable at high altitudes. When the variati from sea level is not great, the relative air density may be used as the correction facto when the variation is great, or greater accuracy is desired, the correction factor corr sponding to the relative air density should be taken from Table 204 in which

$$\text{Relative air-density} = \frac{0.392b}{273+t}$$

b = barometric pressure in mm.

t = temperature in deg. C.

Corrected curves may be plotted for any given altitude, if desired. It will be noted Table 213 that for values of relative air density above 0.9 the correction factor does n differ greatly from the relative air density.

e sphere-gap is more sensitive than the needle-gap to momentary rises of ge and the voltage required to spark over the gap should be obtained by / closing the gap under constant voltage, or by slowly raising the voltage a fixed setting of the gap. Open arcs should not be permitted in proximity : gap during its operation, as they may affect its calibration.

1.10	1.090	1.092	1.094	1.096

Insulation Resistance

2380. General. — The insulation resistance test shall be made with all circuits of equal voltage above ground connected together. Circuits or groups of circuits of different voltage above ground shall be tested separately.

2381. Voltage for Insulation Resistance Test. — Insulation resistance tests shall, if possible, be made at a d-c. pressure of 500 volts. Since the insulation resistance varies with the pressure, it is necessary that, if a pressure other than 500 volts is to be employed in any case, this other pressure shall be clearly specified.

2382.* Minimum Values. — The insulation resistance of a machine at its operating temperature shall be not less than that given by the following formula:

$$\text{Insulation Resistance in megohms} = \frac{\text{voltage at terminals}}{\text{rating in kv-a.} + 1000}.$$

The formula applies only to dry apparatus. Such high values are not attainable in oil-immersed apparatus.

Regulation

2390. Conditions for Tests of Regulation. — (a) *Speed and Frequency:* The regulation of generators shall be determined at constant speed, and that of alternating-current machines at constant frequency.

(b) *Wave Form:* A sine wave of voltage shall be assumed in determining the regulation of alternating-current machinery receiving electric power, except where expressly specified otherwise. See § 2340.

(2382) The order of magnitude obtained by this rule is shown in the following table:

TABLE 206

Insulation Resistance of Machines Excluding Oil-immersed Apparatus

Rated voltage of machine	Megohms		
	100 kv-a	1000 kv-a.	10,000 kv-a.
100	0.091	0.05	
1,000	0.91	0.50	0.091
10,000	9.1	5.0	0.91
100,000	.....	50	9.1

Digitized by Google

) *Temperature:* It is desirable that all parts of the machine affecting the lation be maintained at constant temperature between the two loads and re the influence of temperature is of consequence, a reference temperature of C. shall be considered as standard. If change of temperature should occur ng the tests the results shall be corrected to the reference temperature of C.

CONSTRUCTION

Rating Plates

01. Marking of Rating Plate. — (a) *Distinctive Marking:* It is recomded that the rating plate of machines which comply with the Institute s shall carry a distinctive special sign, such as "A.I.E.E. 1922 Rating" or " Rating.

) *Significance of Marking:* The absence of any statement to the contrary he rating plate of a machine implies that it is intended for continuous service for the standard altitude and ambient temperature. See §§ 2211, 2212, , and 2220.

) *Marking for Various Ratings:* The rating plate of a machine intended to r under various kinds of rating must carry the necessary information in rd to those kinds of ratings.

CHAPTER III

GENERAL DEFINITIONS

i this chapter are given definitions which are of general application to electric its, machines and systems. Definitions pertaining to a specific class of ratus are given in the chapter on the class of apparatus in question. The itions here given are primarily descriptive rather than scientifically precise. he definitions given below for currents are also applicable, in most cases, to romotive forces, potential differences, magnetic fluxes, etc.

DEFINITIONS

General

00. Ambient Temperature. — The ambient temperature is the tempera- of the air or water which comes into contact with the heated parts of a hine and carries off its heat. See §§ 2300 and 2301.

10. Electrical Tension.—Electrical tension is electromotive force, or differ- of potential.

11. Voltage.—Voltage is electrical tension expressed in volts.

20. Resistivity. — The resistivity of a material is the resistance expressed hms between two opposite faces of a centimeter cube of the material, and is ally coupled with a statement of the temperature. See § 9050.

Apparatus

64. Resistor. — A resistor is a device used primarily because it possesses property of electrical resistance. Resistors are used in electric circuits for poses of operation, protection, or control. See § 7017.

76. Inductor. — An inductor is a device used primarily because it possesses property of inductance.

78. Reactor. — A reactor is a device used primarily because it possesses property of reactance. Reactors are used in electric circuits for purposes peration, protection or control. See § 7018.

Kinds of Currents

04. Direct Current. — A direct current is a unidirectional current. As inarily used, the term designates a practically non-pulsating current.

08. Pulsating Current. — A pulsating current is a current which has regu- y recurring variations in magnitude. As ordinarily employed the term rs to a unidirectional current.

12. Continuous Current. — A continuous current is a practically non-

3116. Alternating Current. — An alternating current is a current the direction of which reverses at regularly recurring intervals. Unless distinctly otherwise specified, the term *alternating current* refers to a periodically varying current with successive half waves of the same shape and area. See § 3212.

3120. Oscillating, or Free Alternating Current. — An oscillating, or free alternating current is the current following any electro-magnetic disturbance in a circuit having capacity, inductance, and less than the critical resistance. When the critical resistance of a circuit is reached the current becomes aperiodic.

Alternating Currents

3204. Cycle. — A cycle is one complete set of positive and negative values of an alternating current.

3206. Period. — The period of an alternating current is the time required for the current to pass through one cycle.

3208. Frequency. — The frequency of an alternating current is the number of cycles through which it passes per second, that is, the reciprocal of the period.

3212. Wave Shape. — The wave shape, or wave form, of an alternating current is the shape of the curve obtained when the instantaneous values of the current are plotted against time in rectangular coordinates.

Two alternating quantities are said to have the same wave shape when the ordinates of corresponding phase bear a constant ratio to each other. The wave shape, as thus understood, is therefore independent of the frequency of the current and of the scale to which the curve is plotted.

3214. Sine Wave, or Simple Alternating Current. — A sine wave, or simple alternating current, is a current whose wave shape is sinusoidal.

3218.* Root-Mean-Square or Effective Value. — The root-mean-square or effective value of an alternating current is the square root of the mean of the squares of the instantaneous values for one complete cycle. It is usually abbreviated r.m.s. Unless otherwise specified, the numerical value of an alternating current refers to its r.m.s. value. The word " virtual " is sometimes used in place of r.m.s., particularly in Great Britain.

3222. Phase. — Phase is the fraction of the period of an alternating current which has elapsed since the current passed through the zero position of reference.

This fraction is usually expressed in angular measure, and the period corresponding to one complete cycle is taken as representing 2π radians or 360 degrees. The angles are frequently called electric angles, and the degrees electric degrees.

In the usual equation $$i = I_m \sin(\omega t + \phi)$$

the quantity $(\omega t + \phi)$ is the phase and ϕ is the phase angle of the current.

3224.* Phase Difference; Lead and Lag. — The phase difference of two alternating quantities of the same frequency is the difference between their phases at any instant. That quantity whose maximum occurs first in time is said to lead the other, and the latter is said to lag behind the former.

Fig. 3–1.

3228. Vector Representation and Angular Velocity. — A sine-wave current or voltage may be represented by a vector of constant length rotating counter-clockwise at a constant angular velocity ($\omega = 2\pi f$); this angular velocity is frequently termed the angular velocity of the current or voltage.

3230.* Counter-clockwise Convention. — It is recommended that in any vector diagram, the leading vector be drawn counter-clockwise with respect to the lagging vector, as in Fig. 3-1 where OI rep-

(3218) The r.m.s. value of a sine wave (see Section 3214) is equal to its maximum, or crest value, divided by $\sqrt{2}$.

(3224) When the two alternating quantities do not have the same wave form, the phase difference as here defined may not be identical with equivalent phase difference as defined in Section 3262.

(3230) See Publication 12 of the International Electrotechnical Commission (Report of Turin meeting, Sept. ...

Digitized by Google

sents the vector of a current in a simple alternating-current circuit lagging hind the vector OE of impressed electromotive force.

3234. Power. — Power is the rate of transfer of energy. In the case of an ernating-current circuit the word power is generally used to denote the aver- e value of the power over a cycle. The power in an electric circuit at any tant is equal to the product of the values of the current and voltage at that tant, and is generally called the instantaneous power.

3238. Apparent Power or Volt-amperes. — The apparent power, or volt- pperes, in an alternating-current circuit is the product of the r.m.s. value of e voltage across the circuit by the r.m.s. value of the current in the circuit. pparent power is also expressed in kilovolt-amperes, abbreviated kv-a.

3242.* Power Factor. — Power factor is the ratio of the power to the appar- t power.

3243. Power Factor in Polyphase Circuits.—The power factor of a polyphase rcuit, either balanced or unbalanced, is the ratio of the total active power in itts to the total vector volt-amperes.

The total vector volt-amperes is the square root of the sum of the squares of e total active power and the total reactive power.

The total reactive power is the algebraic sum of the reactive powers correspond- g to the separate harmonic components of the system.

3244. Momentary and Average Power Factors.—Power factors are either omentary power factors or integrated "average power factors"; i.e., extended er a specific time interval by averaging the active and reactive powers over e interval. Thus, a power factor may be an integrated average five-minute wer factor, or an integrated average hour power factor, or an integrated erage monthly power factor, etc.

The difference between a polyphase power factor (momentary) and a poly- ase power factor (integrated average) lies only in the period of time over hich the active and reactive powers are taken.

3246.* Reactive Volt-amperes. — The reactive volt-amperes in a circuit is e square root of the difference between the square of the apparent power and e square of the power.

3250.* Reactive Factor. — The reactive factor is the ratio of the reactive lt-amperes to the total volt-amperes.

3254.* Active Component. — The active component of the current in a cir- uit is the average power divided by the voltage.

3256.* Reactive Component. — The reactive component of the current in a rcuit is the square root of the difference between the square of the current and ie square of the active component of the current.

3260. Equivalent Sine Wave. — An equivalent sine wave is a sine wave hich has the same frequency and the same r.m.s. value as the actual wave.

3262. Equivalent Phase Difference. — The equivalent phase difference pplicable to non-sinusoidal currents and voltages) is the phase difference etween the equivalent sine waves of current and voltage when so related as to ave the same power factor as the non-sinusoidal quantities.

There are cases, however, where this equivalent phase difference is misleading,

---

(3242) The power factor when both the current and voltage are sinusoidal is equal to e cosine of the angle which expresses their difference in phase (see Section 3224).

(3246) The reactive volt-amperes, when both current and voltage are sinusoidal, is ual to the volt-amperes times the sine of the angle which expresses the phase difference tween current and voltage.

(3250) The reactive factor, when both current and voltage are sinusoidal, is equal to ie sine of the angle which expresses their phase difference.

(3254) The active, or in-phase component of the current in a circuit corresponds to verage power passing in a given direction through the circuit. With sine-wave voltage nd current, the active component of the current is in phase with the voltage.

(3256) The reactive, or quadrature, component of the current in a circuit corresponds power alternating in direction in the circuit so that the average value of the power ansferred in a given direction through a cycle is zero. With sine-wave current and oltage the reactive component of the current is in quadrature with the voltage.

since the presence of harmonics in the voltage wave, current wave, or in both may reduce the power factor without producing a corresponding displacement of the two wave forms with respect to each other; *e.g.*, the case of an arc lamp. In such cases, the components of the equivalent sine waves, the equivalent reactive factor and the equivalent reactive volt-amperes may have no physical significance.

3266.* Crest Factor or Peak Factor. — The crest factor or peak factor of a wave is the ratio of the crest, or maximum, value to the r.m.s. value.

3270.* Form Factor of a Wave. — The form factor of a wave is the ratio of the r.m.s. to the algebraic mean ordinate taken over a half-cycle beginning with the zero value. If the wave passes through zero more than twice during a single cycle, that zero shall be taken which gives the largest algebraic mean for the succeeding half-cycle.

3274. Deviation Factor of a Wave. — The deviation factor of a wave is the ratio of the maximum difference between corresponding ordinates of the wave and of the equivalent sine wave to the maximum ordinate of the equivalent sine wave when the waves are superposed in such a way as to make this maximum difference as small as possible.

3278. Telephone Interference Factor of a Wave. (See § 4352.) — The telephone interference factor is the ratio of the square root of the sum of the squares of the weighted values of all the sine-wave components (including the alternating waves both fundamental and harmonics) to the r.m.s. value of the wave.

Circuits and Phases

3304. Electric Circuit. — An electric circuit is a path in which an electric current may flow. Strictly speaking, an electric circuit is a complete circuitous path, but the term circuit is commonly employed to designate a specific part of a complete path. When part of a complete path is referred to, such as a branch circuit, a derived circuit, or a conductor, both the terminals and the conductor which form that path should be specified in order to avoid ambiguity; *e.g.*, the circuit *a-b-c*. When the whole circuit is referred to, it may be designated as a complete or closed circuit.

3324.* Single-phase Circuit. — A single-phase circuit is a circuit energized by a single alternating electromotive force.

3326.* Three-phase Circuit. — A three-phase circuit is a combination of circuits energized by alternating electromotive forces which differ in phase by one-third of a cycle; *i.e.*, 120 degrees.

3328.* Quarter-phase or Two-phase Circuit. — A quarter-phase or two-phase circuit is a combination of circuits energized by alternating electromotive forces which differ in phase by a quarter of a cycle; *i.e.*, 90 degrees.

3330.* Six-phase Circuit. — A six-phase circuit is a combination of circuits energized by alternating electromotive forces which differ in phase by one-sixth of a cycle, *i.e.*, 60 degrees.

3338. Polyphase Circuit. — A polyphase circuit is a circuit of more than one single phase. This term is ordinarily applied to symmetrical systems.

3344. Symmetrical Voltages and Currents. — Polyphase voltages or currents are symmetrical when the voltages or currents have the same wave shape and r.m.s. value and differ in phase each from the next by the same angle.

3348. Symmetrical Polyphase System. — A symmetrical polyphase system is a polyphase system in which the voltages are symmetrical.

(3266) The crest factor of a sine wave is $\sqrt{2}$.

(3270) The form factor of a sine wave is $\frac{\pi}{2\sqrt{2}}$ or 1.11.

(3324) A single-phase circuit is usually supplied through two wires. The currents in these two wires, counted outwards from the source, differ in phase by 180 degrees or a half-cycle.

(3326) In practise the phases may vary several degrees from the specified angle.

(3328) In practise the phases may vary several degrees from the specified angle.

(3330) In practise the phases may vary several degrees from the specified angle.

382.* **Balanced Polyphase System.** — A balanced polyphase system is a yphase system in which both the currents and voltages are symmetrical.

Loads

404. Reactive Load. — A reactive load is a load in which the current lags ind or leads the voltage across the load.

406. Non-reactive Load. — A non-reactive load is a load in which the cur- : is in phase with the voltage across the load. (The term non-inductive load metimes used for non-reactive load.)

408. Inductive Load. — An inductive load is a reactive load in which the ent lags behind the voltage across the load.

410. Condensive Load. — A condensive load is a reactive load in which the ent leads the voltage across the load.

414.* **Balanced Polyphase Load.** — A balanced polyphase load is a load to ch symmetrical currents are supplied when it is connected to a system having metrical voltages.

424. Connected Load. — The connected load on any system, or part of a em, is the combined continuous rating of all the receiving apparatus on con- ers' premises which is connected to the system, or part of the system under ideration.

434. Peak Power. — The peak power is the average power during a time rval of specified duration occurring within a given period of time, that rval being selected during which the average power is greatest.

438. Load Factor. — The load factor is the ratio of the average power to the k power.

In each case, the interval of maximum load and the period over which the age is taken should be definitely specified, such as a "half-hour monthly" factor. The proper interval and period are usually dependent upon local litions and upon the purpose for which the load factor is to be used.

442. Plant Factor. — The plant factor is the ratio of the average load to the d capacity of the power plant; *i.e.*, to the aggregate ratings of the generators.

454. Demand of an Installation or System. — The demand of an installation ystem is the load which is drawn from the source of supply at the receiving minals averaged over a suitable and specified interval of time. Demand is essed in kilowatts, kilovolt-amperes, amperes, or other suitable units.

458. Maximum Demand. — The maximum demand of an installation or em is the greatest of all the demands which have occurred during a given od. It is determined by measurement, according to specifications, over a scribed time interval.

460. Demand Factor. — The demand factor of any system or part of a em, is the ratio of the maximum demand of the system, or part of a system, he total connected load of the system, or of the part of the system under ideration.

464. Diversity Factor. — The diversity factor of any system, or part of a em, is the ratio of the sum of the maximum power demands of the sub- ions of the system, or part of a system, to the maximum demand of the e system, or part of the system under consideration, measured at the point pply.

---

382) The term balanced polyphase system is applied also to a quarter-phase (or two- e) system in which the voltages have the same wave form and r.m.s. value and in the currents have the same wave form and r.m.s. value and differ in phase by ninety rical degrees.

414) The term balanced polyphase load is applied also to a load to which are supplied currents having the same wave form and r.m.s. value and differing in phase by ninety rical degrees when it is connected to a quarter-phase (or two-phase) system having ages of the same wave form and r.m.s. value.

Machinery and Apparatus

3504. Capacity (or Properly, Capability). — The word "capacity" is frequently used in the general sense of "capability." It is also used in a more exact sense to denote the load which, when carried by a machine, apparatus or device will, under specified conditions of test, cause it to reach *any one of its physical limitations*, such for example, as operating temperature or ability to maintain required voltage.

Capacity should be distinguished from rating. On account of the different senses in which it has been employed (see § 3508), capacity is less used than formerly was, rating being more useful commercially.

3508.* Rating. — A rating of a machine, apparatus or device is an arbitrary designation of an operating limit.

(The rating of a machine is the output marked on the rating plate, and shall be based on, but shall not exceed the maximum load which can be taken by the machine under prescribed conditions of test. This is also called the normal output. *Maximum possible rating obviously corresponds with capability as defined in* § 3504).

3514. Efficiency. — The efficiency of an electric machine or apparatus is the ratio of its useful output to its total input. Unless otherwise specified the terms output and input shall mean the power output and the power input respectively.

3524.* Conventional Efficiency. — The conventional efficiency of an electric machine or apparatus is the ratio of the output to the sum of the output and losses, or of the input minus the losses to the input, when, in either case, conventional values are assigned to one or more of these losses.

3534. Plant, or System, Efficiency. — Plant, or system, efficiency is the ratio of the energy delivered from the plant or system to the energy received by it in a specified period of time. In calculating plant, or system, efficiency it may be desirable to calculate the losses in each individual machine, or part of the system, at the actual temperature of that machine, or part, during the specified interval. These losses may be appreciably different from the losses at 75° C., which shall be the standard temperature of reference for all efficiency guarantees. This definition is not applicable to storage batteries. See § 2332.

3535. Regulation. — The regulation of a machine in regard to some characteristic quantity (such as terminal voltage or speed) is the change in that quantity occurring between any two loads. Unless otherwise specified, the two loads considered shall be zero load and rated load, and at the temperature attained under normal operation. The regulation may be expressed by stating the numerical values of the quantity at the two loads, or it may be expressed as the "percentage regulation," which is the percentage ratio of the change in the quantity occurring between the two loads, to the value of the quantity at one or the other load, taken as the normal value. The normal value may be either the no-load value, as the no-load speed of induction motors; or it may be the rated-load value, as in the voltage of a-c. generators.

It is assumed that all parts of the machine affecting the regulation are at constant temperature between the two loads, and where the influence of temperature is of consequence a reference temperature of 75° C. shall be considered as standard.

Systems

3560. Normal Voltage.—In systems employing transformers, the normal voltage of the system or circuit is defined as the highest rated voltage of the secondaries of transformers supplying the system or circuit. This voltage rating applies to all parts of that particular system or circuit.

(3508) The term maximum load does not refer to loads applied solely for the purpose of commutation, or similar tests.

(3524) The need for assigning conventional values to certain losses arises from the fact that some of the losses in electric machinery are practically indeterminable, and may in many cases, either be approximated by an approved method of test, or else values recommended by the Institute and designated "conventional" values shall be employed for them in arriving at the "conventional efficiency."

CHAPTER IV

STANDARDS FOR ROTATING MACHINES (OTHER THAN RAILWAY MOTORS, RAILWAY SUBSTATION MACHINERY CARRYING TRACTION LOADS, AND AUTOMOBILE PROPULSION MACHINES)

The A. I. E. E. Standards for Rotating Machines are the General Standards shown in Chapters II and III and the Standards in other chapters which are applicable to the devices involved, together with the modifications and additions given in this chapter.

DEFINITIONS

General

Certain rules applying exclusively to railway machinery have, for convenience, been placed in Chapter V, with cross-references in all cases in this chapter. The rules of Chapter IV apply to railway machinery except as they are modified by rules of Chapter V.

4000. Classification of Electric Rotating Machinery. — Rotating electric machinery may be classified in various ways, these classifications over-lapping or interlocking in considerable degree. *First*, Rotating electric machinery may be classified as Direct-Current and Alternating-Current; *Second*, according to the function of the machines; *e.g.*, Motors, Generators, Boosters, Motor-Generators, Dynamotors, Double-Current Generators, Converters and Phase Advancers; *Third*, according to construction or principle of operation; as Commutating, Synchronous, Induction, Unipolar, Rectifying. Obviously some of these machines could be rationally included in either classification, as Motor-Generators and Rectifying Machines.

In the following, self-evident definitions have for the most part been omitted.

Functional Classification of Rotating Electric Machines

4001. Generator. — A generator is a machine which transforms mechanical power into electric power.

4002. Motor. — A motor is a machine which transforms electric power into mechanical power.

Digitized by Google

3905. Booster. — A booster is a generator inserted in series in a circuit to ge its voltage. A booster may be driven by an electric motor (in which e it is termed a motor-booster) or otherwise.

3904. Motor-generator Set. — A motor-generator set is a transforming ce consisting of one or more motors mechanically coupled to one or more erators.

3906. Dynamotor. — A dynamotor is a transforming device combining both tor and generator action in one magnetic field, either with two armatures, or h one armature having two separate windings and independent commutators.

3906. Direct-current Compensator or Balancer. — A direct-current com-sator or balancer is a machine which comprises two or more similar direct-rent machines (usually with shunt or compound excitation) directly coupled ach other and connected in series across the outer conductors of a multiple-e system of distribution, for the purpose of maintaining the potentials of the rmediate wires of the system, which are connected to the junction points ween the machines.

3907. Double-current Generator. — A double-current generator is a machine ch supplies both direct and alternating currents from the same armature-ding.

3908. Converter. — A converter is a machine which employs mechanical tion in changing electric energy from one form into another. There are ral types of converters, as defined in §§ 4009 to 4013 below.

3909. Direct-current Converter. — A direct-current converter is a machine ch converts from a direct current to a direct current, usually with a change oltage. Such a machine may be either a motor-generator set or a dynamotor.

3910. Synchronous Converter. — A synchronous converter (sometimes called tary converter) is a machine which converts from an alternating to a direct ent, or vice-versa. It is a synchronous machine with a single closed-coil mature winding, a commutator and slip rings.

3911. Cascade Converter. — A cascade converter (also called a motor con-er) is a combination of an induction motor with a synchronous converter, secondary circuit of the former feeding directly into the armature of the r; *i.e.*, a synchronous converter concatenated with an induction motor.

3912. Frequency Converter. — A frequency converter is a machine which rerts the power of an alternating-current system from one frequency to ther, with or without a change in the number of phases, or in the voltage.

3913. Rotary Phase-converter. — A rotary phase-converter is a machine ch converts from an alternating-current system of one or more phases to an rnating-current system of a different number of phases, but of the same uency.

3914. Phase Advancer. — A phase advancer is a machine which supplies tive volt-amperes to the system to which it is connected. Phase advancers be either synchronous or asynchronous.

3915. Synchronous Condenser or Synchronous Phase Advancer. — A syn-nous condenser or synchronous phase advancer is a synchronous machine, ning either idle or with load, the field excitation of which may be varied so as odify the power factor of the system, or through such modification to influ-the load voltage.

Constructional Classification of Rotating Electric Machines

3916. Direct-current Commutating Machines. — A direct-current commu-g machine comprises a magnetic field of constant polarity, an armature, a commutator connected therewith. Specific types of direct-current com-ating machines are: Direct-Current Generators; Direct-Current Motors; ct-Current Boosters; Direct-Current Motor-Generator Sets and Dyna-ors; Direct-Current Compensators or Balancers; and Arc Machines.

3917. Alternating-current Commutating Machine. — An alternating-current mutating machine comprises a magnetic field of alternating polarity, an ature, and commutator connected therewith. See §§ 4071 to 4074.

Digitized by Google

4018. Synchronous Commutating Machine. — Synchronous commutating machines include synchronous converters, cascade-converters, and dou current generators.

4019. Synchronous Machine. — A synchronous machine comprises a stant magnetic field and an armature receiving or delivering alternating-cu in synchronism with the motion of the machine; *i.e.*, having a frequency wh proportional to the speed of the machine. Specific types of synchron machines are defined in §§ 4020 to 4023 below.

4020. Alternator. — An alternator is a synchronous alternating-cu generator, either single-phase or polyphase.

4021. Polyphase Alternator. — A polyphase alternator is a polyphase chronous alternating-current generator, as distinguished from a single-p alternator.

4022. Inductor Alternator. — An inductor alternator is an alternator in wh both field and armature windings are stationary, and in which masses of iro inductors, by moving past the coils, alter the magnetic flux through them. may be either single-phase or polyphase.

4023. Synchronous Motor. — A synchronous motor is a machine structu identical with an alternator, but operated as a motor.

4024. Induction Machine. — An induction machine is a machine wh primary and secondary windings rotate with respect to each other; *e.g.*, in tion motors, induction generators, certain types of frequency converter certain types of rotary phase-converters.

4025. Induction Motor. — An induction motor is an alternating-cu motor, either single-phase or polyphase, comprising independent primary secondary windings, one of which, usually the secondary, is on the ro member. The secondary winding receives power from the primary by el magnetic induction.

4026. Induction Generator. — An induction generator is a machine st turally identical with an induction motor, but driven above synchronous s as an alternating-current generator.

4027. Engine Type Generator. — An engine type generator is one cons an engine in such a way that it cannot be run independently of the engine.

4028. Unipolar or Acyclic Machine. — A unipolar, or acyclic machine, direct-current machine, in which the voltage generated in the active conduc maintains the same direction with respect to those conductors.

Speed Classification of Motors

4035. Constant-speed Motor. — A constant-speed motor is one whose spe either constant or does not materially vary; such as a synchronous motor, induction motor with small slip, and an ordinary direct-current shunt motor.

4036. Multispeed Motor (or Change Speed Motor). — A multispeed mot a motor which can be operated at any one of several distinct speeds (these spe being practically independent of the load), but which cannot be operated intermediate speeds.

4037. Adjustable-speed Motor. — An adjustable-speed motor is one in wh the speed can be varied gradually over a considerable range, but when adjusted remains practically unaffected by the load; such as a shunt mo designed for a considerable range of speed variation.

4038. Base Speed of an Adjustable-speed Motor. — The base-speed of adjustable-speed motor is that speed of the motor obtained with full field an full load with no resistor in the armature circuit.

4039. Varying-speed Motor. — A varying speed motor is one whose sp varies with the load, ordinarily decreasing when the load increases; such a series motor, a compound-wound motor, and a series-shunt motor. As a c class of varying-speed motors, may be cited adjustable varying-speed moto or motors in which the speed can be varied over a considerable range at a given load, but when once adjusted, varies with the load; *e.g.*, compound wound motors arranged for adjustment of speed by varying the strength of th shunt field.

Digitized by Google

Classification of Rotating Electric Machines Relative to their Degree of Enclosure

1041. Open Machine. — An open machine is of either the pedestal-bearing or l bracket type where there is no restriction to ventilation, other than that ssitated by good mechanical construction.

1042. Protected Machine. — A protected machine is one in which the armae, field coils, and other live parts are protected mechanically from accidental careless contact, while free ventilation is not materially obstructed.

1043. Enclosed Ventilated Machine. — An enclosed ventilated (or semiosed machine is one in which the ventilating openings in the frame are tected with wire screen, expanded metal, or other suitable perforated covers, ing apertures not exceeding ½ square inch (3.2 sq. cm.) in area. See § 4316.

1044. Totally Enclosed Machine. — A totally enclosed machine is one so losed as to prevent circulation of air between the inside and the outside of the e, but not sufficiently to be termed air-tight.

1045. Separately Ventilated Machine. — A separately ventilated machine its ventilating air supplied by an independent fan or blower external to the chine.

1046. Self-ventilated Machine. — A self-ventilated machine differs from a arately ventilated machine only in having its ventilating air circulated by a , blower, or centrifugal device integral with the machine.
f the heated air expelled from the machine is conveyed away through a pipe ached to the machine, this should be so stated.

1047. Water-cooled Machine. — A water-cooled machine is one which inly depends on water circulation for the removal of its heat.

1048. Drip-proof Machine. — A drip-proof machine is one so protected as to lude falling moisture or dirt. A drip-proof machine may be either open or ii-enclosed, if it is provided with suitable protection integral with the machine, o enclosed as to exclude effectively falling solid or liquid material.

1051. Explosion-proof Machine (or Flame-proof Machine). — An explosionof machine is a machine in which the enclosing case can withstand, without ny, any explosion of gas that may occur within it, and will not transmit the se to any inflammable gas outside it.

1052. Machine with Explosion-proof Slip-ring Enclosure. — A machine in ich the slip rings and brushes alone are included within an explosion-proof e should not be described as an explosion-proof machine, but as a machine h explosion-proof slip-ring enclosure.

Classification of Alternating-Current Commutator Motors

An alternating-current commutator motor may be classified under more than one of the following groups)

ssification by Phases of Energy Supply.

1061. Single-phase Commutator Motor. — A single-phase commutator motor ne that receives the whole of its energy from only one phase of an alternatingrent supply system, without requiring external phase-converting apparatus.

1062. Polyphase Commutator Motor. — A polyphase commutator motor is that receives its energy from a plurality of phases of an alternating-current ply system, or from a single-phase system through phase-converting apparatus ernal to the motor.

ssification by Speed Characteristics.

1063. General. — For convenience, alternating-current commutator motors y be classified with reference to their speed characteristics as (1) constanted motors, (2) multi-speed motors, (3) adjustable-speed motors, and (4) ying-speed motors. Definitions of these terms as given in §§ 4035 to 4039 motors in general, should be adopted for alternating-current commutator tors, in so far as they are applicable.

ssification by Excitation.

1064. Stator-excited Commutator Motor. — A stator-excited commutator tor is one in which the torque-producing field is due to a current in a winding

located on the stator. By the "torque-producing field" is meant that component of the magnetic field which, with the in-phase component of the current produces the torque of the motor.

4065. Rotor-excited Commutator Motor. — A rotor-excited commutator motor is one in which the torque-producing field is due to a current in a winding located on the rotor. See § 4064.

4066. Stator- and Rotor-excited Commutator Motor. — A stator- and rotor-excited commutator motor is one in which the torque-producing field is due to currents in windings located on the stator and on the rotor. See § 4064.

4067.* Constant-field Commutator Motor. — A constant-field commutator motor is one in which the torque-producing field remains practically constant independent of the load. See § 4064.

4068.* Varying-field Commutator Motor. — A varying-field commutator motor is one in which the torque-producing field varies in some proportion to the current in the armature (which latter is generally the rotor). See § 4064.

Classification by Neutralization and Compensation.

4069. Neutralized Commutator Motor. — A neutralized commutator motor is one in which use is made of a winding for producing a magnetizing force which at each instant and at each point in the air-gap under the pole face is practically equal and opposite to the magnetizing force due to the armature current.

4070. Compensated Commutator Motor. — A compensated commutator motor is one in which means, other than a neutralizing winding, are provided within the motor for improving the power-factor.

Classification by Energy Reception.

4071. Conduction Commutator Motor. — A conduction commutator motor is one in which the working energy is supplied to only one of the members, and is conveyed to it by conduction. By "working energy" is meant the energy which is directly converted into mechanical energy, and which includes the shaft energy output plus core losses and friction.

4072. Transformer Commutator Motor. — A transformer commutator motor is one in which the working energy is transmitted from one member to the other by transformer action.

A motor in which the energy required by its armature (which is generally the rotor) is conveyed to it by electromagnetic induction or transformer action, is properly be referred to either as an "induction motor," or as a "transformer motor." Although it is equally applicable to a motor having a commutator, the term "induction motor" is usually applied to a motor without a commutator. The term "transformer commutator motor" is therefore recommended for use with motors of the induction, or transformer type, having commutators.

4073. Transformer-conduction Commutator Motor. — A transformer-conduction commutator motor is one in which the energy required by its armature (which is generally the rotor) is conveyed to it by both conduction and electromagnetic induction.

4074. Repulsion Commutator Motor. — A repulsion commutator motor is a transformer commutator motor in which use is made of brushes for short-circuiting a number of coils of the commutated winding.

Miscellaneous Definitions

4085. Saturation Factor. — The saturation factor of a machine is the ratio of a small percentage increase in field excitation to the corresponding percentage increase in voltage thereby produced. Unless otherwise specified, the saturation factor of a machine refers to the no-load excitation required at normal

(4067) Alternating-current commutator motors of this class will in general have low-speed characteristics similar to those of the direct-current shunt motor, but such alternating-current commutator motors having such load-speed characteristics are constant-field machines.

(4068) Such a motor will in general have load-speed characteristics similar to those of the direct-current series motor.

Digitized by Google

ted and voltage. It is determined from measurements of saturation made on
en circuit at rated speed.

4088. Percentage Saturation. — The percentage saturation of a machine at
y excitation may be found from its saturation curve (generated voltage as
inates, against excitation as abscissas), by drawing a tangent to the curve at
ordinate corresponding to the assigned excitation, and extending the tangent
intercept the axis of ordinates drawn through the origin. The ratio of the
ercept on this axis to the ordinate at the assigned excitation, when expressed
per cent, is the percentage saturation, and is independent of the scales selected
excitation and voltage. This ratio as a fraction, is equal to the reciprocal of
saturation-factor at the same excitation, deducted from unity; or, if f be the
uration factor and p the percentage saturation,

$$p = 100\left(1 - \frac{1}{f}\right).$$

4088.* Variation in Alternators. — The variation in alternators, or alter-
ing-current circuits in general is the maximum angular displacement,
ressed in electrical degrees (see § 3222) of corresponding ordinates of the
tage wave and of a wave of absolutely constant frequency equal to the aver-
frequency of the alternator or circuit in question, and may be due to the
iation of the prime mover. See §§ 14010 and 14011.

4089. Per cent Resistance Drop. — The per cent resistance drop in an electric
chine is the ratio of the internal resistance drop at 75° C. to the terminal
tage expressed in per cent.
Unless otherwise specified this per cent drop shall be referred to rated load
l rated power factor.
The per cent resistance drop in an induction motor is expressed in terms of
internally induced electromotive force.

4090. Per cent Reactance Drop. — The per cent reactance drop in an electric
chine or apparatus is the ratio of the internal reactance drop to the terminal
age, expressed in per cent.
Unless otherwise specified this per cent drop shall be referred to rated load
rated power factor.
The per cent reactance drop in an induction motor is expressed in terms of the
rnally induced electromotive force.

4091. Per cent Impedance Drop. — The per cent impedance drop in an electric
chine is the ratio of the internal impedance drop at 75° C. to the terminal
tage, expressed in per cent.
Unless otherwise specified this per cent drop shall be referred to rated load and
ed power factor.
The per cent impedance drop in an induction motor is expressed in terms of the
rnally induced electromotive force.

4092. Magnetic Degree. — A magnetic degree is the 360th part of the angle
tended, at the axis of a machine, by a pair of its field poles. One *mechanical*
ree is thus equal to as many magnetic degrees as there are pairs of poles in the
chine.

4094. Regulation of D-C. Generators. — The regulation of a d-c. generator
sually stated by giving the numerical values of the voltage at no load and
ed load, and in some cases it is advisable to state regulation at intermediate
ds. The regulation of d-c. generators refers to changes in voltage correspond-
to gradual changes in load, and does not relate to the comparatively large
mentary fluctuations in voltage that frequently accompany instantaneous
nges in load.

4095. Regulation of Constant-potential A-C. Generators. — In constant-
ential a-c. generators, the regulation is the rise in voltage (when the specified
l at specified power factor is reduced to zero) expressed in per cent of normal
ed-load voltage.

(4088) If p is the number of pairs of poles, the variation of an alternator is p times the
ation of its prime mover, if direct-connected, and pn times the variation of the prime
ver if rigidly connected thereto in such a manner that the angular speed of the alternator
times that of the prime mover.

Digitized by Google

4096. Regulation of Constant-current Machines. — In constant-current machines the regulation is the ratio of the maximum difference of current from the rated-load value (occurring in the range from rated-load to short-circuit or minimum limit of operation), to the rated-load current.

4097. Regulation of Constant-speed Motors. — In constant-speed direct-current motors and induction motors, the regulation is the ratio of the difference between full-load and no-load speeds to the no-load speed.

4098. Regulation of Converters, Dynamotors, Motor-Generators and Frequency Converters. — In converters, dynamotors, motor-generators, and frequency converters, the regulation is the change in the terminal voltage of the output side between the two specified loads. This may be expressed by giving the numerical values, or as the percentage of the terminal voltage at rated load.

OPERATION

Temperature Limits

4105. Exceptions to General Temperature Limits Given in Chapter II.

(a) Railway Motors: See §§ 5202 and 5101.

(b) Automobile Propulsion Machines: See § 5205.

(c) Railway Substation Machines: See §§ 5201 and 5102.

(d) Squirrel Cage and Amortisseur Windings. The temperature may attain any value such as will not occasion mechanical injury to the machine.

(e) Field Control Railway Motors: See § 5204.

4106. Collector Rings. — The observable temperature of collector rings shall not be permitted to exceed the values set forth in § 2231 (b) for the insulation employed either in the collector rings themselves or in adjacent insulation whose life would be affected by the heat from the collector rings.

4107. Commutators. — The observable temperature shall in no case be permitted to exceed the values given in § 2231 (b) for the insulation employed either in the commutator or in an insulation whose life would be affected by the heat of the commutator. These temperature limits are intended only to protect the insulation of the commutator and of the adjacent parts and are not intended as a criterion of successful commutation.

4108. Cores. — The observable temperature of those parts of the iron cores in contact with insulating materials shall in no case be permitted to exceed the values given in §§ 2231 (b) for the insulation employed.

4109. Other Parts (Such as Brush-holders, Brushes, Bearings, Pole-tip Cores, etc.). — All parts of electrical machinery other than those whose temperature affects the temperature of the insulating material may be operated at such temperatures as shall not be injurious in any other respect.

4110. Maximum Temperature Rise in Service. — Whatever may be the ambient temperature when the machine is in service, the limits of the maximum observable temperature or of temperature rise specified in the rules should not be exceeded in service; for, if the maximum temperature be exceeded, the insulation may be endangered, and if the rise be exceeded, the excess load may lead to injury, by exceeding limits other than those of temperature: such as commutation, stalling load and mechanical strength. For similar reasons, loads in excess of the rating should not be taken from a machine.

RATING

Units in Which Rating Shall be Expressed

4220. Rating of D-C. Generators.—The rating of direct-current generators shall be expressed in kilowatts (kw.) available at the terminals at a specified voltage.

4221. Rating of Alternators.— The rating of alternators shall be expressed in kilovolt-amperes (kv-a.) available at the output terminals, at a specified voltage and power factor.

4222.* Rating of Motors. — It is strongly recommended that the rating

(4222) Since the input of machinery of this class is measured in electrical units and since the output has a definite relation to the input, it is logical and desirable to measure the delivered power in the same units as are employed for the received power. Therefore, the output of motors should be expressed in kilowatts instead of in horsepower.

notors shall be expressed in kilowatts (kw.) available at the shaft. (An exception to this rule is made in the case of railway motors, which, for some purposes, re also rated by their *input*.) See § 5203.

4333. Rating of Auxiliary Machinery. — Auxiliary machinery, such as regulators, balancer sets, synchronous-condensers, etc., shall have their ratings appropriately expressed. It is also essential to specify the voltage (and frequency, a-c.), of the circuits on which the machinery may appropriately be used.

Limitations Other than Temperature Rise

4350.* Mechanical Limitations. — *(a) *General:* All types of rotating achines shall be so constructed that they will safely withstand an over-speed 25 per cent, except in the case of steam turbines, which, when equipped with nergency governors, shall be constructed to withstand 20 per cent over-speed.
(b) *Generators:* Water-wheel generators shall be constructed for the maximum runaway speed which can be attained by the combined unit.
(c) *Motors:* Motors for continuous service shall, except when otherwise ecified, be required to develop running torque at least 175 per cent of that rresponding to the running torque at their rated load, without stalling. bviously, duty-cycle machines must carry their peak loads without stalling.

4351. Commutation Limitations. — (a) *Continuously Rated Machines:* Continuously rated machines shall be required to commutate successfully momentary ads of 150 per cent of the amperes corresponding to the continuous rating, keeping e rheostat set for rated-load excitation. Successful commutation is such that ither brushes nor commutator are injured by the test. See §§ 2220 and 5203.

(b) *Machines for Duty-cycle Operation:* Machines for duty-cycle operation th widely fluctuating loads shall commutate successfully under their specified erating conditions. See §§ 2222 and 2223.

4352. Limitations of Stability. — Continuously rated machines shall be quired to carry momentary loads of 150 per cent of the amperes corresponding the continuous rating, keeping the rheostat set for rated-load excitation.
In the case of direct-connected generators, this clause is not to be interpreted requiring the prime mover to drive the generator at this overload.

TESTS

Ambient Temperature

4300. Measurement of the Ambient Temperature During Tests of Machines. (See § 2300) (a) *Machines Cooled by Forced Draught:* In the testing of rotating achines, cooled by forced draught, a conventional weighted mean shall be ployed, a weight of four being given to the temperature of the circulating air pplied through ducts and a weight of one to the surrounding room air. See oo Note.

(b) *Machines Below Floor Line:* Where machines are partly below the floor e in pits, the temperature of the rotor shall be referred to a weighted mean of pit and room temperatures, the weight of each being based on the relative portions of the rotor in and above the pit. Parts of the stator constantly in pit shall be referred to the ambient temperature in the pit.

Machine Temperatures

4316. Machines with Small Ventilating Apertures. — Machines having ventiing openings smaller than 0.02 sq. in. (0.13 sq. cm.) in area, when intended to operated in locations or under conditions where the openings are liable to ome clogged, should be considered as totally enclosed machines and tested as

---

wever, on account of the hitherto prevailing practise of expressing mechanical output orsepower, it is recommended that for machinery of this class the rating should, for present, be expressed both in kilowatts and in horsepower; as follows:

Kw.————Approx. equiv. h.p.————

or the purposes of these rules the horsepower shall be taken as 746.0 watts.
n order to lay stress upon the preferred future basis, it is desirable that on rating tes, the rating in kilowatts shall be shown in larger and more prominent characters a the rating in horsepower.
One kilowatt is equal to 102 kilogrammeters per second.
4250 a) In the case of series motors, it is impracticable to specify percentage values the guaranteed overspeed, on account of the varying service conditions.

Google

such with openings closed, and in all cases the rating on this basis should be indicated on the rating plate.

4319. Exception to Temperature Limits Used in Method 1. — In the case of enclosed motors and generators, the limits of the observable temperature rise shall be 5° C. higher than allowed by the general rule. This rule does not apply to those types of machines defined in §§ 4043, 4045 and 4046.

4320. Exception to Temperature Limits Used in Method 2. — In the case of enclosed motors and generators, the limits of the observable temperature rise shall be 5° C. higher than allowed by the general rule. This rule does not apply to those types of machines defined in §§ 4043, 4045 and 4046.

4321. Method of Temperature Measurement Used in Determining Temperature of Stators of Machines. — Method 3 should be applied to all stators of machines with cores having a width of 50 cm. (20 in.) or over. It should also be applied to all machines of 5000 volts or more, if rated over 500 kv-a., regardless of core width.

Efficiency

4324.* Classification of Losses. — Losses are classified as shown in Table 401.

4325.* Losses to be Considered in Machines. — Conventional efficiency shall be based upon the losses listed in Table 402, and these losses shall be measured as specified in §§ 4336–4342 inclusive.

TABLE 401

Classification of Losses in Machinery

Accurately Measurable	Approximately Measurable or Determinable	Indeterminable
No-load core losses including eddy-current losses in conductors at no-load	Brush Friction loss	Iron loss due to distortion
Load I^2R losses in windings No-load I^2R losses in windings	Brush-contact loss	Eddy-current loss conductors due transverse flux caused by the currents
	Losses due to windage and to bearing friction	Eddy-current loss conductors due tooth saturation resulting from distortion of the main
		Tooth-frequency loss due to flux distortion under load
	Dielectric losses	Short-circuit loss commutation

(4334) The losses in constant-potential machinery, either of the stationary type or the constant-speed rotary type, are of two classes; namely, those which remain essentially constant at all loads, and those which vary with the load. The former include core losses, windage and friction, also I^2R losses in any shunt windings. The latter include losses in series windings. The constant losses may be determined by measuring the power required to operate the machine at no load, deducting any series I^2R losses. The total loss at any load may be computed from the measured resistance of the armature and the given load current.

4336. I^2R Loss. — (a) *General:* The I^2R loss shall be based upon the current d the measured resistance.

(b) *Polyphase Induction-motor Rotor:* The I^2R loss in the rotors of polyphase luction motors should be determined from the slip, whenever the latter is curately determinable, using the following equation:

$$\text{Rotor } I^2R \text{ loss} = \frac{\text{output} \times \text{slip}}{1 - \text{slip}}.$$

otes: (1) Except railway motors.

) When there are collector rings.

) Brush friction and brush contact losses are negligible except in the case of revolv- rmature machines.

) For the booster type of synchronous converter, where the booster forms an integral of the unit, its losses shall be included in the total converter losses in estimating the iency.

) These losses, while usually of low magnitude, are erratic, and the Institute is not his time prepared to make recommendations for approximating them.

large slip-ring motors, in which the slip cannot be directly measured by ling, the rotor I^2R loss shall be determined by direct resistance measure- it; the rotor full-load current to be calculated by the following equation:

$$\text{Current per ring} = \frac{\text{watts output}}{\text{rotor voltage at stand-still} \times \sqrt{3} \times K}.$$

(335) This simple method of determining the losses and hence the efficiency is only roximate, since the losses which are assumed to be constant do actually vary to some nt with the load, and also because the actual loss in the copper windings is sometimes reciably greater than the calculated I^2R loss. The difference between the approximate es, as above determined, and the actual losses, is termed "stray-load losses." These r are due to distortions in electric or magnetic fluxes from their no-load distributions values, brought about by the load current. They are usually only approximately surable, or may be indeterminable, but certain of them reach values in various kinds achinery, which require that they should be taken into account.

lectric losses are usually negligible.

he stray-load losses include the items in the column of Table 401 headed "Indeter- able" but do not include the increased core losses due to increased excitation for resating internal drop under load.

This equation applies to three-phase rotors. For rotors wound for two-pha use 2 instead of the $\sqrt{3}$. K may be taken as 0.95 for motors of 150 kw. or lar The factor K usually decreases as the size of motor is reduced, but no gen value can be stated for smaller sizes.

(c) *Synchronous Converters:* The I^2R losses in the armature winding shall derived from those corresponding to its use as a direct-current generator, by us suitable factors.

4337. Bearing Friction and Windage. — (a) *General:* Drive the machine tr an independent motor, the output of which shall be suitably determined. T machine under test shall have its brushes removed and shall not be excit This output represents the bearing friction and windage of the machine us test.

(b) *Induction Motors:* The bearing friction and windage of induction mot may be measured by running motors free at the lowest voltage at which th will rotate continuously at approximately rated speed; the watts input, mi I^2R loss, under these conditions being taken as the friction and windage.

(c) *Engine-type Generators:* In the case of engine-type generators (see § 433 the windage and bearing friction loss is ordinarily very small, amounting to fraction of one per cent of the output. This loss shall be neglected owing to small value and the difficulty of measuring it.

(d) *D. C. Railway Motors:* See § 5337.

4338. Brush Friction of Commutator and Collector Rings.—(a) *Gener* Drive the machine from an independent motor, the output of which shall suitably determined. The brushes shall be in contact with the commutator collector rings, but the machine shall not be excited. The difference between t output obtained in the test in § 4337 and this output shall be taken as the bru friction. The surfaces of the commutator and brushes should be smooth a glazed from running when this test is made.

(b) *D. C. Railway Motors:* See § 5338.

4339. Core Losses. — (a) *General:* Drive the machine from an independe motor, the output of which shall be suitably determined. The brushes shall in contact, and the machine shall be excited, so as to produce at the terminal voltage corresponding to the calculated internal voltage for the load un consideration. The difference between the output obtained by this test and th obtained by test under § 4338 (a) shall be taken as the core loss.

(b) *Synchronous Machines:* The internal voltage of synchronous machi shall be determined by correcting the terminal voltage for the resistance dr only.

(c) *Induction Motors:* The core loss of an induction motor may be determi by measuring the watts input to the motor when running free at rated volta and frequency and subtracting therefrom the no-load copper loss, bearing fri tion and windage.

(d) *D. C. Railway Motors:* See § 5339.

4341.* Brush-contact I^2R Loss. — (a) *General:* One volt drop per brus shall be considered as the Institute standard drop corresponding to the I^2 brush-contact loss, for carbon and graphite brushes with pigtails attache

(4341) The brush-contact I^2R loss depends largely upon the material of which th brush is composed.

As indicating the range of variation the following table will be of interest:

TABLE 403
Brush-contact Drop

Grade of brush	Volts drop across one brush-contact (Average of positive and negative brushes)
Hard carbon	1.1
Soft carbon	0.9
Graphite	0.5 to 0.8
Metal-graphite types	0.15 to 0.5 (The former for largest proportion of metal)

Digitized by Google

and one-half volts per brush shall be allowed where pigtails are not attached. al-graphite brushes shall be considered as special.

) *Automobile Motors:* See § 5341.

342.* Stray Load-losses.—(a) *Synchronous Machines:* These include iron s, and eddy-current losses in the copper, due to fluxes varying with load also to saturation.

ray load-losses shall be determined by operating the machine on short uit and at rated-load current. This, after deducting the windage and ion and I^2R loss, gives the stray load-loss for polyphase generators and ors. These losses in single-phase machines are large; but the Institute is yet prepared to specify a method for measuring them.

) *Induction Machines:* These include eddy-current losses in the stator ver, and other eddy-current losses due to fluxes varying with the load. In lings consisting of relatively small conductors, these eddy-current losses usually negligible.

Vith rotor removed, measure the power input to the stator with different ies of current at the rated frequency. The curve plotted with these values s the combined I^2R and stray load-losses due to eddy-currents in the stator ver. Deduct the I^2R loss determined from the resistance, and the differ- will represent the stray load-losses corresponding to the various currents. ile this method is not accurate for some types of motors it usually represents efficiently good approximation.

343. Miscellaneous Losses. — (a) *Field-rheostat Losses:* Field-rheostat es shall be included in the generator losses where there is a field rheostat in es with the field magnets of the generator, even when the machine is sepa- ly excited.

) *Ventilating Blower:* When a blower is supplied as part of a machine set, power required to drive it shall be charged against the complete unit, but not nst the machine alone.

) *Other Auxiliary Apparatus:* Auxiliary apparatus, such as a separate ter for a generator or motor, shall have its losses charged against the plant hich the generator and exciter are a part, and not against the generator. exception should be noted in the case of turbo-generator sets with direct- nected exciters, in which case the losses in the exciter shall be charged against generator. The actual energy of excitation and the field-rheostat losses, if , shall be charged against the generator. See § 4343 (a).

Wave Shape

351. Deviation Factor of a Wave. — The deviation factor of the open circuit minal voltage wave of synchronous machines shall not exceed ten per cent ess otherwise specified. See § 3274.

352. Telephone Interference Factor of a Wave. — (For trial only.) (See 178.) — (a) *Conditions of Test.* The weighting of the sine-wave components lifferent frequencies shall be as given in Fig. 4-1.

he telephone interference factor of a voltage wave, corresponding to this ghting, may be measured by the use of the network shown in Fig. 4-2.

Vith this network the telephone interference factor of a voltage wave is the o of the current I in micro-amperes in the meter branch of the network to voltage E applied to the external terminals of the network. The measure- nt may be made on the low-tension side of a potential transformer. A sensi- vacuum thermo-couple provided with a shunt, and a direct-current mil- meter have been found convenient for measuring the current.

b) The appropriate limiting value of the telephone interference factor of a re (see §3278), either for machines or for circuits, has not yet been determined, l cannot now be specified. The whole matter of interference, including

Tests of Dielectric Strength

4358. Frequency of Test Voltage. — In d-c. machines, and in general commercial application of a-c. machines, the testing frequency of 60 cycles per second is recommended.

4361.* Exceptions to Standard Test Voltage Given in Section 2286.

(a) *Field Windings of Alternating-current Generators:* Field windings of alternating-current generators shall be tested with 10 times the exciter voltage, but in no case with less than 1500 volts nor more than 3500 volts.

(b) *Field Windings of Synchronous Machines:* Field windings of synchron- machines including motors and converters which are to be started with alter- ing current are to be tested as follows:
When machines are to be started with field short-circuited, the field windings ll be tested as specified in § 4361 (a).
When machines are to be started with fields open-circuited and sectionalized ile starting, the field windings shall be tested with 5000 volts.
When machines are to be started with fields open-circuited and connected all eries while starting, the windings shall be tested with 5000 volts for less than volts excitation and 8000 volts for excitation of 275 volts to 750 volts.
(c) *Phase-wound Rotors of Induction Motor:* The secondary windings of ind rotors of induction motors shall be tested with twice their normal induced tage, plus 1000 volts. When induction motors with phase-wound rotors are be reversed, while running at approximately normal speed, by reversing the nary connections, the test shall be four times the normal induced voltage s 1000 volts.
d) *Small Motors and Generators:* Small machines taking not over 660 watts aving an output not exceeding ½ h. p. (373 watts), such as fractional horse- er motors, and intended solely for operation on supply circuits not exceeding volts, shall be tested with 900 volts.
e) *Alternating-current Machines Connected to Permanently Grounded Single- se Systems:* Alternating-current machines connected to permanently unded single-phase systems, for use on permanently grounded circuits operat- at more than 300 volts shall be tested with 2.73 times the voltage of the uit to ground, plus 1000 volts. This does not refer to three-phase machines i grounded star neutral.
(f) *Machines for Use on Circuits of 25 Volts or Lower:* Machines for use on uits of 25 volts or lower, such as bell-ringing apparatus, electric machines l in automobiles, machines used on low-voltage battery circuits, etc., shall ested with 500 volts.

Regulation

390. Conditions for Tests of Regulation (see § 2390). — (a) *Power Factor:* alternating-current generators the power factor of the load to which the ulation refers should be specified. Unless otherwise specified, it shall be erstood as referring to non-inductive load, that is, to a load in which the ent is in phase with the e.m.f. at the terminals of the machine.
) *Excitation:* In commutating machines, rectifying machines and syn- nous machines, the regulation shall be determined under such conditions e maintain the field adjustment constant at a value which gives rated-load age at rated-load current. These conditions are as follows:
i the case of separately excited fields: constant excitation.
i the case of shunt machines: constant resistance in the shunt-field circuit.
i the case of series or compound machines: constant resistance shunting the es field windings.

391.* Tests and Computation of Regulation of A-C. Generators. — (a) *hods Available:* The regulation of alternating-current generators may be rmined by any one of the three following methods, which are given in the er of preference:
) *Method I. By Loading:* The regulation can be measured directly, by ing the generator at the specified output and power factor, then reducing load to zero, and measuring the terminal voltage, with speed and excitation ained to the same values as before the change. This method is not generally licable for shop tests, particularly on large generators and it becomes neces- to determine the regulation from such other tests as can be readily made.
(c) *Method II. From Test Curves:* This method consists in computing the

---

361 b) Series-field windings should be regarded as part of the armature circuit and ed as such.
361 c) By normal induced voltage is here meant the voltage between slip rings on circuit at standstill with normal voltage impressed on the primary.
361 f) The present National Electrical Code limit for a single outlet is 660 watts.
391 c) Method II for deducing the load-saturation curve, at any assigned power

regulation from experimental data of the open-circuit saturation curves and the zero-power-factor saturation curve. The latter curve, or one approximating very closely to it, can be obtained by over-exciting the generator while carrying a load of idle-running under-excited synchronous motors. The power factor under these conditions is very low and the load-saturation curve approximates very closely the zero-power-factor saturation curve. From this curve and the open-circuit curve, points for the load-saturation curve for any specified power factor can be obtained by means of vector diagrams.

regarded as empirical. Its value depends upon the fact that experience has demonstrated the reasonable correctness of the results obtained by it.

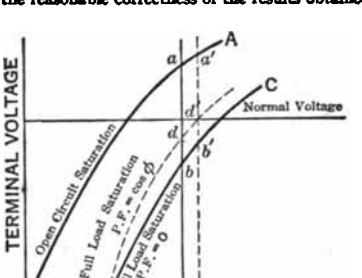

Fig. 4-3

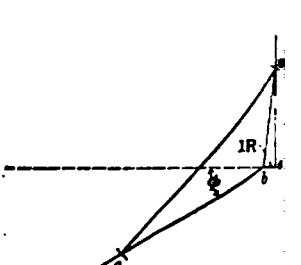

Fig. 4-4

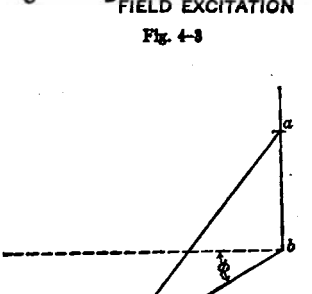

Fig. 4-5

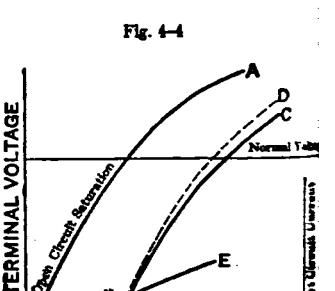

Fig. 4-6

To apply Method II, it is necessary to obtain from test the open-circuit saturation curve Fig. 4-3, and the load-saturation curve $B\,C$ at zero power factor and rated-load current. At any given excitation $O\,c$, the voltage that would be induced on open circuit is $c\,a$; the terminal voltage at zero power factor is $c\,b$ and the apparent internal drop is $a\,b$. The terminal voltage $c\,d$ at any other power factor can then be found by drawing an exact diagram as in Fig. 4-4, where ϕ is an angle such that $\cos\phi$ is the power factor of the load, $b\,e$ the resistance drop ($I\,R$) in the stator winding, $b\,a$ the total internal drop and $a\,c$ the total induced voltage; $b\,a$ and $a\,c$ being laid off to correspond with the values obtained from Fig. 4-3. The terminal voltage at power factor $\cos\phi$ is then c-b Fig. 4-4, which when laid off in Fig. 4-3 gives point d. By finding a number of such points, the curve $B\,d\,d'$ for power factor $\cos\phi$ is obtained and the regulation at this power factor (expressed in per cent) is $\frac{100\times a'\,d'}{c'\,d'}$ since $a'\,d'$ is the rise in voltage when the load at power factor $\cos\phi$ is thrown off at normal voltage $c'\,d'$.

Generally, the ohmic drop can be neglected as it has little influence on the regulation.

Digitized by Google

(d) *Method III. From Estimated Zero-power-factor Curve.* Where it is not sible to obtain by test a zero-power-factor curve as in Method II this curve be estimated closely from open-circuit and short-circuit curves, by reference tests at zero power factor on other machines of similar magnetic circuit. ving obtained the estimated zero-power-factor curve, the load saturation for other power factor is obtained as in Method II, § 4394 (c).

396. Compound Wound D-C. Generator. — In determining the regulation compound-wound d-c. generator, two tests shall be made, one bringing the d down and the other bringing the load up, between no-load and rated load. ese may differ somewhat, owing to residual magnetism. The mean of the results shall be used.

s where regulation at unity power factor is being estimated. For low power factors effect is negligible in practically all cases. If resistance is neglected, the simpler gram Fig. 4-5, may be used.

4394 d) Method III is the same as Method II except that the zero-power-factor curve st be estimated. This may be done as follows. In Fig. 4-6, $O A$ is the open-circuit ration curve and $O E$ the short-circuit line as obtained from test. The zero-power- or curve corresponding to any current $B F$ will start from point B, and for machines gned with low saturation and low reactance, will follow parallel to $O A$ as shown by dotted curve $B D$, which is $O A$ shifted horizontally parallel to itself by the distance . In high-speed machines, or in others having low reactance, and a low degree of ration in the magnetic circuit, the zero-power-factor curve will be quite close to $B D$ ticularly in those parts that are used for determining the regulation. This is the case h many turbo-generators and high-speed water-wheel generators.

n many cases, however, the zero-power-factor curve will deviate from $B D$, as shown by and the deviation will be most pronounced in machines of high reactance, high satura- and large magnetic leakage. The position of curve $B C$ with relation to $B D$ can be roximated with sufficient exactness by investigating the corresponding relation as ained by test at zero power factor on machines of similar characteristics and magnetic uit. Curve $B C$ can also be calculated by methods based on the results of test at power factor. After curve $B C$ has been obtained, the load-saturation curve and lation for any other power factor can be derived as in Method II, § 4394 (c).

CHAPTER V

STANDARDS FOR ELECTRIC RAILWAYS AND FOR AUTOMOBILE PROPULSION MACHINES

The A. I. E. E. Standards for Electric Railways and for Automobile Propulsion Machines are the General Standards shown in Chapters II and III, and the Standards in other Chapters which are applicable to the devices involved, together with the modifications and extensions given in this Chapter.

DEFINITIONS

General

5000. Contact Conductors. — A contact conductor is that part of the distribution system other than the traffic rails, which is in immediate electrical contact with the circuits of the cars or locomotives.

Contact Rails

5003.* Contact Rail. — (a) *General:* A contact rail is a rigid contact conductor.

*(b) *Overhead Contact Rail:* An overhead contact rail is a contact rail which is above the elevation of the maximum equipment line.

(c) *Third Rail:* A third rail is a contact conductor placed at either side of the track, the contact surface of which is a few inches above the level of the top of the track rails.

(c) *Center Contact Rail:* A center contact rail is a contact conductor placed between the track rails, having its contact surface above the ground level.

(e) *Underground Contact Rail:* An underground contact rail is a contact conductor placed beneath the ground level.

(f) *Gage of Third Rail:* The gage of a third rail is the distance, measured parallel to the plane of running rails, between the gage line of the nearest track rail and the inside gage line of the contact surface of the third rail.

(g) *Elevation of Third Rail:* The elevation of a third rail is the elevation of the contact-surface of the third rail, with respect to the plane of the top of running rails.

(h) *Third Rail Protection:* A third rail protection is a guard for the purpose of preventing accidental contact with the third rail.

Trolley Wires

5004. Trolley Wire. — A trolley wire is a flexible contact conductor, customarily supported above the cars.

5005. Messenger Wire or Cable. — A messenger wire or cable is a wire or cable running along with and supporting other wires, cables or contact conductors.

A primary messenger is directly attached to the supporting system. A secondary messenger is intermediate between a primary messenger and the wires, cables or contact conductors.

5006. Classes of Construction. — (a) *General:* Overhead trolley constructions are classed as *Direct Suspension* and *Messenger or Catenary Suspension.*

(b) *Direct Suspension:* A direct suspension is the form of overhead trolley construction in which the trolley wires are attached, by insulating devices, directly to the main supporting system.

(c) *Messenger or Catenary Suspension:* A messenger or catenary suspension is the form of overhead trolley construction in which the trolley wires are attached, by suitable devices, to one or more messenger cables, which in turn may be carried either in *Simple Catenary, i.e.,* by primary messengers, or in *Compound Catenary, i.e.,* by secondary messengers.

(5003 b) The maximum equipment line is the contour which embraces cross-sections of all rolling stock under all normal operating conditions.

Digitized by Google

5027. Supporting Systems. — (a) *General:* Supporting systems for trolley res shall be classed as follows:

(b) *Simple Cross-Span Systems:* Simple cross-span systems are those having at each support a single flexible span across the track or tracks.

(c) *Messenger Cross-span Systems:* Messenger cross-span systems are those having at each support two or more flexible spans across the track or tracks, the upper span carrying part or all of the vertical load of the lower span.

(d) *Bracket Systems:* Bracket systems are those having at each support an arm or similar rigid member, supported at only one side of the track or tracks.

(e) *Bridge Systems:* Bridge systems are those having at each support a rigid member, supported at both sides of the track or tracks.

5030.* Transmission System. — When the current generated for an electric ilway is changed in kind or voltage, between the generator and the cars or omotives, that portion of the conductor system carrying current of a kind or ltage substantially different from that received by the cars or locomotives, nstitutes the *transmission system.*

5031.* Distribution System. — That portion of the conductor system of an ctric railway which carries current of the kind and voltage received by the cars locomotives, constitutes the *distribution system.*

5032. Substation. — A substation is a group of apparatus or machinery hich receives current from a transmission system, changes its kind or voltage, d delivers it to a distribution system.

OPERATION

Temperature Limits

5101.* Railway Motors in Continuous Service. — The following maximum bservable temperatures are permissible in the windings of railway motors, hen in continuous service.

TABLE 501

Temperatures of Railway Motors in Continuous Service

Class of material See § 1004	Temperature	
	By Thermometer See § 1002	By Resistance See § 1002
A	85° C.	110° C.
B	100° C.	130° C.

5120. Railway Substation Machines and Transformers. — Under conditions pecified in § 5201, the windings of railway substation machines and transformers carrying traction loads may have observable temperature rises 5° C. n excess of the limiting observable temperature rises specified in Table 200.

5130.* Automobile Propulsion Machines. — On stand test, the *observable* emperature rises shall not exceed the limits specified in § 5205.

RATING

Ratings of Railway Substation Machinery and Transformers

5201.* Nominal Rating of Railway Substation Machines and Transformers. — The nominal rating of a substation machine or transformer carrying traction

(5030 and 5031) These definitions are identical in sense, although not in words, with [illegible]

Digitized by Google

loads shall be the kv-a. output at a stated power factor input, which, having produced a constant temperature in the machine or transformer, may be increased 50 per cent for two hours, without producing temperature rises exceeding by more than 5° C. the limiting values given in Table 200. These machine or transformers should be capable of carrying a load of twice their nominal rating for a period of one minute, without disqualifying them for continuous service. The name plate should be marked "nominal rating."

Ratings of Railway Motors

5202.* Nominal Rating of Railway Motors. — The nominal rating of a railway motor shall be the mechanical output at the car or locomotive axle, measured in kilowatts, which causes a rise of temperature above the surrounding air, by thermometer, not exceeding 90° C. at the commutator, and 75° C. at any other normally accessible part after one hour's continuous run at its rated voltage (and frequency in the case of an alternating-current motor) on a stand with the motor covers arranged to secure maximum ventilation without external blower. The rise in temperature as measured by resistance shall not exceed 100° C. The statement of the nominal rating shall include the corresponding voltage and armature speed.

5203.* Continuous Ratings of Railway Motors. — The continuous ratings of a railway motor shall be the *inputs* in amperes at which it may be operated continuously at ⅓, ½ and full voltage respectively, without exceeding the observable temperature rises specified in Table 502, when operated on stand test with motor covers and cooling system, if any, arranged as in service. Inasmuch as the same motor may be operated under different conditions as regards ventilation, it will be necessary in each case to define the system of ventilation which is used. In case motors are cooled by external blowers, the flow of air on which the rating is based shall be given.

TABLE 502

Stand-test Temperature Rises of Railway Motors

Class of material See § 1004	Temperature rises of windings	
	By Thermometer See § 1002	By Resistance See § 1002
A	65° C.	85° C.
B	80° C.	105° C.

5204. Field-control Railway Motors. — The nominal and continuous ratings of field-control motors shall relate to their performance with the operating field which gives the maximum motor rating. Each section of the field windings shall be adequate to perform the service required of it, without exceeding the specified temperature rises.

Ratings of Automobile Propulsion Machines

5205. Automobile Propulsion Machines. — The rating of automobile motors and generators shall be based upon temperature rise, on a stand test and with motor covers arranged as in service, fifteen degrees by thermometer or twenty-five degrees by resistance, above those of Table 200.

(5201 and 5202) In the absence of any specification as to the kind of rating the "nominal" rating shall be understood.

(5203) The temperature rise in service may be very different from that on stand-test. See § 5502 for the relation between stand-test and service temperatures as affected by ventilation.

Digitized by Google

Ratings of Electric Locomotives

§210. Rating. — Locomotives shall be rated in terms of the weight on drivers, nominal one-hour tractive effort, continuous tractive effort and corresponding speeds.

§211. Weight on Drivers. — The weight on drivers, expressed in pounds, shall be the sum of the weights carried by the drivers and of the drivers themselves.

§212. Nominal Tractive Effort. — The nominal tractive effort, expressed in pounds, shall be that exerted at the rims of the drivers when the motors are operating at their nominal (one-hour) rating.

§213. Continuous Tractive Effort. — The continuous tractive effort, expressed in pounds, shall be that exerted at the rims of the drivers when the motors are operating at their full-voltage continuous rating, as indicated in § 5203.

In the case of locomotives operating on intermittent service, the continuous tractive effort may be given for ½ or ¾ voltage, but in such cases the voltage shall be clearly specified.

§214. Speed. — The rated speed, expressed in miles per hour, shall be that at which the continuous tractive effort is exerted.

TESTS

Efficiency

Losses in D-C. Railway Motors

§337. Losses in Gearing and Axle Bearings. — The losses in gearing and axle bearings for single-reduction single-geared motors, varies with the type, mechanical finish, age and lubrication. The following values, based upon accumulated tests, shall be used in the comparison of single-reduction single-geared motors § 5339.

TABLE 503

Losses in Axle Bearings and Single-reduction Gearing of Railway Motors

Per cent of input at nominal rating	Loses as per cent of input
200	3.5
150	3.0
125	2.7
100	2.5
75	2.5
60	2.7
50	3.2
40	4.4
30	6.7
25	8.5

Note. — Further investigation may indicate the desirability of giving separate values of the losses for full and tapped fields, or low- and high-speed motors.

§338. Brush Friction, Armature-bearing Friction and Windage. — The brush friction, armature-bearing friction and windage shall be determined as a total under the following conditions:

In making the test, the motor shall be run without gears. The kind of brushes and the brush pressure shall be the same as in commercial service. Drive the machine idle as a series motor on low voltage. The product of armature counter-

electromotive-force and amperes at any speed shall be the sum of the above losses at that speed. See § 5339.

5339.* No-load Core Loss, Brush Friction, Armature-bearing Friction and Windage. — The no-load core loss, brush friction, armature-bearing friction and windage shall be determined as a total under the following conditions:

In making the test, the motor shall be run without gears. The kind of brushes and the brush pressure shall be the same as in commercial service. With the field separately excited, such a voltage shall be applied to the armature terminals as will give the same speed for any given field current as is obtained with that field current when operating at normal voltage under load. The sum of the losses above-mentioned, is equal to the product of the counter-electromotive force and the armature current.

The no-load core loss is obtained by deducting from the total losses thus obtained the power required to drive the motor at corresponding speeds as determined under § 5338.

The core loss under load shall be assumed to have the values given in Table 504.

TABLE 504

Core Loss in D-C. Railway Motors at Various Loads

Per cent of input at nominal rating	Loss as per cent of no-load core loss
200	165
150	145
100	130
75	125
50	123
25 and under	122

Note. — With motors designed for field control the core losses shall be assumed as the same for both full and permanent field. It shall be the mean between the no-load losses at full and permanent field, increased by the percentages given in the above table.

5341. Automobile Motors. — When automobile motors are of low voltage, the great influence of brush-contact losses on the efficiency requires that these losses be determined experimentally for the type of brush used.

(5339) In comparing projected railway motors, and in case it is not possible or desirable to make tests to determine mechanical losses, the following values of these losses, determined from the averages of many tests over a wide range of sizes of single-reduction, single-geared motors, will be found useful, as approximations. They include axle-bearing, gear, armature-bearing, brush-friction, windage, and stray-load losses.

TABLE 505

Approximate Losses in D-C. Railway Motors

Input in per cent of that at nominal rating	Losses as per cent of input
100 or over	5.0
75	5.0
60	5.3
50	6.5
40	8.8
30	13.3
25	17.0

The core loss of railway motors may also be determined as specified for other machines.

Digitized by Google

CHARACTERISTIC CURVES OF RAILWAY MOTORS

[illegible] General. — The Characteristic Curves of railway motors shall be [illegible]etted with the current as abscissas and the tractive effort, speed and efficiency [illegible]ordinates. In the case of a-c. motors, the power factor shall also be plotted [illegible]ordinates.

[illegible] Voltage. — Characteristic curves of direct-current motors shall be based on full voltage, which shall be taken as 600 volts, or a multiple thereof.

[illegible] Field-Control Motors. — In the case of field-control motors, characteristic curves shall be given for all operating field connections.

SELECTION OF RAILWAY MOTOR FOR SPECIFIED SERVICE

[illegible] Data Required in Selecting Motor. — The following information, relative to the service to be performed, is required, in order that an appropriate motor may be selected.

(a) Weight of total number of cars in train (in tons of 2000 lb.) exclusive of electrical equipment and load.
(b) Average weight of load and durations of same, and maximum weight of load and durations of same.
(c) Number of motor cars or locomotives in train, and number of trailer cars in train.
(d) Diameter of driving wheels.
(e) Weight on driving wheels, exclusive of electrical equipment.
(f) Number of motors per motor car.
(g) Voltage at train with power on the motors—average, maximum and minimum.
(h) Rate of acceleration in miles per hour per second.
(i) Rate of braking (in miles per hour per second).
(j) Speed limitations, if any (including slowdowns).
(k) Distances between stopping points.
(l) Average duration of stops.
(m) Schedule speed, including stops, in miles per hour.
(n) Train resistance in pounds per ton of 2000 pounds at stated speeds.
(o) Moment of inertia of revolving parts, exclusive of electrical equipment.
(p) Profile and alignment of track.
(q) Distance coasted as a percentage of the distance between stopping points.
(r) Duration of layover at end of run, if any.

[illegible] Method of Comparing Motor Capacity with Service Requirements. When it is not convenient to test motors under actual specific service conditions, recourse may be had to the following method of determining temperature from the stand-tests.

The essential motor losses affecting temperatures in service are those in the armature windings, core and commutator. The mean service conditions may be assumed, as a close approximation, in terms of that continuous current and core loss which will produce the same losses and distribution of losses as the average service.

[illegible]3027] Calculation for comparing motor capacity with service requirements. The rating of a motor should be determined, wherever possible, by testing it in service, or on an equivalent duty-cycle. When the service or equivalent duty-cycle tests are not available, the ratings of the motor may be utilized as follows to determine its temperature rise.

The motor losses which affect the heating of the windings are as stated above, those in the windings and in the core. The former are proportional to the square of the current, the latter vary with the voltage and current, according to curves which can be supplied by the manufacturers. The procedure is therefore as follows:

Plot a time-current curve, a time-voltage curve, and a time-core loss curve for the duty-cycle which the motor is to perform, and calculate from these the root-mean-square current and the average core loss.

If the calculated r.m.s. service current exceeds the continuous rating, when run with average service core loss and speed, the motor is not sufficiently powerful for the duty-cycle contemplated.

Digitized by Google

A stand-test with the current and voltage which will give losses equal to those in service, will determine whether the motor has sufficient capacity to meet the service requirements. In service, the temperature rise of an enclosed motor (§ 4044), well exposed to the draught of air incident to a moving car or locomotive, will be from 75 to 90 per cent (depending upon the character of the service) of the temperature rise obtained on a stand-test with the motor completely enclosed and with the same losses. With a ventilated motor (§ 4045 and § 4047) the temperature rise in service will be 90 to 100 per cent of the temperature rise obtained on a stand-test with the same losses.

In making a stand-test to determine the temperature rise in a specific service it is essential in the case of a self-ventilated motor (§ 4046) to run the armature at a speed which corresponds to the schedule speed in service. In order to obtain this speed it may be necessary, while maintaining the same total armature losses, to change somewhat the ratio between the I^2R and core-loss components.

CONSTRUCTION

5601.* Standard Height of Trolley Wire on Street and Interurban Railways. — It is recommended that supporting structures shall be of such height that the lowest point of the trolley wire shall be at a height of 18 feet (5.5 m.) above the top of rail under conditions of maximum sag, unless local conditions prevent. On trackage operating electric and steam road equipment and at crossings with steam roads, it is recommended that the trolley wire shall be not less than 21 feet (6.4 m.) above the top of rail, under conditions of maximum sag.

5602. Standard Gage of Third Rails. — The gage of third rails shall be not less than 26 inches (66 cm.) and not more than 27 inches (68.6 cm.).

5603. Standard Elevation of Third Rails. — The elevation of third rails shall not be less than 2¾ inches (7 cm.) and not more than 3½ inches (8.9 cm.).

BIBLIOGRAPHY

United States

American Electric Railway (Engineering) Association: Engineering Manual.
Association of Railway Electrical Engineers: Standards.

(c) If the calculated r.m.s. service current does not exceed the continuous rating, the motor will run with average service core loss and speed, the motor is ordinarily suitable for the service.

In some cases, however, it may not have sufficient thermal capacity to avoid excessive temperature rises during the periods of heavy load. In such cases a further calculation is required, the first step of which is to compute the equivalent voltage which, with the r.m.s. current, will produce the average core loss. Having obtained this, determine as follows, the temperature rise due to the r.m.s. service current and equivalent voltage:

Let θ_0 = temperature rise
$p_0 = I^2R$ loss, kw.
p_c = core loss, kw.
} with r.m.s. service current, and equivalent service voltage.

θ_s = temperature rise
$P_0 = I^2R$ loss, kw.
P_c = core loss, kw.
} with continuous load current corresponding to the equivalent service voltage.

Then

$$\theta = \theta_s \frac{p_0 + p_c}{P_0 + P_c}, \text{ approximately.}$$

(d) The thermal capacity of a motor is approximately measured by the ratio of the electrical loss in kw. at its nominal (one-hour) capacity, to the corresponding maximum observable temperature rise during a one-hour test starting at ambient temperature.

(e) Consider any period of peak load and determine the electrical losses in kilowatt hours during that period from the *electrical* efficiency curve. Find the excess of these losses over the losses with r.m.s. service current and equivalent voltage. The excess is divided by the coefficient of thermal capacity, will equal the extra temperature rise during the peak load. This temperature rise added to that due to the r.m.s. service current and equivalent voltage, gives the total temperature rise. If the total temperature rise in such period exceeds the safe limit, the motor is not sufficiently powerful for the service.

(f) If the temperature reached, due to the peak loads, does not exceed the safe limit, the motor may yet be unsuitable for the service, as the peak loads may cause excessive sparking and dangerous mechanical stresses. It is, therefore, necessary to compare the peak loads with the short-period overload capacity. If the peaks are also within the capacity of the motor, it may be considered suitable for the given duty-cycle.

CHAPTER VI

STANDARDS FOR TRANSFORMERS AND OTHER STATIONARY INDUCTION APPARATUS

Wherever the General Standards in Chapters II and III apply to transformers r are referred to in the following Chapter by cross references.
Certain rules applying exclusively to railway machinery have, for convenience, n placed in Chapter V with cross references in all case to this Chapter. es in Chapter VI apply to railway machinery except as they are modified he rules in Chapter V.
Note: The word "Transformer" will be used throughout this Chapter as abbreviation of "Transformer or other stationary induction apparatus."

DEFINITIONS

Apparatus

100. Stationary Induction Apparatus. — For the purpose of these Standards, onary induction apparatus is defined as electric apparatus which changes ric energy to electric energy through the medium of magnetic energy, with- mechanical motion. It comprises several forms, as defined in §§ 6001 and 2 to 6015.

101. Transformer. — A transformer is a form of stationary induction appa- s in which the primary and secondary windings are ordinarily insulated one n another.

110. Auto-transformer. — An auto-transformer is one which has a part of urns common to both primary and secondary circuits.

111. Voltage-regulator. — A voltage-regulator is a form of stationary uction apparatus which has turns in shunt and turns in series with the circuit, rranged that the voltage ratio of the transformation, or the phase relation reen the circuit-voltages, is variable at will.

112. Contact Voltage-regulator. — A contact voltage-regulator is a voltage lator in which the number of turns in one or both of the coils is adjustable.

113. Induction Voltage-regulator. — An induction voltage-regulator is one hich the relative position of the primary and secondary coils is adjustable.

114. Magneto Voltage-regulator. — A magneto voltage-regulator is one in h the direction of the magnetic flux with respect to the coils is adjustable.

115. Reactor. — A reactor is a device used primarily because it possesses roperty of reactance. Reactors are used in electric circuits for purposes of ation, protection or control.

Parts of Apparatus

120. High-voltage and Low-voltage Winding. — The terms "high voltage" "low voltage" are used to distinguish the winding having the greater from having the lesser number of turns.

Digitized by Google

6021. Primary and Secondary Windings. — The terms "primary" a "secondary" serve to distinguish the windings in regard to energy flow, t primary being that which receives the energy from the supply circuit, and t secondary that which receives the energy by induction from the primary.

6022. Full Capacity Tap.—A full capacity tap is a tap from a transfor winding on which the unit may be operated at rated kv-a. capacity with exceeding the specified temperature rise.

6023. Reduced Capacity Tap.—A reduced capacity tap is one on which t unit may not be operated at full capacity without exceeding the specified tem erature rise.

Properties of Apparatus

6031. Rated Current of a Constant-potential Transformer. — The rated c rent of a constant-potential transformer is that secondary current which, m plied by the rated-load secondary voltage, gives the kv-a. rated output. T is, a transformer of given kv-a. rating must be capable of delivering the r output at rated secondary voltage, while the primary impressed voltag increased to whatever value is necessary to give rated secondary voltage.

6032. Full or Reduced Capacity Taps.—Where transformers are provi with taps from either the high-voltage or low-voltage windings, a definite st ment shall be made as to whether such are full capacity or reduced capacity t

6033. Rated Primary Voltage of a Constant-potential Transformer. — T rated primary voltage of a constant-potential transformer is the rated secon voltage multiplied by the turn ratio.

6034. Ratio of a Transformer. — The ratio of a transformer, unless other specified, shall be the ratio of the number of turns in the high-voltage win to that in the low-voltage winding; *i.e.*, the "turn-ratio."

6035. Voltage Ratio of a Transformer. — The voltage ratio of a transfo the ratio of the r.m.s. primary terminal voltage to the r.m.s. secondary te voltage, under specified conditions of load.

6036. Current Ratio of a Transformer. — The current ratio of a tra transformer is the ratio of the r.m.s. primary current to the r.m.s. secon current, under specified conditions of load.

6037. Volt-ampere Ratio of Transformer. — The volt-ampere ratio, w should not be confused with real efficiency, is the ratio of the volt-ampere ou to the volt-ampere input of a transformer at any given power factor.

6050.* Per Cent Resistance Drop. — The per cent resistance drop in a tra former is the ratio of the internal resistance drop at 75° C. to the secon terminal voltage expressed in per cent.

6051.* Per Cent Reactance Drop. — The per cent reactance drop in a tra former is the ratio of the internal reactance drop to the secondary termi voltage expressed in per cent.

6052.* Per Cent Impedance Drop. — The per cent impedance drop in a tra former is the ratio of the internal impedance drop at 75° C. to the secon terminal voltage expressed in per cent.

6053. Regulation of Constant-Potential Transformer. — In constant-po tial transformers, the regulation is the difference between the no-load and fu load values of the secondary terminal voltage at the specified power fa (with constant primary impressed terminal voltage) expressed in per cent rated-load secondary voltage, the primary voltage being adjusted to th value that the apparatus delivers rated output at rated secondary volt See § 6390.

Ambient Temperature. — See § 3000.

(6050-6051-6052) The internal drop in a transformer is the sum of the primary d (reduced to secondary terms) and the secondary drop.

RATING

General

6201 TABLE 601

Limiting Observable Temperatures and Temperature Rises for Transformers Using Class A* Insulation

	†Air cooled and air blast	Oil cooled	Water cooled
Limiting observable temperature	95° C.	95° C.	80° C.
Standard ambient temperature	40° C.	40° C.	25° C.
Limiting observable temperature rise	55° C.	55° C.	55° C.

* For cotton, silk, paper and similar materials when neither treated, impregnated nor immersed in oil, the limits of the observable temperature rise shall be 15° C. below the limits fixed for these materials when impregnated.

† For exceptions in the case of Airblast Transformers, see § 6320 (b).

The temperature of the windings of transformers is always to be ascertained by Method 2.

6202. Limiting Observable Temperature of Oil (From § 2232). — The oil in which apparatus is permanently immersed shall, in no part, have a temperature, observable by thermometer, in excess of 90° C.

Permissible Temperatures of Insulations of More than One Class. — See § 2104.

Temperatures of Metallic Parts of Transformers. — See § 2116.

Protection Against Short Circuit. — See § 2120.

Nominal Rating of Railway Substation Transformers. — See § 5201.

Expression of Rating. — See § 2202.

Institute Rating. — See § 2204.

6204.* Rating of Protective Reactors. — Protective reactors shall be rated on the following characteristics:

(a) Kilovolt-amperes absorbed by normal current.

(b) Normal current, frequency and line (delta) voltage.

(c) Current which the device is required to stand under short-circuit conditions.

Ambient Temperature of Reference

Ambient Temperature of Reference for Air. — See § 2211.

Ambient Temperature of Reference for Water-cooled Transformers. — See § 2212.

Transformers Cooled by Other Means. — See § 2213.

Outdoor Transformers Exposed to Sun's Rays. — See § 2214.

Altitude Correction

Altitude. — See § 2215.

6215. Exception to "Altitude." — See § 2215. — Water-cooled oil-immersed transformers are exempt from this reduction.

Units in Which Rating Shall be Expressed

6221. Rating of Transformers. — The rating of transformers shall be expressed in kilovolt-amperes (kv-a.) available at the output terminals, at a specified frequency and voltage.

6223. Rating of Other Stationary Induction Apparatus. — Other stationary induction apparatus, such as auto-transformers, regulators, reactors, etc., shall have their ratings appropriately expressed. It is also essential to specify the voltage and frequency of the circuits on which the apparatus may be used.

(6204) Reactors shall be so designed as to be capable of withstanding the sudden application, without mechanical injury, of rated current at normal frequency.

Kinds of Rating

Continuous Rating. — See § 2220.
Short-time Rating. — See § 2221.
Duty-cycle Operation. — See § 2222.
Standard Short-time Ratings. — See § 2223.
A. I. E. E. and I. E. C. Ratings. — See § 2224.
Continuous Rating Implied. — See § 2225.

6236. Nominal Ratings. — Nominal ratings are ratings which do not conform with §§ 2220 and 2221. They are sometimes used for railway substation transformers carrying traction loads. Transformers with nominal rating shall be capable of operating under the conditions enumerated in § 5201.

Rating by Temperature Rise

Permissible Temperature Rises for Various Ambient Temperatures above Standard. — See § 2231 (c).

TESTS

Ambient Temperature

Measurement of Ambient Temperatures during Tests of Transformers. — See § 2300.

6300. Measurement of the Ambient Temperature During Tests of Water-cooled Transformers. — The temperature rise of water-cooled transformers shall be based entirely upon the temperature of the cooling water and it is not necessary to take into account the heat carried off by the air, unless it exceeds the amount specified below. If, under assumed standard conditions of water at 25° C., and air at 40° C., the amount of heat which would be carried off by the air is 15 per cent or more of the total, the temperature of the cooling water, during test, should be maintained within 5° C. of that of the surrounding air. Where this is impracticable the ambient temperature should be determined from the change in the resistance of the windings, using a disconnected transformer, supplied with the normal amount of cooling water, until the temperature of the windings has become constant.

Oil Cup. — See § 2301.

Transformer Temperatures

Temperature Rise for Any Ambient Temperature. — See § 2310.

Correction for the Duration of the Ambient Temperature of the Cooling Medium, at the Time of the Heat Test, from the Standard Ambient Temperature of Reference. — See § 2311.

6311.* Correction for the Deviation of the Ambient Temperature of the Cooling Medium, at the Time of the Heat Test of Air-blast Transformers from the Standard Ambient Temperature of Reference. — A correction shall be applied to the observed temperature rise of the windings of air-blast transformers due to difference in resistance, when the temperature of the ingoing cooling air differs from that of the standard of reference. This correction shall be the ratio of the inferred absolute ambient temperature of reference to the inferred absolute temperature of the ingoing cooling air, *i.e.*, the ratio $274.5/(234.5+\theta)$; where θ is the ingoing cooling-air temperature.

Duration of Temperature Test of Transformers for Continuous Service. — See § 2312.

Duration of Temperature Test of Transformer with a Short-time Rating. — See § 2313.

Duration of Temperature Test for Transformer Having More than One Rating. — See § 2314.

Temperature Measurements During Heat Run. — See § 2315.

(6311) Thus, a cooling-air room temperature of 30° C. would correspond to an inferred absolute temperature of 264.5° on the scale of copper resistivity, and the correction to 40° C. (274.5° inferred absolute temperature) would be $274.5/264.5 = 1.04$, making the correction factor 1.04; so that an observed temperature rise of say 50° C. at the testing ambient temperature of 30° C. would be corrected to $50 \times 1.04 = 52$° C., this being the temperature rise which would have occurred had the test been made with the standard ingoing cooling-air temperature of 40° C.

§317. Methods of Loading Transformers for Temperature Tests. — (a) *General:* Whenever practicable, transformers should be tested under conditions that will give losses approximating as nearly as possible to those obtained under normal or specified load conditions, maintained for the required time. The maximum temperature rises measured during this test should be considered as the observable temperature rises for the given load. See §§ 2312 to 2314.

An approved method of making these tests is the *loading-back* method. The principal variations of this method are given in § 6317 (b), (c) and (d).

(b) *Loading-back with duplicate single-phase transformers:* Duplicate single-phase transformers may be tested in banks of two, with both primary and secondary windings connected in parallel. Normal magnetizing voltage should then be applied and the required current circulated from an auxiliary source. One transformer can be held under normal voltage and current conditions while the other may be operating under slightly abnormal conditions.

(c) *Loading-back with one three-phase transformer:* One three-phase transformer may be tested in a manner similar to § 6317 (b) provided the primary and secondary windings are each connected in delta for the test. Normal three-phase magnetizing voltage should be applied and the required current circulated from an auxiliary single-phase source.

(d) *Loading-back with three single-phase transformers:* Duplicate single-phase transformers may be tested in banks of three in a manner similar to that described in § 6317 (c), by connecting both primary and secondary windings in delta, applying normal three-phase magnetizing voltage and circulating the required current from an auxiliary single-phase source.

(e) *Other Methods:* Among other methods that have a limited application and can be used only under special conditions may be mentioned:

Applying dead load by means of some form of rheostat.

Running alternately for certain short intervals of time on open circuit and then on short-circuit, alternating in this way until the transformer reaches a steady temperature. In this test, the voltage for the open-circuit interval and the current for the short-circuit interval shall be such as to give the same integrated core loss, and the same integrated copper loss as in normal operation.

§320. Method of Temperature Measurement. — (a) *Description:* The temperature of transformer windings shall be measured by their increase in resistance, corrected to the instant of shut-down when necessary, and by thermometers. Whichever measurement yields the higher temperature, that temperature shall be taken as the highest observable temperature by Method 2.

(b) In the case of air-blast transformers, it is important to have the thermometers well distributed and in good contact with the coils, and it is especially important to note the temperature near the air outlet. In measuring the temperature of air-blast transformers, the air supply shall be shut off immediately at the end of the temperature run and the air intake closed to prevent further admission of cooling air. With the above procedure, the observable temperature rise for air-blast transformers may attain a value not in excess of 40° C. as determined by thermometer, although it must not exceed 55° C. as determined by resistance.

(c) *Temperature Correction for Cooling of Transformer Windings after Shut-down:* Since a drop in temperature occurs in a winding between the instant of shut-down and the time of measuring the hot resistance, a correction shall be applied to the temperature determined from this measurement so as to obtain, as nearly as practicable, the temperature at the instant of shut-down. This correction may be determined approximately by plotting a time-temperature curve with temperatures as ordinates and times as abscissas and extrapolating back to the instant of shut-down.

In cases where successive measurements show increasing temperatures after shut-down the highest value shall be taken.

In certain cases, however, other correction factors may be applied as follows:

Oil-Immersed Transformers: For the purpose of simplifying the application of the rule to transformers when the weight of copper in each winding is known and the copper loss as determined by wattmeter measurement does not exceed 10 watts per pound, the extrapolation method has been reduced to the following

under ordinary conditions of testing. The correction in degrees C. shall be the product of the watts loss per pound of copper for each winding multiplied by a factor depending upon the time elapsed between shut-down and the time of the temperature reading as given in the following table:

Time in minutes	Factor
1	0.19
2	0.32
3	0.43
4	0.50

For intermediate times, the value of the factor can be obtained by interpolation.

When the copper loss, measured by wattmeter, does not exceed 7 watts per pound an arbitrary correction of one degree per minute may be used provided the time elapsed between the instant of shut-down and the measurement of the hot resistance does not exceed four minutes.

For determining the copper loss in watts per pound, the total loss in both windings as measured by the wattmeter should be apportioned between the high- and low-voltage windings in the same ratio as their respective I^2R losses.

Air-blast Transformers: An arbitrary correction of one degree per minute may be used provided the time elapsed between the instant of shut-down and the measurement of the hot resistance does not exceed four minutes.

(d) *Covering of Thermometers:* Thermometers used for taking the temperature of air-cooled or air-blast transformers shall have their bulbs covered for protection from air currents. This shall be done by felt pads, approximately 4 cm. × 5 cm. (1½ in. × 2 in.) and 3 mm. (⅛ in.) thick, except that where pads are inconvenient, as in ventilating ducts between coils, grooved wooden strips may be used.

Temperature Coefficient of Copper. — See § 2321.

Efficiency

Efficiencies Recognized. — See § 2331.

Normal Conditions for Efficiency Tests. — See § 2332.

Direct Measurement of Efficiency. — See § 2333.

6334. Classification of Losses. — (a) *General:* Losses are classified as shown below.

(b) *No-load Losses:* No-load losses include the core loss, the I^2R loss due to the exciting current and the dielectric loss in the insulation.

(c) *Load Losses:* Load losses include I^2R losses, and stray load-losses due to eddy-currents caused by fluxes varying with load.

6335. Losses to be Considered in Transformers. — Conventional efficiencies shall be based upon the losses listed in § 6334 and these losses shall be measured as specified in §§ 6336 and 6337.

6336. No-load Losses. — The no-load losses shall be measured with open secondary circuit at the rated frequency, and with an applied primary voltage giving the rated secondary voltage plus the IR drop which occurs in the secondary under rated-load conditions.

6337. Load Losses. — The load losses include I^2R and stray load-losses. They shall be measured by applying a primary voltage, at rated frequency, sufficient to produce rated load current in the windings, with the secondary windings short-circuited.

Wave Shape

Standard Wave Shape. — See § 2340.

Tests of Dielectric Strength

Condition of Transformers to be Tested. — See § 2350.

Where High-voltage Tests are to be Made. — See § 2351.

Temperatures at which High-voltage Tests are to be Made. — See § 2352.

Points of Application of Voltage. — See § 2353.

Frequency and Wave Form of Test Voltage. — See § 2354.

Duration of Application of Test Voltage. — See § 2355.

Digitized by Google

[illegible]. Standard Test Voltage. — (From § 2356.) *General:* The standard
t voltage for all machines, except as otherwise specified, shall be twice the
mal voltage of the circuit to which the machine is connected plus 1000 volts.
exception § 6361.

360. Transformers for Star Connection. — Transformers which may be
d in star connection on three-phase circuits shall be tested on the basis of the
to line voltage for which they are rated. See § 6361(f).

361.* Exceptions to Standard Test Voltage Given in Section [illegible]. — (a)
tributing Transformers: Transformers for primary pressures from 550 to
volts, the secondaries of which are directly connected to consumer's cir-
s and commonly known as distributing transformers, shall be tested with
00 volts from primary to core and secondary combined. The secondary
dings shall be tested with twice their normal voltage plus 1000 volts.
) *Auto-transformers:* Auto-transformers used for starting purposes, shall
ested with the same voltage as the test voltage of the apparatus to which
are connected.
) *Household Devices:* Transformers taking not over 660 watts and intended
ly for operation on supply circuits not exceeding 275 volts, shall be tested
900 volts.
(d) *Transformers for Use on Circuits of 25 Volts or Lower:* Transformers for
on circuits of 25 volts or lower, such as bell-ringing apparatus, shall be
ed with 500 volts.
) *Alternating-current Transformers Connected to Permanently Grounded Single
e Systems, for use on Permanently Grounded Circuits of more than 300 Volts:*
nsformers used under these conditions shall be tested with 2.73 times the
age of the circuit to ground plus 1000 volts. This does not refer to three-
e transformers operating with grounded neutral.
) *Transformers to be used on Star-connected Three-phase Circuits:* Trans-
ers which may be used in star connection on three-phase circuits shall have
line to line (as distinguished from line to neutral) voltage of the circuits on
h they may be used indicated on the rating plate and the test shall be based
he line to line voltage. See § 6360.
) *Testing Transformers:* Rules do not apply to testing transformers, for
h no definite rule has yet been established.
) *Protective Reactors:* Protective reactors shall be tested from conductors
round with 2000 volts plus 2¼ times the line voltage.

[illegible].* Testing Transformers by Induced Voltage. — Under certain condi-
it is permissible to test transformers by inducing the required voltage in
windings in place of using a separate testing transformer. By "required
ge" is meant a voltage such that the line end of the winding shall receive
t to ground equal to that required by the general rules.

363. Transformers with Graded Insulation. — Where transformers have
ed insulation they shall be so marked. They shall be tested by inducing
required test voltage in the transformer and connecting the successive line
to ground.
ansformer windings permanently grounded within the transformer shall be
d by inducing the required test voltage in such windings. See § 6361.
e of Voltmeter and Spark-gaps in Dielectric Tests. — See § 2359.
e of Spark-gap with Transformers of Low Capacitance. — See § 2360.
e of Spark-gap with Transformers of High Capacitance. — See § 2361.
easurements with Voltmeter. — See § 2362.
easurements with Spark-gap. — See § 2363.

---

361 d) This rule does not include bell-ringing transformers of ratio 125 to 6 volts.
362) This test can be made by connecting the windings of two or more transformers
ries, with one end of the series grounded and a voltage impressed such as will give the
from the free end to ground required by the above rule.
391 a) This method is not generally applicable for shop tests, particularly on large
sformers.

Regulation

Conditions for Tests of Regulation. — See § 2390.

6390. Conditions for Test of Regulation. — (a) *Frequency:* The regulation of transformers is to be determined at constant frequency.

(b) *Power Factor:* In transformers, the power factor of the load to which the regulation refers should be specified. Unless otherwise specified, it shall be understood as referring to non-inductive load, that is, to a load in which the current is in phase with the e.m.f. at the output side of the transformer. See § 2390.

6391.* Tests and Computation of Regulation. — (a) *Method I. By Loading.* The regulation of a constant potential transformer can be determined by loading the transformer and measuring the change in voltage with change in load, at the specified power factor.

(b) *Method II. From Impedance Watts and Volts:* The regulation of a constant potential transformer for any specified load and power factor can be computed from the measured impedance watts and impedance volts as follows:

Let P = impedance watts, as measured in the short-circuit test,

E_s = impedance volts, as measured in the short-circuit test,
P_{75} = impedance watts, as measured in the short-circuit test, and corrected to 75° C.,
IX = Reactance Drop in Volts,
I = Rated Primary Current,
E = Rated Primary Voltage,
q_r = per cent drop in phase with current,
q_z = per cent drop in quadrature with current,

$$IX = \sqrt{E_s^2 - \left(\frac{P}{I}\right)^2}.$$

$$q_r = 100\frac{P_{75}}{EI}.$$

$$q_z = 100\frac{IX}{E}.$$

Then:

For unity power factor, we have approximately,

$$\text{Per cent regulation} = q_r + \frac{q_z^2}{200}.$$

For *inductive loads* of power-factor m and reactive-factor n,

$$\text{Per cent regulation} = mq_r + nq_z + \frac{(mq_z - nq_r)^2}{200}.$$

CONSTRUCTION

Rating Plates

Marking of Rating Plates. — See § 2401.

Transformer Connections

(These rules do not apply to auto-transformers)

General:

6402.* Scope. — These rules specify the markings of leads brought out of the case but not the markings of winding terminals inside of the case, except that these terminals shall be marked with numbers in any manner that will permit of convenient reference and that cannot be confused with the markings of the leads brought out of the case.

(6402) It is recognized that special cases will arise from time to time that these rules will not cover and that it would be very difficult to cover by any set of general rules. A

TRANSFORMER LEAD MARKINGS SINGLE-PHASE TRANSFORMERS

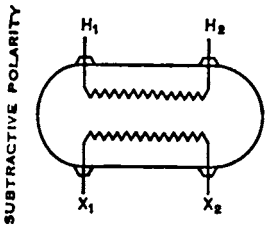

Fig. 6-1

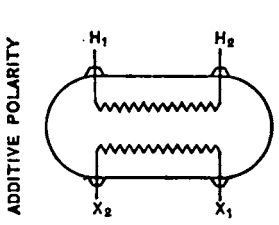

Fig. 6-2

Simple High- and Low-voltage Windings without Taps

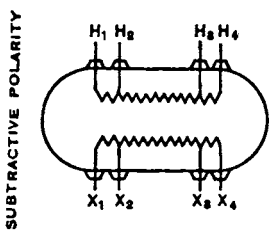

Fig. 6-5

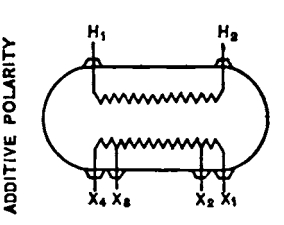

Fig. 6-4

Simple High- and Low-voltage Windings with Taps

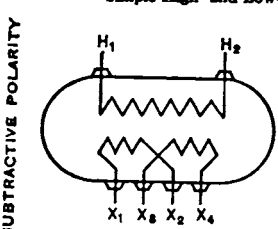

Fig. 6-3

Series Multiple Low-voltage Winding without Taps

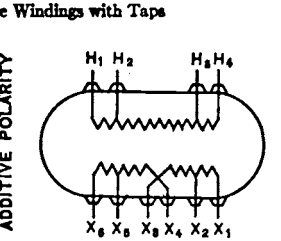

Fig. 6-6

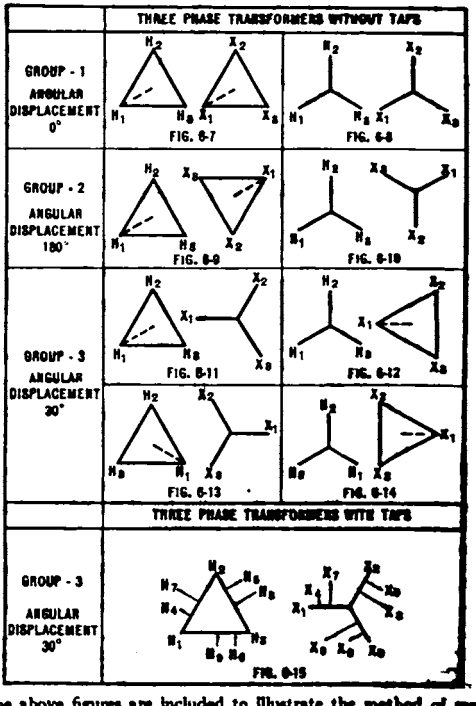
Series Multiple Low-voltage Winding with Taps

lote. — The above figures illustrate the application of the rules on lead markings to nsformers having subtractive and additive polarity.

403.* Markings of Leads. — *(a) *General:* The leads shall be distinguished n one another by marking each lead with a capital letter followed by a nber. The letters to be used are: *H* for high-voltage leads, *X* for low-volt- *leads* and *Y* for tertiary winding leads. The numbers to be used are 1, 2, 3,

403 a) By "tertiary winding" is meant a third winding that, compared with both of other two windings, has smaller kv-a. rating than either or, if the kv-a. rating is the e as one or both of the other two, has lower voltage. *E.g.*, if a transformer has three rate windings, one for 1000 kv-a., 33,000 volts, one for 600 kv-a., 550 volts and one for kv-a. 6,600 volts, the 400 kv-a. winding is the tertiary winding; or, if a transformer three separate windings each with a capacity of 1,000 kv-a., and with voltages of 00, 6,600 and 550 respectively, the 550-volt winding is the tertiary winding. ccording to this definition neither one of two similar windings arranged for series- llel connection is to be classed as a tertiary winding.

*(b) *Neutral Lead:* A neutral lead shall be marked with the proper le followed by *O, e.g., HO, XO.*



6404. Diagrammatic Sketch of Connections. — The manufacturer sh furnish with each transformer a complete diagrammatic sketch showing the le and internal connections and their markings and the voltages obtainable w the various connections.

This sketch should preferably be on a metal plate attached to the transfor case.

Single-phase Transformers:

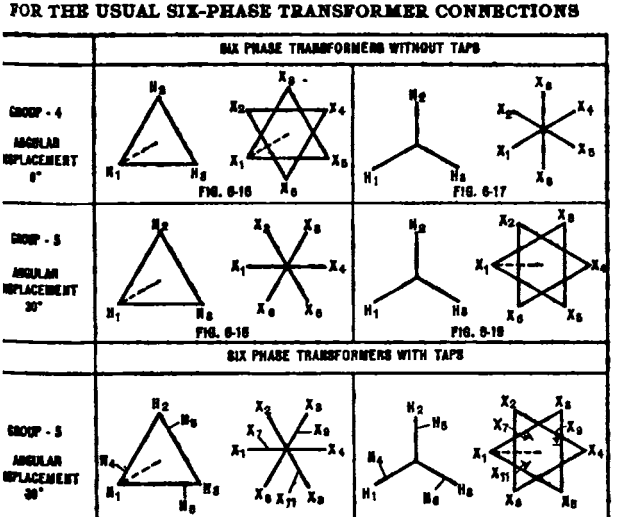
6405. Order of Numbering Leads in any Winding. — The leads of any wi ing (high-voltage, low-voltage or tertiary) brought out of case shall be numb 1, 2, 3, 4, 5, etc., the lowest and highest numbers marking the full winding the intermediate numbers marking fractions of winding or taps. All numb shall be so applied that the potential difference from any lead having a l number toward any lead having a higher number shall have the same sig any instant.

TRANSFORMER LEAD MARKINGS AND VOLTAGE VECTOR DIAGR FOR THE USUAL THREE-PHASE TRANSFORMER CONNECTIO

Note. — The above figures are included to illustrate the method of marking t former leads that are brought out of the case and are not intended to standardize nections, vector diagrams or polarity.

(6403 b) A lead brought out from the middle of a winding for some other unit, that of neutral lead, *e.g.*, a 50 per cent starting tap, shall be marked as a tap lead

a winding is divided into two or more parts for series-parallel connections, the leads of these parts are brought out of case, the above rule shall apply be series connection with the addition that the leads of each portion of wind- shall be given consecutive numbers. See Figs. 6-5 and 6-6.



86. Relation of Order of Numbering Leads of Different Windings. — The bering of the high-voltage and low-voltage leads shall be so applied that H_1 and X_1 are connected together and voltage applied to the transformer, voltage between the highest numbered H lead and the highest numbered ad shall be less than the voltage of the full high-voltage winding.
e same relation shall apply between high-voltage and tertiary and low- ge and tertiary winding.

87. Polarity. — When leads are marked in accordance with the above rules, olarity of a transformer is:

ubtractive when H_1 and X_1 are adjacent. See Figs. 6-1, 6-3 and 6-5.
dditive when H_1 is diagonally located with respect to X_1. See Figs. 6-2, nd 6-6.

88. Location of H_1 Lead. — To simplify the work of connecting trans- ers in parallel it is recommended that the H_1 lead shall be brought out on ight-hand side of the case, facing high-voltage side of the case.

NSFORMER LEAD MARKINGS AND VOLTAGE VECTOR DIAGRAMS FOR THE USUAL SIX-PHASE TRANSFORMER CONNECTIONS

e. — The above figures are included to illustrate the method of marking trans- r leads that are brought out of the case and are not intended to standardize con- es, vector diagrams or polarity.

89.[9] Parallel Operation. — Transformers having leads marked in accord- with these rules may be operated in parallel by connecting similarly marked together, provided their ratio, voltages, resistances and reactances are such permit parallel operation.

---

[9] In some cases design may be such as to permit parallel operation, although due difference in the number of tap leads, the leads to be connected together may not the same number.

Three-phase Transformers:

6410. Marking of Full Winding Leads. — The three high-voltage leads of the three low-voltage leads which connect to the full-phase windings, shall be marked H_1, H_2, H_3, and X_1, X_2, X_3. The full-phase winding of a tertiary winding shall be marked Y_1, Y_2, Y_3.

6411.* Relation between High-voltage and Low-voltage Windings. — *General:* The markings shall be so applied that if the phase sequence of voltage on the high-voltage side is in the time order H_1, H_2, H_3 it is in the time order of, X_1, X_2, X_3 on the low-voltage side and Y_1, Y_2, Y_3 for a tertiary winding.

*(b) *Angular Displacement:* In order that the markings of lead connections between phases shall indicate definite phase relations, they shall be made in accordance with one of the three three-phase groups as shown. The angular displacement between the high-voltage and low-voltage windings is the angle in each of the voltage vector diagrams (Figs. 6-7 to 6-14 inclusive) between the lines passing from its neutral point through H_1 and X_1 respectively.

6412. Tap Leads. — (a) *General:* Where tap leads are brought out of the case (neutral lead excepted) they shall be marked with the proper letter followed by the numbers, 4, 7, etc., for one phase, 5, 8, etc., for another phase and 6, 9, etc., for the third phase. See Fig. 6-15.

(b) *Delta Connection:* The order of numbering tap leads shall be as follows: 4, 7, etc., from lead 1 toward lead 2; 5, 8, etc., from lead 2 toward lead 3. 6, 9, etc., from lead 3 toward lead 1. See Fig. 6-15.

(c) *Star Connection:* The order of numbering tap leads shall be as follows: 4, 7, etc., from lead 1 towards neutral; 5, 8, etc., from lead 2 towards neutral and 6, 9, etc., from lead 3 towards neutral. See Fig. 6-15.

6413. Interphase Connection Made Outside of Case. — Where the interphase connections are made outside of case, the leads shall be marked with the proper letter followed by the numbers 1, 4, 7, 10, etc., for one phase; 2, 5, 8, 11, etc., for the second phase; and 3, 6, 9, 12, etc., for the third phase.

The markings shall be so applied that when a star connection is made by joining together the highest numbered leads of each phase, all rules have been complied with excepting § 6403 (b) apply.

6414.* Parallel Operation. — Transformers having leads marked in accordance with these rules may be operated in parallel by connecting similarly marked leads together provided their angular displacements are the same and provided also their ratios, voltages, resistances, and reactances are such as to permit satisfactory parallel operation.

6415. Location of H1 Lead. — To simplify the work of connecting transformers in parallel it is recommended that the $H1$ lead shall be brought out on the right-hand side of the case, facing the high-voltage side of the case.

Three-Phase to Six-phase Transformers:

6416. Rules that are Applicable for Three-Phase Transformers. — Sections 6411 (b) and 6413 shall apply to three-phase to six-phase transformers. Rules 6410 and 6412 shall apply to three-phase windings but not to six-phase windings.

6417. Markings of Six-phase Leads. — The six leads which connect to the full-phase windings shall be marked $X1$, $X2$, $X3$, $X4$, $X5$, $X6$. See Figs. 6-16 to 6-19 inclusive.

6418. Relation between Three-phase and Six-phase Windings. — *General:* The markings shall be so applied that if the phase sequence of voltage

---

(6411 b) Any three-phase transformer having a delta-Y connection may be represented by voltage vector diagram either in accordance with Fig. 6-11 or Fig. 6-13. A three-phase transformer having Y-delta connection may be represented by voltage vector diagram either in accordance with Fig. 6-12 or Fig. 6-14. Since these voltage vector diagrams are equivalent, it is recommended that the terminal markings for three-phase transformers having delta-Y connection be always made in accordance with Fig. 6-13 and that the terminal markings for three-phase transformers having Y-delta connection be always made in accordance with Fig. 6-12.

(6414) In some cases designs may be such as to permit parallel operation although due to a difference in the number of tap leads, the leads to be connected together are not similarly marked.

the three-phase side is in the time order $H1$, $H2$, $H3$, it is in the time order $X1$, $X2$, $X3$, $X4$, $X5$, $X6$ on the six-phase side.

b) *Angular Displacement:* In order that the markings of lead connections ween phases shall indicate definite phase relations, they shall be made in ordance with one of the four six-phase groups shown in Figs. 6-16 to 6-19 usive. The angular displacement between the high-voltage and low-tage windings is the angle in each of the voltage vector diagrams from its tral through $H1$ and $X1$ respectively.

419.* **Tap Leads.** — (a) *General:* Where tap leads from low-voltage wind- are brought out of the case (neutral lead excepted), they shall be marked llows:

) *Diametrical Connection:* Diametrical connection tap leads shall be ked from the two ends of each phase winding towards the middle or neutral t in the following order; $X7$, $X13$, etc., from $X1$ towards neutral; $X8$, , etc., from $X2$ towards neutral; $X9$, $X15$, etc., from $X3$ towards neutral; $X16$, etc., from $X4$ towards neutral; $X11$, $X17$, etc., from $X5$ towards tral; $X12$, $X18$, etc., from $X6$ towards neutral. See Fig. 6-20.

ap from the middle point of any phase winding, not intended as a neutral, l be given a number determined by counting from $X1$, $X2$ or $X3$ and not $X4$, $X5$, or $X6$; *e.g.*, if the only taps brought out are 50 per cent starting , they shall be numbered $X7$, $X8$, and $X9$.

c) *Double Delta Connection:* Tap leads shall be marked in the following r; $X7$, $X13$, etc., from $X1$ towards $X3$; $X8$, $X14$, etc., from $X2$ towards $X9$, $X15$, etc., from $X3$ towards $X5$; $X10$, $X16$, etc., from $X4$ towards $X11$, $X17$, etc., from $X5$ towards $X1$; $X12$, $X18$, etc., from $X6$ towards See Fig. 6-21.

STANDARDS FOR SWITCHING, CONTROL AND PROTECTIVE APPARATUS

he A. I. E. E. Standards for Switching Control and Protective Apparatus the General Standards shown in Chapters II and III and the Standards in r Chapters which are applicable to the devices involved, together with the ifications and extensions given in this Chapter.

419 c) For starting purposes it is generally customary to bring out only two taps one delta and start three-phase.

Digitized by Google

DEFINITIONS

Devices—General

7000.* Switching and Control Apparatus. — For the purpose of these Standardization Rules switching and control apparatus is defined as electric apparatus whose function is primarily to control or protect in some predetermined manner electric apparatus to which it is connected.

7001. Switch. — A switch is a device for making, breaking or changing connections in an electric circuit.

7002. Master-switch. — A master-switch is a switch which serves to govern the operation of contactors and auxiliary devices of an electric controller.

7003. Control Switch. — A control switch is a switch for controlling electrically-operated switches and circuit breakers.

7004. Auxiliary Switch. — An auxiliary switch is a switch actuated by a main device, for signalling, interlocking, etc.

7005. Circuit Breaker. — A circuit breaker is a device (other than a fuse) constructed primarily for the interruption of a circuit under *infrequent* abnormal conditions.

7006. Contactor. — A contactor is a device for repeatedly establishing and interrupting an electric circuit under normal conditions.

7007.* Electric Controller. — An electric controller is a device, or group of devices, which is designed to control in some predetermined manner the operation of the apparatus to which it is connected.

7008.* Motor-starter. — A motor-starter is an electric controller designed for accelerating a motor to normal speed in one direction of rotation.

7009. Automatic Motor-starter. — An automatic motor-starter is a motor-starter designed to automatically control the acceleration of a motor.

7010. Auto-transformer Motor-starter. — An auto-transformer motor-starter is a motor-starter having an auto-transformer to furnish a reduced voltage for starting. The device includes the necessary switching mechanism, and is frequently called a Compensator or Auto-starter.

7015.* Fuse. — A fuse is an element designed to melt or dissipate at a predetermined current value, and intended to protect against abnormal conditions of current.

7016. Electric Protective Relay.—An intermediate device, equipped with contacts to open or close an auxiliary circuit, by means of which one circuit is indirectly controlled by a change in conditions in the same or other circuits.

7017. Rheostat. — A rheostat is a resistor which is provided with means for readily varying its resistance. See § 3064.

7018. Protective Reactor. — A protective reactor (See § 3078) is a device for protecting circuits by limiting the current flow and localizing the disturbance under short-circuit conditions.

(7000) The "National Electrical Code" of the National Fire Protection Association deals with certain circuit breakers up to 550 volts rating and switches and fuses of 600 volts rating fuses.

(7007) A switch (see § 7001) should not be called a controller.

(7008) A device designed for starting a motor in either direction of rotation but not a controller (see § 7007).

(7015) Any terminals, tubes, etc., integral with this element are included as part of the fuse.

Fuses may be divided into two classes:

(a) Those designed to protect the circuit and apparatus both against short-circuits and against definite amounts of overload (*e.g.* fuses of the National Electric Code which blow on overload in excess of 10 per cent).

(b) Those designed to protect the system only against short-circuits; (*e.g.*, expulsion fuses, which blow at several times the current which they are designed to carry continuously). The line separating these two classes is not definitely fixed.

7019.* **Lightning Arrester.** — A lightning arrester is a device for protecting cuits and apparatus against lightning or other abnormal potential rises of ort duration.

7020. Under-voltage or Low-voltage Release Switching and Control Appara- — Under-voltage or low-voltage release switching and control apparatus is paratus which, on the reduction or failure of voltage, operates to cause the erruption of power to the main circuit, but which does not prevent the re-ablishment of the main circuit on return of voltage.

7021. Under-voltage or Low-voltage Protection Switching and Control paratus. — Under-voltage or low-voltage protection switching and control paratus is apparatus which, on the reduction or failure of voltage, operates to se and maintain the interruption of power to the main circuit.

7022. Phase-failure Protection Switching and Control Apparatus. — Phase-ure protection switching and control apparatus is apparatus which, on the re of power in one wire of a polyphase circuit, operates to cause and main-the interruption of power on the circuit.

7023. Phase-reversal Protection Switching and Control Apparatus. — Phase-rsal protection switching and control apparatus is apparatus which, on the rsal of the phase relations in a polyphase circuit, operates to cause and main-the interruption of power on the circuit.

Electric Protective Relays—Classified According to Functions

7026. Directional Relay.—Any relay which functions in conformance with ction of power or voltage or current or phase rotation, etc.

7027. Power-Directional Relay.—Any relay which functions in conformance h direction of power.

NOTE.—This includes both unidirectional relays with single-throw contacts duodirectional relays with double-throw contacts. The reason this name is erred to "reverse power" is that the device is frequently used to function er normal direction of power. Furthermore, in some cases, the normal dition of the system may permit power to flow in either direction. Relays se in either alternating or direct-current circuits are to be classed as power-ctional relays.

7028. Polarity-directional Relay.—Any relay which functions by reason of a ge of the direction of polarity.

7029. Phase-rotation Relay. — Any relay which functions by reason of a nge of the direction of phase rotation.

7030. Current Relay. — Any relay which functions at a predetermined value the current. These may be either over-current relays or under-current ys.

7031. Voltage Relays. — Any relay which functions at a predetermined ue of the voltage. These may be either over-voltage relays or under-voltage ys.

7032. Power Relay. — Any relay which functions at a predetermined value the power. These may be either over-power relays or under-power ys.

7033. Frequency Relay. — Any relay which functions at a predetermined ue of the frequency. These may be either over-frequency relays or under-quency relays.

7034. Temperature Relay. — Any relay which functions at a predetermined mperature in the apparatus protected.

7035. Open-phase Relay. — Any relay which functions by reason of the ening of one phase of a polyphase circuit.

7019) Lightning arresters may be divided into two classes:
a) Those intended to discharge for a very short time.
b) Those intended to discharge for a period of several minutes.

Digitized by Google

7036. Differential Relay. — Any relay which functions by reason of the difference between two quantities, such as current or voltage, etc.

NOTE.—This term includes relays heretofore known as "ratio balance relays," "biased," and "percentage differential relays."

Electric Protective Relays—Classified According to Applications

7040. Locking Relay. — Any relay which renders some other relay or other device inoperative under predetermined values of current or voltage, etc.

7041. Trip-free Relay. — Any relay which prevents holding in an electrically operated device, such as a circuit breaker, while an abnormal condition exists on the circuit.

7042. Auxiliary Relay. — Any relay which assists another relay in the performance of its function and which operates in response to the opening or closing of its operating circuit.

7043. Signal Relay. — An auxiliary relay which operates an audible or a visible signal.

Electric Protective Relays—General Qualifying Terms

7050. Notching. — A qualifying term applied to any relay, indicating that a number of separate impulses are required to complete operation.

7051. Inverse Time. — A qualifying term applied to any relay indicating that there is purposely introduced a delayed action, which delay decreases as the operating force increases.

7052. Definite Time. — A qualifying term applied to any relay indicating that there is purposely introduced a delayed action, which delay remains substantially constant regardless of the magnitude of the operating forces. If the forces slightly above the minimum operating value, the delay may be inverse.

7053. Instantaneous. — A qualifying term applied to any relay indicating that no delayed action is purposely introduced.

7054. Use of Terms. — Where relays operate in response to changes in more than one condition, all functions should be mentioned.

Characteristics of Devices—General

7060. "Air" as a Prefix. — The prefix "air" applied to a device which interrupts an electric circuit indicates that the interruption occurs in air.

7061. "Oil" as a Prefix. — The prefix "oil" applied to a device which interrupts an electric circuit indicates that the interruption occurs in oil.

7062. Fume-resisting. — Fume-resisting switching and control apparatus is apparatus so constructed that it will not be readily injured by the specified fume.

7063.* Drip-proof. — Drip-proof switching and control apparatus is apparatus so protected as to exclude falling moisture or dirt.

7064. Dust-proof. — Dust-proof switching and control apparatus is apparatus so constructed or protected that the accumulation of dust within or without the device will not interfere with its successful operation.

7065. Dust-tight. — Dust-tight switching and control apparatus is apparatus so constructed that the dust will not enter the enclosing case.

7066. Explosion-proof. — Explosion-proof switching and control apparatus is apparatus so constructed that explosions of gas within the casing will not injure it or ignite inflammable gas outside it.

7067. Gas-proof. — Gas-proof switching and control apparatus is apparatus so constructed or protected that the specified gas will not interfere with successful operation.

(7063) Drip-proof apparatus may be either open or semi-enclosed, if it is provided with suitable protection integral with the apparatus, or so enclosed as to exclude effectively falling solid or liquid material.

7068. Gas-tight. — Gas-tight switching and control apparatus is apparatus constructed that the specified gas will not enter the enclosing case.

7069. Moisture-resistant. — Moisture-resistant switching and control apparatus is apparatus so constructed or treated that it will not be readily injured by moisture. (Such apparatus shall be capable of operating in a very humid atmosphere, such as found in mines, evaporating rooms, etc.).

7070. Splash-proof. — Splash-proof switching and control apparatus is apparatus so constructed or protected that external splashing will not interfere with its successful operation.

7071. Submersible. — Submersible switching and control apparatus is apparatus so constructed that it will operate successfully when submerged in water under specified conditions of pressure and time.

7072. Sleet-proof. — Sleet-proof switching and control apparatus is apparatus so constructed or protected that the accumulation of sleet will not interfere with its successful operation.

Parts of Devices—General

7080. Conducting Parts. — Conducting parts of switching and control apparatus are those designed to carry current or which are conductively connected therewith.

7081. Contact. — A contact is a surface common to two conducting parts, held by pressure, for the purpose of carrying current.

7082. Magnet Brake. — A magnet brake is a friction brake controlled by electro-magnetic means.

7083. Grounded Parts. — Grounded parts are those parts which may be considered to have the same potential as the earth.

Properties of Devices—General

7090. Interrupting Rating. — Interrupting (breaking or rupturing) rating is a rating based upon the r.m.s. current at normal voltage which the device can interrupt under prescribed conditions at stated intervals a specified number of times.

OPERATION

Temperature Limits

7101.* **Circuit Breakers, Relays and Switches.** — The maximum observable temperature rises of the various parts of circuit breakers, relays and switches shall not exceed the following limits for ambient temperatures up to and including 40° C. not greater than 40° C. See § 7301.

Contacts in air when clean and bright	30° C.
Contacts in oil	30° C.
Oil	40° C.
Potential Coils, Class O insulation	35° C.
Series Coil, Class O insulation	50° C.
Series and Potential Coils, Class A insulation	50° C.
Series and Potential Coils, bare or Class B insulation	70° C.
All other parts	70° C.

7102. Magnetic Contactors. — The maximum observable temperature rises of the various parts of magnetic contactors shall not exceed the following limits

---

7101) The Institute calls attention to the inherent decrease in current which can be carried by switch and circuit-breaker contacts in air, due to oxidization of the contact surfaces. The rating of air switches and circuit breakers is, therefore, based on sufficient maintenance to keep the temperature rise within the specified limits. Relays which form part of controllers are to have the temperature limits specified in § 7102.

for ambient temperatures up to and including but not greater than 40° C. § § 7302.

Laminated contacts	65° C.
Operating coils	70° C.
Solid contacts	100° C.
Current-carrying parts insulated with asbestos or other fireproof material	150° C.

7105.* **Fuses.** — The maximum observable temperature rise of coils or wi ings, measured by thermometer, shall not exceed the following limits for ambi temperatures up to and including but not greater than 40° C.

If insulation is of unimpregnated fibrous material	35° C.
If insulation is of fibrous material treated to withstand heat	50° C.
If insulation is of asbestos, mica or similar heat-resisting material with a cotton binder	70° C.

7106. Cast Grid Resistors. — The maximum observable temperature rise cast grids used as resistors shall not exceed 350° C. for ambient temperatures to and including but not greater than 40° C.

RATING

Expression of Rating

7201. Rating of Circuit Breakers and Switches. — The rating of a circ breaker or switch shall include the following items:

(a) the normal r.m.s. current which it is designed to carry.

(b) the normal r.m.s. voltage of the circuit on which it is intend to operate.

(c) the normal frequency of the current.

(d) the interrupting rating of the device. See § 7060.

7202. Continuous Current-carrying Capacity of Fuses. — Fuses shall be constructed that they will carry continuously 110 per cent of their rated curr

7205. Rating of Lightning Arresters. — The rating of a lightning arre shall be the voltage of the circuit on which it is to be used.

TESTS

Heat Tests

7301. Circuit Breakers, Relays and Switches. — The rated current of circ breakers, relays and switches at rated frequency shall be applied continuou until the temperature becomes constant. The temperature rises measured thermometer or thermocouple (Method No. 1) placed on the surface of the to be measured shall not exceed the limits specified in § 7102.

The ambient temperature shall be determined by taking the average of readings of three thermometers placed as follows:

One 12 inches above;

One 12 inches below;

One midway but 12 inches from the breaker as installed.

7302. Magnetic Contactors. — The rated current of magnetic contactor rated frequencies shall be applied continuously or until the temperature becom constant when continuous duty is specified. It shall be applied for the specif length of time when given a short time rating. The temperature rises measu by thermometer shall not exceed the limits specified in § 7102.

Tests of Dielectric Strength

7322.* **Standard Test Voltage.** — (a) *Apparatus rated at 600 volts or l* The standard test voltage for all switching and control apparatus rated at volts or less shall be twice the normal voltage of the circuit to which the ap ratus is to be connected plus 1000 volts.

(7105) Coils or windings such as accompany fuses of the magnetic blow-out type.

(7323) This assumes a precipitation of 1/10th inch (2.54 mm.) per minute at an an of 45° from the perpendicular with water having a resistivity as low as 7000 ohm-cen meters.

) *Apparatus rated above 600 volts:* Apparatus rated above 600 volts shall be ed at 2½ times rated voltage, plus 2000 volts, at a specified altitude.
As a supplementary test, devices for outdoor use should be capable of withding for 10 seconds a dielectric wet test at twice rated voltage plus 1000 volts.
) *Auto-Transformers for Motor-starters:* Auto-transformers for motor-starters l be tested with the same voltage as the test voltage of the apparatus to ch they are to be connected.

Tests of Lightning Arresters.

171. Resistance. — The resistance of the arrester at double potential and at normal potential, shall be determined by observing the discharge currents ugh the arrester.

172. Arrester with Gap. — In the case of any arrester using a gap, a test shall nade of the spark potential on either direct-current or 60 cycle a-c. excitation.

173. Equivalent Sphere Gap. — The equivalent sphere gap under disruptive harge shall be measured, using a considerable quantity of electricity.

174. Continuous Surges. — The endurance of the arrester to continuous es shall be tested.

175. Dielectric Strength. — See §§ 2355 and 7323.

CHAPTER VIII

STANDARDS FOR METERS, INSTRUMENTS AND INSTRUMENT TRANSFORMERS

he A.I.E.E. Standards for Meters, Instruments and Instrument Transers are the General Standards shown in Chapters II and III, and the Standin other Chapters which are applicable to the devices involved, together with modifications and extensions given in this Chapter.

DEFINITIONS

900.* Meter. — A meter is a device which registers through a totalising hanism, the integral, with respect to time, of the electrical quantity to which sponds. (This definition does not preclude the general use of " meter " as a r, or in compound words, to mean a " measuring device.")

901.* Instrument. — An instrument is a device which indicates or records present value of the quantity under observation.

902. General Nomenclature. — In general, the names of meters and instrus are self-defining. The following names are preferred to others some-

---

900 and 8001) While the word "instrument" is a general term which may properly ude indicating, integrating and recording devices, there is a tendency to restrict its o indicating devices and to recording (graphic or curve drawing) devices. Integrating ces are then denoted by the word "meter." This distinction gives rise to the above ral definitions.

times used for the same devices: Reactive-factor Meter, Power-factor Meter, Watthour Meter, Reactive Volt-Ammeter (or Reactive Volt-ampere Indicator) etc.

8003. Recording Instruments. — Recording ammeters, voltmeters, wattmeters, etc., are instruments which record graphically, upon time charts, the values of the quantities they measure.

8004.* Crest Voltmeter. — A crest voltmeter is a voltmeter depending for its indications upon the crest, or maximum value of the voltage of the system to which it is connected. Crest voltmeters shall be marked in true crest volts and also in the r.m.s. value of the sinusoidal wave having the same crest value. (See § 2362.)

8005. Synchronoscope (also called a Synchroscope or Synchronism Indicator). — A synchronoscope is a device which indicates synchronism between two machines, and in addition shows whether the incoming machine is fast or slow.

8006. Line-drop Voltmeter Compensator. — A line-drop voltmeter compensator is a device used in connection with a voltmeter which causes the latter to indicate the voltage at some distant point of the circuit.

8007. Demand-meter. — (a) *General:* A demand-meter is a device which indicates or records the demand or maximum demand. In practise, two types are recognized. See §§ 3454, 3458, 3460 and 3464.

(b) *Integrated-Demand-Meter:* An integrated-demand-meter is a demand meter which indicates or records the maximum demand obtained through integration.

(c) *Lagged-Demand-Meter:* A lagged-demand-meter is a demand-meter in which the indication of maximum demand is subject to a characteristic time lag.

8020.* Period of an Instrument. — The period of an instrument, sometimes called the "periodic time," is the time taken for the pointer to make one complete oscillation (two consecutive swings). A swing is a complete movement in either direction.

8030. Instrument Transformer. — An instrument transformer is a transformer suitable for use with measuring instruments; that is, one in which the conditions of phase and of current or potential in the primary circuit, are represented with acceptable accuracy in the secondary circuit. An instrument transformer may be either an instrument current transformer or an instrument potential (voltage) transformer.

8031.* Secondary Burden. — The secondary burden of a current transformer is an expression in ohms and henrys of the resistance and inductance of the external circuit connected to the secondary of that transformer.

8032. Voltage Ratio of Instrument Transformer. — The voltage ratio of an instrument potential transformer is the ratio of the r.m.s. primary terminal voltage to the r.m.s. secondary terminal voltage, under specified secondary burden.

8033. Current Ratio of Instrument Transformer. — The current ratio of an instrument current transformer is the ratio of r.m.s. primary current to r.m.s. secondary current, under specified secondary burden.

8034. Marked Ratio of Instrument Transformer. — The marked ratio of an instrument transformer is the ratio which the apparatus is designed to give under average conditions of use. When a precise ratio is required, it is necessary to specify the voltage or current, frequency, load and secondary burden.

(8004) Corona voltmeter (see Transactions of the A. I. E. E., Volume XXXIX, page 1057) is recognized as a satisfactory form of crest voltmeter.

(8020) In strongly damped instruments, the period is influenced by the amplitude of the movement.

(8031) Considerable uncertainty of meaning has been occasioned by the use of the terms, load, secondary load, and secondary connected load for this quantity, and such use is discouraged.

OPERATION

8101. Permissible Temperature in Shunts. — (a) *General:* The limiting observable temperature of shunts measured by Method I shall not exceed 120° C. (b) *Exceptions:* The above rule shall not apply to shunts having no soldered joint and made of material which is not permanently changed in resistance if continuously subjected to a higher temperature.

8110. Grounding of Meters and Instruments. — The covers of meters and instruments, which are used with current and potential transformers, shall be connected to the grounded sides of the secondary circuits of such transformers in all cases where the indications of the instrument are liable to be influenced by electrostatic action.

8111. Instrument Current Transformers on Open Secondary Circuit.— Under conditions of open secondary circuit, current transfomers shall be capable of carrying continuously rated primary current without damage to the primary insulation and without interruption of service.

8112. Instrument Current Transformers on Closed Secondary Circuit. — Under conditions of closed secondary circuit, current transformers shall withstand 40 times rated current applied for 1 second, without injury.

RATING

8200. General. — The rating of a meter is a designation assigned by the manufacturer to indicate its operating limitations. The full scale marking of an instrument does not necessarily correspond to its rating, but if the rating differs from the full scale marking, the rating shall be marked on the instrument.

8201. Standard Ambient Temperature.— For purposes of rating meters and instruments, the standard ambient temperature shall be 40° C. See §§ 8301 and 2211.

8202. Rating Limitation of the Circuits of Meters and Instruments. — No circuit of a meter or instrument shall be given a rating higher than that corresponding to the maximum current or voltage to which it may be continuously subjected.

8203.* Temperature Rise of Meter and Instrument Windings. — The permissible temperature rises in meters and instruments shall be based upon the temperatures specified in § 1005 and the standard ambient temperature of 40° C.

8204. Temperature Rise in Shunts. — Shunts shall be rated in accordance with their observable temperature rise by Method 1, assuming the ultimate temperatures specified in § 8101 and an ambient temperature specified in § 8201.

TESTS

8300. Measurement of Temperature Rise of Shunts. — Observable temperature shall be measured in such a manner as not to cause local change of temperature.

8301. Standard Temperature of Reference for Meter and Instrument Characteristics. — The standard temperature of reference for meter and instrument characteristics shall be 20° C. See §§ 8201, 2211.

8302. Damping. — The pointer being at zero before any load is applied, damping shall be measured by suddenly applying and maintaining a load which will give a steady deflection of one-half full angular scale, and observing the following quantities:

(a) The number of swings taken by the pointer in coming to rest.

(8203) Heating is frequently an immaterial consideration in determining the rating of meters and instruments. Losses, impairment of accuracy and other factors often determine the rating.

(b) The time, in seconds, required for the pointer to come to rest.
(c) The overshooting, in per cent of the angular displacement due to the disturbance.

Dielectric Strength of Instrument Transformers.

8310. Test Voltage Instrument Potential Transformers. — The test voltage for instrument potential transformers shall be twice the normal voltage of the circuit to which it is connected plus 1000 volts.

8311. Test Voltage of Instrument Current Transformers. — The test voltage of instrument current transformers shall be 2½ times the rated voltage plus 2000 volts.

8312. Test Voltage for Meters and Instruments. — Meters and instruments which have a potential circuit shall withstand a test of twice potential of the circuit plus 1000 volts. Instruments without a potential circuit shall withstand a test of 1000 volts.

SPECIFICATION OF CHARACTERISTICS

8500. Errors of Indicating Instruments. — In specifying the accuracy of an indicating instrument, the error at any point on the scale shall be expressed as a percentage of the full scale reading.

8501. Torque. — The torque of meters and instruments shall be expressed in millimeter-grams.

8502. Damping. — The damping of an instrument shall be expressed in terms of the quantities enumerated in § 8302, all three of which are essential to a complete description.

8503.* Marking of Switchboard Shunts. — The marking of switchboard shunts shall include the rating in amperes, the drop in volts at that rating and the serial number of any instrument in connection with which the shunt may be calibrated. When shunts are designed to be used with devices taking sufficient current to be an appreciable proportion of the whole, this fact shall be indicated.

CHAPTER IX

STANDARDS FOR WIRES AND CABLES

DEFINITIONS

9000.* Wire. — A wire is a slender rod or filament of drawn metal.

9001.* Conductor. — A conductor is a wire or combination of wires not sulated from one another, suitable for carrying a single electric current.

9002.* Stranded Conductor. — A stranded conductor is a conductor com-sed of a group of wires, or of any combination of groups of wires.

9003. Strand. — A strand is one of the wires, or groups of wires, of any randed conductor.

9004.* Cable. — A cable is either a stranded conductor (single-conductor ble), or a combination of conductors insulated from one another (multiple-nductor cable).

9005.* Stranded Wire. — A stranded wire is a group of small wires, used as ingle wire.

9006.* Cord. — A cord is a small, flexible, insulated cable.

9007. Concentric Strand. — A concentric strand is a strand composed of a ntral core surrounded by one or more layers of helically-laid wires or groups wires.

9008. Concentric-lay Cable. — A concentric-lay cable is a single-conductor ble composed of a central core surrounded by one or more layers of helically-d wires.

9009.* Rope-lay Cable. — A rope-lay cable is a single-conductor cable com-sed of a central core surrounded by one or more layers of helically-laid groups wires.

9000) The definition restricts the term to what would ordinarily be understood by the m "solid wire." In the definition, the word "slender" is used in the sense that the gth is great in comparison with the diameter. If a wire is covered with insulation, it roperly called an insulated wire; while primarily the term "wire" refers to the metal, nevertheless when the context shows that the wire is insulated, the term "wire" will be derstood to include the insulation.

9001) The term "conductor" is not to include a combination of conductors insulated m one another, which would be suitable for carrying several different electric currents. ded conductors (such as bus-bars) are, of course, conductors, but are not considered der the terminology here given.

9002) The wires in a stranded conductor are usually twisted or braided together.

9004) The first kind of cable is a single conductor, while the second kind is a group of eral conductors. The component conductors of the second kind of cable may be her solid or stranded, and this kind of cable may or may not have a common insulating ering. The term "cable" is applied by some manufacturers to a solid wire heavily ulated and lead-covered; this usage arises from the manner of the insulation, but such onductor is not included under this definition of "cable." The term "cable" is a eral one, and in practise, it is usually applied only to the larger sizes. A small cable is led a "stranded wire" or a "cord," both of which are defined below. Cables may be re or insulated, and the latter may be armored with lead, or with steel wires or bands.

9005) A wire has been defined as a slender rod or filament of drawn metal. If such a ment is subdivided into several smaller filaments or strands, and is used as a single re, it is called a "stranded wire." There is no sharp dividing line of size between a stranded wire" and a "cable." If used as a wire, for example in winding inductance ls or magnets, it is called a stranded wire and not a cable. If it is substantially insu-ed, it is called a "cord," defined below.

(9006) There is no sharp dividing line in respect to size between a "cord" and a able," and likewise no sharp dividing line in respect to the character of insulation tween a "cord" and a "stranded wire." Rubber is used as the insulating material r many classes of cords.

(9009) This kind of cable differs from the preceding in that the main strands are them-ves stranded.

Digitized by Google

9010.* N-conductor Cable. — An N-conductor cable is a combination of N conductors insulated from one another.

9011.* N-conductor Concentric Cable. — An N-conductor concentric cable is a cable composed of an insulated central conductor with (N-1) tubular stranded conductors laid over it concentrically and separated by layers of insulation.

9012.* Duplex Cable. — A duplex cable is a cable composed of two insulated stranded conductors twisted together.

9013. Twin Cable. — A twin cable is a cable composed of two insulated stranded conductors laid parallel, having a common covering.

9014. Twin Wire. — A twin wire is a cable composed of two small insulated conductors laid parallel, having a common covering.

9015.* Triplex Cable. — A triplex cable is a cable composed of three insulated single-conductor cables twisted together.

9016.* Twisted Pair. — A twisted pair is a cable composed of two small insulated conductors, twisted together, without a common covering.

9017.* Sector Cable. — A sector cable is a multiple-conductor cable in which the cross-section of each conductor is substantially a sector, an ellipse, or a figure intermediate between them.

9018. Round Conductor. — A round conductor is either a solid or stranded conductor of which the cross-section is substantially circular.

9019.* Split Conductor. — A split conductor is a conductor which is divided into two or more parts, separated from one another by insulation which is thin compared with the insulation around the conductor.

9030. Factor of Assurance. — The factor of assurance of wire or cable insulation is the ratio of the voltage at which it is tested to that at which it is used.

9031. Insulation Resistance. — The insulation resistance of an insulated conductor is the electrical resistance offered by its insulation, to an impressed voltage tending to produce a leakage of current through the same.

9032.* Circular Mil. — A circular mil is a unit of area equal to $\frac{\pi}{4}(=0.7854\ldots)$ of a square mil. The cross-sectional area of a circle in circular mils is therefore equal to the square of its diameter in mils. A circular inch is equal to a million circular mils.

9033.* Lay. — The lay of any helical element of a cable is the axial length of a turn of the helix of that element.

9034. Direction of Lay. — The direction of lay is the lateral direction in which the strands of a cable run over the top of the cable as they recede from an observer looking along the axis of the cable.

(9010) It is not intended that the name as here given be actually used. One would instead speak of a "3-conductor cable," a "12-conductor cable" etc. In referring to the general case, one may speak of a "multiple-conductor cable" (as in § 9004 above).

(9011) This kind of cable usually has only two or three conductors. Such cables are used particularly for alternating currents. The remark on the expression "N-conductor" given for the preceding definition also applies here.

(9012) They may or may not have a common insulating covering.

(9015) They may or may not have a common insulating covering.

(9016) The two conductors of a "twisted pair" are usually substantially insulated, so that the combination is a special case of a "cord."

(9017) Sector cables are used in order to obtain decreased overall diameter and thus permit the use of larger conductors in a cable of given diameter.

(9019) The term split conductor usually designates a conductor in two parts or splits which may be either concentric or external to one another.

(9032) A mil is the one-thousandth part of an inch. There are 1974 circular mils in a square millimeter.

(9033) Among the helical elements of a cable may be each strand in a concentric-lay cable, or each insulated conductor in a multiple-conductor cable.

ANNEALED COPPER STANDARD

10.* Standard Annealed Copper. (a) *General:* The following shall be taken rmal values for standard annealed copper.

Resistance: At a temperature of 20° C., the resistance of a wire of stand- nnealed copper one meter in length and of a uniform section of 1 square neter is $1/58$ ohm $= 0.017241 \ldots$ ohm.

Density: At a temperature of 20° C., the density of standard annealed er is 8.89 grams per cubic centimeter.

Temperature Coefficient of Resistance: At a temperature of 20° C., the stant mass " temperature coefficient of resistance of standard annealed r, measured between two potential points rigidly fixed to the wire, is $93 = 1/254.45 \ldots$ per degree centigrade.

Resistance of Standard Annealed Copper at 20° C.: As a consequence, it ws from (b) and (c) that, at a temperature of 20° C. the resistance of a of standard annealed copper of uniform section, one meter in length and ing one gram, is $(1/58) \times 8.89 = 0.15328 \ldots$ ohm.

OPERATION

Temperature Limits

20.* Maximum Temperatures. — The temperature of the insulation of a or cable at the surface of the conductor shall not be allowed to exceed the wing values.

t t = maximum safe temperature.

E = r.m.s. operating electromotive force in kilovolts between conductors,

Impregnated paper, $t = 85 - E$

Varnished cambric, $t = 75 - E$

Rubber insulation, $t = 60 - \frac{E}{4}$.

DESIGNATION

100. Designation of Wires by Diameter or Gage Number. — The sizes of s shall be stated by their diameters in mils, the American Wire Gage (Brown harpe) sizes being taken as standard. For brevity, in cases where the t careful specification is not required, the sizes of wires may be stated by the number in the American Wire Gage.

101. Designation of Cables by Cross-sectional Area. — The sizes of nded conductors shall be stated by their cross-sectional area in circular or circular inches, except in the case of flexible stranded conductors, for

---

(050) See I. E. C. Publication No. 28, "International Standard of Resistance for per," March, 1914.

aragraphs (b) and (c) define what are sometimes called "Volume Resistivity" and ass Resistivity," respectively. This may be expressed in other units as follows:

olume Resistivity = 1.7241 microhms-cm. (microhms in a centimeter cube) at 20° C.

lass Resistivity = 875.20 ohms (mile, pound) at 20° C.

or detailed specifications of commercial copper see the Standard Specifications of the erican Society for Testing Materials.

(0100) For example: At a working pressure of 3.3 kv., the maximum safe limiting mperature at the surface of the conductor, or conductors, in a cable would be as follows:

For impregnated paper 81.7° C.
For varnished cambric 71.7° C.
For rubber insulation 59.2° C.

The life of the insulation of a cable depends in a great measure upon the actual temp- ture attained by the insulation. The result of operating at temperatures in excess of safe limit is to shorten the life of the insulating material. When the safe limits are eeded, deterioration is rapid and permanent, the damage increasing with the length of e that the excessive temperature is maintained and with the amount of excess tempera- e until finally the insulation breaks down.

Some of the older types of cable for voltages above 7500 have a dielectric loss that is so h that it may add considerably to the heating that would otherwise result. In such es the dielectric loss is a material factor in determining the safe load to be carried by cable, and the safe operating temperature will be determined by the temperature at ich cumulative heating occurs under the conditions of service, if this occurs at a lower mperature than that at which the insulation deteriorates.

which see § 9402. The cross-sectional area of a cable shall be considered to be the sum of the cross-sectional areas of its component wires, when measured perpendicular to their axes. The sizes of stranded conductors smaller than 250,000 circular mils (*i.e.*, No. 0000 A. W. G. or smaller) may be stated by means of the gage number of a solid wire having the same cross-sectional area.

9202.* Conductivity. — The conductivity of the metal of wires shall be expressed in terms of the conductivity of the Annealed Copper Standard, as defined in § 9050.

9203.* Copper-wire Tables. — The copper-wire tables published by the Bureau of Standards in Circular No. 31 are adopted. Table VI therein gives the values of diameters and cross-sections of A. W. G sizes to four significant figures. These tables are based upon the Annealed Copper Standard described in § 9050.

TESTS

General

9300. Cable Lengths Tested. — Electrical tests of insulation on wires and cables shall be made on the entire lengths to be shipped.

9301. Immersion in Water. — (a) *General:* The outer surface of the insulation of complete insulated wires and cables shall be grounded while being electrically tested. If the insulation is not provided with a conducting covering, and if the covering is not liable to injury by water, the ground shall be obtained by immersing the insulated wire or cable in water for at least twelve hours and testing at the end of that period while immersed. If the outer covering is susceptible to injury by immersion, the insulated conductor shall be tested before the application of such covering.

Dry core paper insulated lead covered cables, such as telephone and telegraph cables, for use in water, shall be tested after at least twelve hours immersion.

(b) *Multiple-conductor Cable:* In the case of multiple-conductor cable without waterproof overall jacket of insulation, no immersion test should be made on finished cables, but only on the individual conductors before assembling.

Tests of Dielectric Strength

9310. Object of Tests. — High-voltage tests are intended to detect weak spots in the insulation and to determine whether its dielectric strength is sufficient for enabling it to withstand the voltage to which it is likely to be subjected in service, with a suitable factor of assurance.

9311. Nature of Tests. — High-voltage tests shall be made at the factory by subjecting the insulation to an alternating voltage. The initially applied voltage must not be greater than the working voltage, and the rate of increase shall be approximately uniform and not over 100 per cent in 10 seconds, and not less than 100 per cent in 60 seconds.

9312.* Magnitude and Duration of the Test Voltage. — (a) *General:* Wires and cables shall be tested at the place of manufacture for five consecutive minutes, except as provided in § 9312 (b) and (f).

(b) *Rubber Insulation, National Electrical Code:* Rubber covered wires and cables for working pressures up to 600 volts alternating, insulated in accordance with the requirements of the National Electrical Code, shall be tested in accordance with that Code.

(9202) For any given wire, let

k = conductivity, in per cent of Annealed Copper Standard;
l = length, meters;
R = resistance, ohms;
W = weight, grams;
θ = temperature, degrees centigrade.

Then the conductivity may be derived from the following formula:

$$k = \frac{15.328}{\frac{WR}{l} + 0.000597\,(20 - \theta)}.$$

(9203) For detailed specifications of commercial copper, see the Standard Specifications of the American Society for Testing Materials.

c) *Thirty per cent to 40 per cent Hevea Rubber Insulation for Pressures up to Volts, a-c.:* Wires and cables for working pressures up to 600 volts alternat- insulated with 30 per cent to 40 per cent Hevea rubber compound, unless insulation thickness is less than specified in § 9405, shall be tested in accord- e with Table 901.

TABLE 901

High-voltage Tests for Rubber Insulated Wires and Cables

per cent to 40 per cent Hevea Rubber Insulation for working pressures up to 600 Volts a-c.)

n A. W.G. or Cir. Mils.	Size Sq. mm.	Test-pressure kilovolts
14–8	2.081– 8.366	3.0
7–0000	10.55 –107.2	3.5
250,000 and larger	127 and larger	4.0

f) *Thirty per cent to 40 per cent Hevea Rubber Insulation for Pressures over Volts, a-c.:* Wires and cables insulated with 30 per cent Hevea rubber com- nd for working pressures over 600 volts alternating, shall be tested with one volt per 64th inch of thickness (2.53 kv., per mm.) up to 10/64th inch 6 mm.). Above 10/64ths inch, (3.96 mm.), the test pressure shall be 10 volts plus 1.5. kilovolts per 64th inch (3.79 kv. per mm.) additional up to 64ths inch (11.89 mm.). Where the insulation thickness is 16/64ths inch 4 mm.) or over, this rule shall apply only to conductors over 26,000 cir. mils 2 sq. mm.) area.

g) *Varnished Cambric and Impregnated Paper Insulation:* Varnished cambric impregnated paper insulated wires or cables shall be tested in accordance h Table 902.

TABLE 902

High-voltage Tests for Varnished Cambric or Impregnated Paper Insulated Cables

(Minimum Values)

1	4	10	25
2	6.5	over 10	2½ times operating pressure
3	9		
4	11.5		

* The minimum thickness of insulation shall be 1/16 in. (1.6 mm.).

or intermediate working voltages, the test voltage shall be interpolated.

) *Telephone, Telegraph and Annunciator Wires and Cables:* Section 9312 l not apply to wires and cables for telephone, telegraph, annunciator and lar devices.

913. Frequency of Test Voltage. — The frequency of the test voltage shall exceed 100 cycles per second, and should approximate as closely as possible sine wave. The source of energy should be of ample capacity.

914. Dielectric Strength Tests. — Ultimate dielectric strength tests, when ured, shall be made on samples not more than 6 meters (20 ft.) long. The

---

9312 c) Hevea rubber is rubber from the Hevea Brasiliensis tree. Compounds con- ing 30 to 40 per cent of Hevea rubber have electrical and mechanical properties rior to compounds insulated in accordance with the requirements of the National trical Code.

9312 e) Different engineers specify different thickness of insulation for the same king voltages. Therefore, at the present time the test kv. corresponding to working given in Table 902, are based on the *minimum* thickness of insulation specified by neers and operating companies.

Digitized by Google

maximum allowable temperature, at which the test is made, for the particular type of insulation and the particular working pressure, shall be not greater than the temperature limits given in § 9100.

9315. Multiple-conductor Cables. — If a multiple-conductor cable is designed for the same operating voltage between conductors and sheath or water as between conductors, each conductor shall be tested against the other conductors connected together and to the sheath or water. If the cable is designed for an operating voltage between conductors and ground different from that between conductors, the test between conductors and the sheath or water shall be made separately and shall be based on the normal operating voltage between conductors and sheath or water as prescribed in § 9312.

Insulation Resistance

9320.* Expression of Insulation Resistance. — Insulation resistance shall be expressed in megohms. Linear insulation resistance, or the insulation resistance of unit length, shall be expressed in terms of the megohm-kilometer, or the megohm-mile, or the megohm-thousand-feet, and shall be corrected to a temperature of 15.5° C., using a temperature coefficient determined experimentally for the insulation under consideration.

9321. Megohms Constant. — The megohms constant of an insulated conductor shall be the factor K in the following equation:

$$R = K \log_{10} \frac{D}{d},$$

where R = insulation resistance, in megohms, for a specified unit length,
D = outside diameter of insulation,
d = diameter of conductor.

Unless otherwise stated, K will be assumed to correspond to the mile unit of length.

9322. Measurement of Insulation Resistance. — The apparent insulation resistance should be measured after the high-voltage test, measuring the leakage current after a one-minute electrification, with a continuous e.m.f. of from 100 to 500 volts, the conductor being maintained negative to the sheath or water.

9323. Insulation Resistance of Multiple-conductor Cables. — The insulation resistance of each conductor of a multiple-conductor cable shall be the insulation resistance measured from each conductor to all the other conductors in multiple with the sheath or water.

Capacitance or Electrostatic Capacity

9330.* Expression of Capacitance. — Capacitance shall be expressed in microfarads. Linear capacitance, or the capacitance of unit length, shall be expressed in microfarads per unit length (kilometer, or mile, or one thousand feet), and shall be corrected to a temperature of 15.5° C., using a temperature coefficient determined experimentally for the insulation under consideration.

9331. Microfarads Constant. — The microfarads constant of an insulated conductor shall be the factor K in the following equation:

$$C = \frac{K}{\text{Log}_{10} \frac{D}{d}}$$

where C = capacitance in microfarads per unit length,
D = outside diameter of insulation,
d = diameter of conductor.

Unless otherwise stated, K will be assumed to refer to the mile unit of length.

(9320) In the case of dry-core paper-insulated cables, the temperature coefficient of insulation resistance cannot be closely determined on account of variations in design and manufacture. Therefore no temperature corrections shall be applied to insulation resistance tests. Tests should be made at a temperature of 15.5° C. or higher.

(9330) In the case of dry-core paper-insulated cables, the temperature coefficient of capacitance cannot be determined closely on account of variations in design and manufacture. Therefore no temperature corrections shall be applied to capacitance tests. Tests should be made at a temperature of 15.5° C. or higher.

TABLE 903

Proposed Standard Cables

This table is offered for consideration but will not be recommended for fi
tion until ratified by other societies interested.)

ote 1. — Nominal diameters and circular mils of the individual wires are taken fr
e VI, circular No. 31 of the Bureau of Standards.
ote 2. — The variation of the mean diameter of any wires shall not exceed 1 per c
e or below the nominal diameter.
ote 3. — The variation of the total cross-section of the cable shall not exceed 1 p
above or below the nominal cross-section.
ote 4. — Sizes are expressed as A. W. G. numbers except where diameters are giv
ils.

332. Measurement of Capacitance. — The capacitance of cable shall
sured with alternating current by comparison with a standard condens
s preferable that the measurement be made either at a frequency appro
ing that of operation or at a frequency giving results approximating the
esponding to the operating frequency or frequencies.

333. Capacitance of Paired Cables. — The capacitance of paired cables sh
measured between the two conductors of any pair, the other wires being co
ted to the sheath or ground.

Digitized by Google

9384. Capacitance of Multiple-conductor Cables (not paired). — The capacitance of multiple-conductor (not paired) cables shall be measured between conductors, and also between each conductor and the other conductors connected to the sheath or ground.

CONSTRUCTION

Stranding

9400.* Proposed Standard Cables. — Insulated cables not requiring special flexibility shall be made of the number and size strands specified in Table 903.

9401. Cables not Requiring Special Flexibility. — Cables not requiring special flexibility and not made in accordance with § 9400 shall be stranded in accordance with Table 904.

TABLE 904

Standard Stranding of Concentric-Lay Cables

Size (see Note 1)	Square mm.	Number of Wires (See note 2.	
		A Bare, insulated or weatherproof cables for aerial use	B Insulated cables for other than aerial use
2.0 Cir. Inches	1013	91	127
1.5 "	760	61	91
1.0 "	507	61	61
0.6 "	304	37	61
0.5 "	253	37	37
0.4 "	203	19	37
0000 A. W. G.	107	19 or 7 (See note 3)	19
00 "	67.4	7	19
2 "	33.6	7	7
7 and smaller	10.5	..	7

Note 1. — For intermediate sizes, use stranding for next larger size.
Note 2. — Conductors of 0000 A. W. G. and smaller are often made solid and this table of stranding should not be interpreted as excluding this practice.
Note 3. — Class A cable, sizes 0000 and 000 A. W. G., is usually made of 7 strands when bare and 19 strands when insulated or weatherproof.

9402.* Flexible Cables. — Conductors of special flexibility should ordinarily be made with wires of regular A. W. G. sizes, and rated by the number and size of wires. The stranding of flexible cables is given in Table 905.

(9400) The basis of this rule is the use of strands of American Wire Gage sizes. To meet existing operating conditions, four sizes of strands other than American Wire Gage sizes have been deemed necessary and their diameters are shown in mils.

(9402) Where necessary to closely approximate a regular size cable, the strands may be made of half-size wires from No. 15 to No. 30 A. W. G.

1. — The A.W.G. cross-sectional areas except for 61 strands, are approximated per cent. In the case of 61 strand cables the approximation is 6 per cent.
2. — Circular mils are based on theoretical diameters of A. W. G. sizes, which ove or below values given in table by less than 0.1 mil.
3. — "61X7" in the rating of a rope-lay cable signifies 61 strands of 7 wires each.

* **Correction for Lay.** — Two per cent shall be taken as the standard nt of resistance and of mass, due to stranding. In cases where the lay itely known, the increment should be calculated and not assumed.

) The resistance and mass of a stranded conductor are greater than in a solid or of the same cross-sectional area, depending on the lay (*i.e.*, the pitch of the the wires).

Digitized by Google

Thickness of Insulation

9405. Thickness of Insulation for Rubber Insulated Wires and Cables. — Unless special conditions warrant departures from this rule, the thickness of insulation for rubber compounds containing from 30 to 40 per cent of Hevea rubber, shall be in accordance with Table 906.

TABLE 906

Thickness of Insulation

30 to 40 per cent Hevea Rubber Compound

Recommended Walls of Insulation, 64ths. Inch

Size A. W. G. or Cir. Mils	Square mm.	Working pressure, volts alternating

550,000–1,000,000	279–507	7	10	10	12	12	14	16	18	20	22	24
1,250,000–2,000,000	633–1013	8	10	10	12	14	16	18	18	20	22	24

Notes. — In multiple-conductor cables, the thickness of insulation on each conductor shall be based on the highest r.m.s. voltage between the conductor and the outside of this insulation. The above table is based upon alternating voltages of commercial frequencies. For voltages over 600, the insulation thickness for direct-current cables has not been established. For intermediate sizes the insulation thickness should be the same as for the next larger sizes.

CHAPTER X

STANDARDS FOR STORAGE BATTERIES

DEFINITIONS

10001. Battery. — A group of cells electrically connected. Storage batteries e conveniently divided in two groups: stationary batteries and portable tteries. Stationary batteries include line batteries, load-regulating batteries, ak-load batteries, oil switch and exciter-reserve batteries, stand-by batteries, sphone exchange batteries and farm light batteries. Portable batteries lude starting and lighting batteries, vehicle batteries, car lighting batteries, ctric locomotive batteries, mine-lamp batteries, and ignition batteries.

10002. Cell. — A single element with electrolyte and container.

10003. Element. — The positive and negative groups with separators assem-d.

10004. Group. — Assembly of a set of positive or a set of negative plates for : cell.

10005. Jar or Tank. — The container for a cell.

NOTE. — The term tank is generally confined to lead containers supported wood.

10006. Separator. — A device for preventing metallic contact between the tes of opposite polarity within the cell.

10007. Electrolyte. — A solution of sulphuric acid for lead batteries and of tain hydroxides for nickel-iron batteries.

10008. Positive Plate. — The grid and active material from which the cur-t flows to the external circuit when the battery is discharging.

10009. Negative Plate. — The grid and active material to which the current vs from the external circuit when the battery is discharging.

10010. Grid. — A metallic framework for conducting current and holding active material or active material units of the plate.

10011. Active Materials. — Substances reacting chemically to produce :trical energy during discharge of the cell, but subject to oxidation or reduc-1 when on charge in the reverse direction, transforming electrical energy into mical energy. In the charged condition, these are lead peroxide on the itive plates and sponge lead on the negative plates of lead-acid cells, but for kel-iron cells they are nickel peroxide in the positive tubes and iron in the ative pockets.

10012. Couple. — One positive and one negative plate connected together a unit for adjacent cells.

10013. Counter Cells. — Cells of practically no capacity used to oppose the : voltage.

10014. End Cells. — Those cells of a battery which may be cut in or out of : circuit for adjusting the voltage.

10015. Terminals. — Fittings to provide electrical connections to storage ls or batteries.

10016. Pilot Cell. — A selected cell whose temperature, voltage and gravity : assumed to indicate the state of charge of the entire battery.

MISCELLANEOUS

10020. Ampere-hour Capacity. — The number of ampere-hours which can delivered by a cell or battery under specified conditions as to temperature, te of discharge and final voltage.

10021. Ampere-hour Efficiency. — The ratio of the ampere-hours output of a ll or battery under specified conditions of temperature, rate of discharge and al voltage, to the ampere-hours of input required for complete charge. See efficiency."

Digitized by Google

10032. Average Voltage. — The average value of the voltage during the period of charge or discharge. It is conveniently obtained from the time integral of the voltage curve.

10033. Boost Charge. — A partial charge, usually at a high rate for a short period.

10034. Charge. — The restoration of the active materials in a battery by passing a direct current through it in the opposite direction to that of the discharge.

10035. Charging Rate. — The current, expressed in amperes, at which a battery is charged.

10036. Closed Circuit Voltage. — The voltage at a cell or terminals of the battery when current is flowing.

10037. Constant-current Charge. — A charge in which the current is maintained at constant value. For portable lead batteries this usually involves two rates called the starting and the finishing rates.

10038. Constant-potential Charge. — A charge in which the voltage at the terminals of the battery is held at a constant value. A modified constant potential system is one in which a fixed resistance is inserted in the charging circuit to limit the initial current.

10039. Discharge. — The conversion of the chemical energy of the battery into electrical energy.

10040. Efficiency. — The ratio of the useful output to the required input. The efficiency from an electro-chemical standpoint is the ampere-hour efficiency. It represents the ratio of the quantity of electricity delivered by the battery to the quantity required for a complete recharge, expressed in ampere-hours. The energy efficiency is the watt-hour efficiency. It represents the ratio of the energy delivered by the battery to the energy expended in charging it, expressed as watt-hours measured at the terminals of the battery. If the measurements are made at the busses, the watt-hour efficiency of the installation may be obtained. The so-called volt efficiency is the ratio of the average voltage on discharge to the average voltage on charge. The watt-hour efficiency of the battery is customarily taken as the product of the ampere-hour efficiency and the volt efficiency.

10041. Final Voltage. — The prescribed voltage upon reaching which the discharge is considered complete. The final voltage is usually chosen so that the useful capacity of the cell is realized. Final voltages vary with the kind of battery and the rate of the discharge.

10042. Equalizing Charge. — A charge given to a lead battery to insure the complete reduction of the lead sulphate. The equalizing charge is ordinarily at the finishing rate or less.

10043. Finishing Rate. — The rate of charge expressed in amperes to which the charging current for lead batteries is reduced near the end of charge to prevent excessive gassing.

10044. Gassing. — The evolution of oxygen or hydrogen, or both.

10046. Polarity. — An electrical condition determining the direction in which current tends to flow. By common usage the discharge current is said to flow from the peroxide plate or position through the external circuit. In a nickel iron battery the positive plate is that containing nickel peroxide.

10047. Reversal. — Change in normal polarity of a storage cell.

10048. Specific Gravity. — The ratio of the weight of a given volume of the liquid electrolyte to the weight of the same volume of water at a specified temperature. It is usually measured in storage battery work by a hydrometer.

10049. Trickle Charge. — A continuous charge at low rate for batteries in wet storage. It is approximately 1 per cent of the finishing rate.

10050. Volt Efficiency. — The ratio of the average voltage of the cell or battery on discharging to the average voltage on charge. See "efficiency."

10051. Watt-hour Capacity. — The ampere-hour capacity multiplied by the average voltage during discharge. It may, however, be measured directly.

2. Watt-hour Efficiency. — The ratio of the watt-hours of useful output watt-hours of input expended in charging. See "efficiency."

TEMPERATURE

1. The capacity obtained from a storage battery on discharge varies with nperature of the electrolyte. In order to compare various batteries, d reference temperatures are necessary; the following standard reference atures are established:

r. The temperature of electrolyte at beginning of discharge shall be ° C. (77° F.).

». The ambient temperature on discharge shall be from 5° C. to 8° C. er than the temperature of the electrolyte, on the beginning of discharge. e ambient temperature shall be kept constant throughout the discharge.

. (a) No limit is placed on the temperatures obtained by the electrolyte discharge.

n lead acid batteries, the limit of temperature of electrolyte permitted on depends upon the specific gravity of the electrolyte, higher temperatures ermitted on low gravity electrolyte. In general, it is desirable that the ature of the electrolyte on charge shall not exceed 45° C. (113° F.).

RATINGS

General

1. The capacities of storage batteries for different classes of service are ectly comparable. The capacity depends upon the discharge rate, e temperature of electrolyte (which has been standardized as 25° C.), gravity of electrolyte, and final voltage allowed.

1. Storage batteries shall be rated in accordance with the following ed capacity specifications:

(a) Ampere-hour capacity.
(b) Discharge rate.
(c) Reference temperature of discharge—25° C.
(d) Specific gravity of electrolyte at 25° C.
(e) Final voltage limit per cell on discharge.

1. The tabulated data required by the capacity specifications shall either n on a name-plate attached to battery, or, where this is not practicable, furnished separately.

TESTS

General

1. Batteries shall be tested as required, to determine if the rated capacity ned under the conditions as given in capacity specifications.

BATTERIES FOR SPECIAL SERVICE

). In certain definite classes of service, some or all of the variables given capacity specifications (No. 10202) can be definitely stated and stand-

CHAPTER XI

STANDARDS FOR ILLUMINATION

chapter consists of extracts from the Report of the Committee on clature and Standards of the Illuminating Engineering Society. It is cluded by permission.

General

0. Radiant flux, ϕ, is the rate of flow of radiation evaluated with refer- energy, and is expressed in ergs per second or in watts.

1.* Luminous flux is the rate of flow of radiant energy evaluated with

)1), (11006), (11007), (11008), (11010), (11011) These are the International ons as agreed on at the Paris meeting of the International Commission on Illumi- in 1921.

Digitized by Google

reference to visual sensation. Although luminous flux must strictly be defined as above, it may be regarded for practical photometric purposes as an entity, since the rate of flow is for such purposes invariable.

11002. Visibility, K_λ, of radiation of a particular wave-length is the ratio of the luminous flux at that wave-length to the corresponding radiant flux.

Defining equation: $$K_\lambda = \frac{F_\lambda}{\Phi_\lambda}.$$

11003.* The mechanical equivalent of light is the ratio of radiant flux to luminous flux for the wave-length of maximum visibility, and is expressed in ergs per second per lumen, or in watts per lumen. It is the reciprocal of the maximum visibility.

11004. Luminosity of a particular wave-length is the product of the visibility of that wave-length and the corresponding ordinate of the spectral curve of radiant flux, and is represented by the ordinate of the spectral curve of luminous flux. This curve is called the spectral luminosity curve and is different with different sources.

11006. The **Luminous efficiency** of any source is the ratio of the luminous flux to the radiant flux from the source and is expressed in lumens per watt.

11006.* Luminous intensity of a point source in any direction is the flux per unit solid angle (one steradian) emitted by the source in that direction. (The flux from any source of dimensions which are negligibly small by comparison with the distance at which it is observed, may be treated as if it were emitted from a point.)

11007*. Illumination at any point of a surface is the luminous flux density at that point, or when the illumination is uniform, the flux per unit of intercepting area.

11008.* International Candle. — The unit of luminous intensity is the International Candle, such as has resulted from international agreement between the three national standardizing laboratories of France, Great Britain and the U. S. A. in 1909.

This unit has been conserved since then by means of incandescent lamps in the laboratories which continue (or remain) charged with conservation.

11009. Candlepower, cp., is luminous intensity expressed in candles.

11010.* Lumen. — The unit of luminous flux is the lumen. It is equal to the flux emitted in a unit solid angle by a uniform point source of one international candle.

11011.* Lux, Phot, Foot-candle. — The practical unit of illumination is the lux. It is equal to one lumen per square meter, or it is the illumination at the surface of a sphere of one meter radius due to a uniform point source of one international candle placed at its center.

As a consequence of certain recognized usages, the illumination can also be expressed by means of the following units:

Using the centimeter as the unit of length, the unit of illumination is one lumen per square centimeter, and is called the phot. Using the foot as the unit of length, the unit of illumination is one lumen per square foot, and is called the foot-candle.

11012. Brightness of an element of a luminous surface may be expressed in either of two ways: (a) in terms of intensity, I, (b) in terms of flux, F.

(a) Brightness in terms of the luminous intensity I (or candle-power) per unit of projected area of the surface (candlepower brightness) corresponds to

defining equation, $$bI = \frac{dI}{dS \cos\theta}$$

where θ is the angle between the normal to the surface and the line of sight.

(b) Brightness in terms of the flux, F, proceeding from a unit area of the sur-

---

(11003) This term has been used in a variety of senses. As here defined it refers only to the minimum mechanical equivalent of light. The reciprocal of this quantity is sometimes called the luminous equivalent of radiation.

(11010) A uniform source of one candlepower emits 4π lumens.

Google

, on the assumption that the surface is a perfect diffuser; *i.e.*, that it obeys cosine law of emission or reflection, (lumen brightness) corresponds to the

$$\text{defining equation, } b_F = \frac{dF}{dS}$$

fect diffusion assumed).
he units in which brightness is measured according to (a) and (b) differ only umerical value. See § 11013.

1013. Lambert, *L*, is the unit of brightness in the lumen system. The bert is the brightness of a perfectly diffusing surface emitting or reflecting lumen per square centimeter. For most purposes the **millilambert,** 0.001 bert, is the preferable practical unit.
o say that the brightness of a surface as viewed from a given point is *n* berts, signifies that its brightness is the same as that of a perfectly diffusing ace emitting or reflecting *n* lumens per square centimeter.
n practice no surface obeys exactly the cosine law of emission or reflection; ce the brightness of a surface generally is not uniform but varies somewhat the angle at which it is viewed.
perfectly diffusing surface emitting one lumen per square foot will have a htness of 1.076 millilamberts.
rightness expressed in candles per square centimeter may be reduced to berts by multiplying by $\pi = 3.14$.
rightness expressed in candles per square inch may be reduced to lamberts multiplying by $\pi/6.45 = 0.487$.

Surfaces and Media Modifying Luminous Flux

1020. Diffusing surfaces and media are those which break up the incident and distribute it more or less in accordance with the cosine law, as for mple, white plaster and opal glass.

1021. Redirecting surfaces and media are those which change the direction he luminous flux in a definite manner; as for example, a mirror or a lens.

1022. Scattering surfaces and media are those which redirect the luminous and break it up into a multiplicity of separate pencils; as for example, le glass, reflecting or transmitting.

1023.* Reflection factor, of a body ρ, is the ratio of the flux reflected by the y to the flux incident upon it. The reflection from a body may be regular, use or mixed. In regular reflection the flux is reflected at an angle of reflec- equal to the angle of incidence. In diffuse reflection the flux is reflected in directions. In perfectly diffuse reflection, the distribution of the reflected is in accordance with Lambert's cosine law. In most practical cases, there superposition of regular and diffuse reflection.

1024.* Absorption factor, of a body a, is the ratio of the flux absorbed by the y to the flux incident upon it.

1025.* Transmission factor, of a body τ, is the ratio of the flux transmitted the body to the flux incident upon it.

$$\rho + a + \tau = 1.$$

Illumination

1030. Unidirectional illumination on a surface is that produced by a single t source of relatively small dimensions. It is characterized by the fact that mall opaque object placed near the illuminated surface casts a sharp shadow.

1031. Multidirectional illumination on a surface is that produced by several arated light sources of relatively small area. It is characterized by the fact t a small opaque object placed near the illuminated surface casts several dows.

11023) (11024) (11025) These terms are introduced to replace the more commonly d terms, Coefficient of reflection, Coefficient of absorption, Coefficient of transmission, ich latter terms refer to the specific properties of materials rather than to the behavior bodies under specified conditions, such as angle of incidence, etc.

11032. Diffused illumination is that produced either by primary or secondary light sources having dimensions relatively large with respect to the distance from the point illuminated, and scattering light in all directions. It is characterized by relative lack of shadow. **Diffused illumination** may be derived principally from a single direction as in the light from a skylit window or from directions as in the open air. Perfectly diffused illumination on a surface is shadowless.

In any practical case of illumination on a surface there is usually a mixture of the above types.

11033. Coefficient of utilization of an illumination installation on a given plane is the total flux received by that plane divided by the total flux from the lamps illuminating it. When not otherwise specified, the plane of reference is assumed to be a horizontal plane 30 inches (76 cm.) from the floor.

11034. Variation factor of an illumination installation is the ratio of either the maximum or minimum illumination on a given plane to the average illumination on that plane.

11035. Variation range of illumination on a given plane is the ratio of the maximum illumination to the minimum illumination on that plane.

11036. Hemispherical ratio for a given lighting unit is the ratio of the luminous flux in the upper hemisphere to that in the lower hemisphere.

11037. Brightness ratio is the ratio of the brightness of any two surfaces. When the two surfaces are opposed, the brightness ratio is commonly called the "brightness contrast."

Illuminants

11040. The output of all illuminants should be expressed in **lumens.**

11041. Illuminants should be rated upon a lumen basis rather than a candle power basis.

11042. Lamp efficiency is the ratio of the luminous flux output to the power input.

11043. The lamp efficiency or **specific output of electric lamps** should be stated in terms of lumens per watt and that of illuminants depending upon combustion should be stated in lumens per British thermal unit per hour.

11044. The power consumption of **auxiliary devices** which are necessarily employed in circuit with a lamp should be included in the input of the lamp. For example, the watts lost in the ballast resistance of an arc lamp are properly chargeable to the lamp.

11045. The specific consumption of an electric lamp is its watt consumption per lumen. "Watts per candle" is a term used commercially in connection with electric incandescent lamps, and denotes watts per mean horizontal candle.

11046. Life Tests. — **Electric incandescent lamps of a given type** may be assumed to operate under comparable **conditions only when their lumens per** watt consumed are the same. Life test results, in order to be compared, must be either conducted under, or reduced to, comparable conditions of operation.

11047. In comparing different luminous sources not only should their candle power be compared, but also their relative form, **brightness,** distribution of illumination and character of light.

Lamp Accessories

11048. A reflector is an appliance the chief use of which is to redirect the luminous flux of a lamp in a desired direction or directions.

11049. A shade is an appliance the chief use of which is to diminish or to interrupt the flux of a lamp in certain directions where such flux is not desirable. The function of a shade is commonly combined with that of a reflector.

11050. A globe is an enclosing appliance of clear or diffusing material the chief use of which is either to protect the lamp or to diffuse its light.

Photometry

1060. **Performance curve** is a curve representing the behavior of a lamp in particular (candlepower, consumption, etc.) at different periods during its

1061. **Characteristic curve** is a curve expressing a relation between two ible properties of a luminous source, as candlepower and volts, candlepower rate of fuel consumption, etc.

1062. **Mean horizontal candlepower** of a lamp is the average candlepower e horizontal plane passing through the luminous center of the lamp. is here assumed that the lamp (or other light source) is mounted in the l manner, or, as in the case of an incandescent lamp, with its axis of sym- y vertical.

1063. **Mean spherical candlepower** of a lamp is the average candlepower of a in all directions in space. It is equal to the total luminous flux of the lamp mens divided by 4π.

1064. **Mean hemispherical candlepower** of a lamp (upper or lower) is the ge candlepower of a lamp in the hemisphere considered. It is equal to the luminous flux emitted by the lamp in that hemisphere divided by 2π.

1065. **Mean zonal candlepower** of a lamp is the average candlepower of a over the given zone. It is equal to the total luminous flux emitted by the in that zone divided by the solid angle of the zone.

1066.* **Spherical reduction factor** of a lamp is the ratio of the mean spherical e mean horizontal candlepower of the lamp.

TABLE 1100

Photometric Units and Abbreviations

otometric quantity	Name of unit	Symbols and defining equations	Abbreviation for name of unit
uminous flux	Lumen	$F.\psi$	l.
aminous intensity.	Candle	$I=\frac{dF}{d\omega}$, $\Gamma=\frac{d\psi}{d\omega}$	cp.
llumination	Phot, foot-candle, lux	$E=\frac{dF}{dS}=\frac{I}{r^2}\cos\theta$	ph. fc.
xposure	Phot-second	Et	
	Micro phot-second		phs. μ phs.
rightness	Apparent candle per sq. cm.	$b_l=\frac{dI}{dS\cos\theta}$	
	Apparent candle per sq. in.		
	Lambert	$b_l=\frac{dF}{dS}$	L. mL.
eflection factor		ρ	
bsorption factor		α	

ransmission factor	τ
lean spherical candlepower	scp.
lean lower hemispherical candlepower	lcp.
lean upper hemispherical candlepower	ucp.
lean zonal candlepower	zcp.
lean horizontal candlepower	mhc.

066) In the case of a uniform point-source, this factor would be unity, and for a ht cylindrical filament obeying the cosine law it would be $\pi/4$.
erfect diffusion assumed.

14. 1 lumen is emitted by 0.07958 spherical candlepower.
15. 1 spherical candlepower emits 12.57 lumens.
16. 1 lux = 1 lumen incident per square meter = 0.0001 phot = 0.1 milliphot.
17. 1 phot = 1 lumen incident per square centimeter = 10,000 lux = 1,000 milliphots = 1,000,000 microphots.
18. 1 milliphot = 0.001 phot = 0.929 foot-candle.
19. 1 foot-candle = 1 lumen incident per square foot = 1.076 milliphots = 10.76 microphots.
20. 1 lambert = 1 lumen emitted per square centimeter of a perfectly diffusing surface.
21. 1 millilambert = 0.001 lambert.
22.*1 lumen, emitted, per square foot = 1.076 millilamberts.
23.*1 millilambert = 0.929 lumen, emitted, per square foot.
24. 1 lambert = 0.3183 candle per square centimeter = 2.054 candles per square inch.
25. 1 candle per square centimeter = 3.1416 lamberts.
26. 1 candle per square inch = 0.487 lambert = 487 millilamberts.

CHAPTER XII

STANDARDS FOR TELEPHONY AND TELEGRAPHY

Many of the following definitions are tentative and not yet fully established. Criticisms and suggestions, addressed to the Secretary of the Standards Committee, will be welcomed. Some of the definitions are specific to telephony and differ in detail from similar definitions appearing in other parts of the rules.

DEFINITIONS

Line Circuits

12000. Ground-return Circuit. — A ground-return circuit is a circuit consisting of one or more metallic conductors in parallel, with the circuit completed through the earth.

12001. Metallic Circuit. — A metallic circuit is a circuit of which the earth forms no part.

12002. Two-wire Circuit. — A two-wire circuit is a metallic circuit formed by two parallel conductors insulated from each other.

12003. Superposed Circuit. — A superposed circuit is an additional circuit obtained from a circuit normally required for another service, and in such a manner that the two services can be given simultaneously without mutual interference.

12004. Phantom Circuit. — A phantom circuit is a superposed circuit, the two sides of which consists of the two conductors of a two-wire circuit in parallel.

12005. Side Circuit. — A side circuit is a two-wire circuit forming one side of a phantom circuit.

12006. Non-phantomed Circuit. — A non-phantomed circuit is a two-wire circuit, which is not arranged for use as the side of a phantom circuit.

12007. Simplexed Circuit. — A simplexed circuit is a two-wire telegraph circuit, arranged for the superposition of a single ground-return signalling circuit operating over the wires in parallel.

12008. Composited Circuit. — A composited circuit is a two-wire telegraph circuit, arranged for the superposition on each of its component metallic conductors of a single independent ground-return signalling circuit.

12009. Quadded or Phantomed Cable. — A quadded or phantomed cable is a cable adapted for the use of phantom circuits.

12010. Simplex Circuit. — A simplex circuit in telegraphy is one arranged for operation in one direction at one time.

12011. Duplex Circuit. — A duplex circuit in telegraphy is one arranged for simultaneous operation in opposite directions.

Digitized by Google

012. Diplex Circuit. — A diplex circuit in telegraphy is one arranged for simultaneous transmission of two messages in the same direction.

013. Quadruplex Circuit. — A quadruplex circuit in telegraphy is one ged for the simultaneous transmission of two messages in each direction.

014. Multiplex Circuit. — A multiplex circuit in telegraphy is one arranged he simultaneous transmission of one or more messages in both directions. duplex and quadruplex are examples of multiplex whereas diplex is not.

015. Linear Electrical Constants. — The linear electrical constants of a re the electrical constants per unit length of the line, *e.g.*, linear resistance, nductance, etc.

016. Smooth Line. — A smooth line is a line whose electrical elements are ntinuously and uniformly distributed throughout its length.

017.* Periodic Line. — A periodic line is a line consisting of successive r sections in each of which one or more electric elements are not distributed rmly. As examples of periodic lines are (1) loaded lines and (2) artificial consisting of successive similar sections of lumped constants.

018. Equivalent Smooth Line. — An equivalent smooth line of a periodic s a smooth line having the same electrical behavior as the periodic line, at a single frequency, when measured at terminals or at corresponding section ions.

019. Equivalent Periodic Line. — An equivalent periodic line of a smooth is a periodic line having the same electrical behavior, for an assumed single ency, as the smooth line, when measured at terminals or at corresponding n junctions. The terms conjugate smooth line and conjugate periodic re also sometimes used.

020. Composite Line. — A composite line is a line consisting of a plurality ccessive sections having different linear electrical constants, as in the case e an underground cable section is joined to an overhead open-wire section.

021. Loaded Line. — A loaded line is one in which the normal reactance of circuit has been altered for the purpose of increasing its transmission effi- y.

023. Series Loaded Line. — A series loaded line is one in which the normal ance has been altered by reactance serially applied.

025. Shunt Loaded Line. — A shunt loaded line is one in which the normal ance of the circuit has been altered by reactance applied in shunt across ircuit.

024. Continuous Loading. — A continuous loading is a series loading in h the added inductance is uniformly distributed along the conductors.

025.* Coil Loading. — A coil loading is one in which the normal inductance ered by the insertion of lumped inductance in the circuit at intervals.

Circuit Constants and Characteristics

050. Damping of a Circuit. — The damping at a given point in a circuit which the source of energy has been withdrawn, is the progressive diminu- in the effective value of electromotive force and current at that point ting from the withdrawal of electrical energy.

051.* Damping Constant. — The damping constant of a circuit is a measure

---

017) The term periodic in this definition refers to the line constants and not to time ons.

025) This lumped inductance may be applied either in series or in shunt. commonly understood, coil loading is a series loading, in which the lumped induct- is applied at uniformly spaced recurring intervals.

051) Applied to the admittance of a condenser or other simple circuit having capacity ance, the damping constant for a harmonic electromotive force of given frequency is atio of the conductance G, of the condenser or simple circuit at that frequency to the capacitance, C, of the condenser at the same frequency. $(G/2C)$.

Digitized by Google

of the ratio of the dissipative to the reactive component of its admittance impedance.

12052.* Mutual Impedance. — The mutual impedance for single frequ alternating currents, between a pair of terminals and a second pair of term of a network, under any given condition, is the negative ratio of the electromo force produced between either pair of terminals on open circuit to the cu flowing between the other pair of terminals.

12053.* Self-impedance. — The self-impedance between a pair of term of a network, under any given condition, is the ratio of the electromotive f applied across the terminals to the entering current.

12054.* Characteristic Impedance. — The characteristic impedance of a is the ratio of the applied electromotive force to the resulting steady-state c rent upon a line of infinite length and uniform structure, or of periodic recur structure.

12055.* Sending-end Impedance. — The sending-end impedance of a is the ratio of the applied electromotive force to the resulting steady-state cu at the point where the electromotive force is applied.

12056.* Propagation Constant. — The propagation constant of a uni line, or section of a line of periodic recurrent structure, is the natural logar of the ratio of the steady-state currents at various points separated by unit in a uniform line of infinite length, or at successive corresponding points in of recurrent structure of infinite length. The ratio is determined by div the value of the current at the point nearer the transmitting end by the va the current at the point more remote.

12057. Attenuation Constant. — The attenuation constant for a single quency is the real part of the propagation constant taken at that frequency.

12058. Wave-length Constant. — The wave-length constant is the imagin part of the propagation constant.

12059. Standard Cable. — A standard cable is an ideal uniform line in ter of which the attenuation of a line or network may be specified. It is ch acterized by the following constants: Linear resistance, 88 ohms per loop m (54.7 ohms per loop km.). Linear capacitance between wires 0.054 microfa per loop mile (0.03355 microfarad per loop km.). Linear inductance and in leakance, 0.

Equivalent Circuits

12102.* Equivalent Circuit. — An equivalent circuit is a simple network series and shunt impedances, which, at a given frequency, is the approxim electrical equivalent of a complex network.

12103.* "T" Equivalent Circuit. — A "T" equivalent circuit is a th star or "Y" connection of three impedances externally equivalent to a com network. See Fig. 12-1 for symbol.

(12052) A receiving-end impedance is an example of a mutual impedance.

Single-frequency voltages and currents are here supposed to be represented by com numbers. Their ratio is therefore a complex number.

(12053) Single-frequency voltages and currents are here supposed to be represe by complex numbers. Their ratio is therefore a complex number.

(12054) In practise, the terms (1) line impedance, (2) surge impedance, (3) iter impedance, (4) sending-end impedance, (5) initial sending-end impedance, (6) final s ing-end impedance, (7) natural impedance and (8) free impedance, have apparently b more or less indefinitely and indiscriminately used as synonyms with what is here de as "characteristic impedance."

Single-frequency voltages and currents are here supposed to be represented by com numbers. Their ratio is therefore a complex number.

(12055) See note under "Characteristic Impedance." In case the line is of infi length of uniform structure or of periodic recurrent structure, the sending-end impeda and the characteristic impedance are the same.

Single-frequency voltages and currents are here supposed to be represented by comp numbers. Their ratio is therefore a complex number.

(12056) Single-frequency voltages and currents are here supposed to be represe by complex numbers. Their ratio is therefore a complex number.

(12102 to 12106 Incl.) As ordinarily considered, the simple networks, as defined, are

4.* "*I*" **Equivalent Circuit.** — An "*I*" equivalent circuit is a connec- five impedances in the form shown in Fig. 12-2, which is externally lent to a complex network. It differs from the "*T*" equivalent circuit the impedances are arranged symmetrically on the two sides of the circuit, is often desirable in connection with practical problems, as indicating e circuit is balanced with respect to ground.

5.* "Π" **Equivalent Circuit.** — A "Π" equivalent circuit is a delta tion of three impedances externally equivalent to a complex network. so called a "*U*" equivalent circuit. See Fig. 12-3 for symbol.

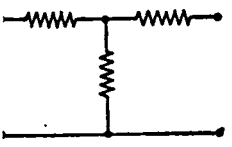

Fig. 12-1

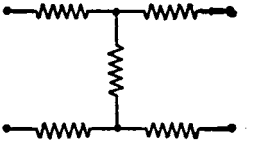

Fig. 12-2

6.* "*O*" **Equivalent Circuit.** — An "*O*" equivalent circuit is a connec- four impedances in the form shown in Fig. 12-4, externally equivalent to lex network. It differs from the Π equivalent circuit in that the impedre arranged symmetrically on the two sides of the circuit, which is often e in connection with practical problems, as indicating that the circuit is d with respect to ground.

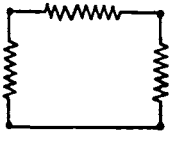

Fig. 12-3

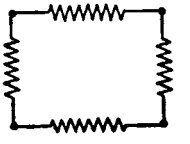

Fig. 12-4

Telephony

). **Manual Telephone System.** — A manual telephone system is one in he calling party gives his order to an operator who completes the call by hand, either with or without the assistance of one or more additional rs.

. **Automatic or Full Mechanical Telephone System.** — An automatic or chanical telephone system is one in which the calling party is enabled to te a call by remote-control switches without the aid of an operator.

. **Semi-automatic or Semi-mechanical Telephone System.** — A semitic or semi-mechanical telephone system is one in which the calling party is order to an operator who completes the call through remote-control s.

. **Telephone Exchange.** — A telephone exchange consists of one or more offices with associated plant, by means of which telephone service is d in a specified local community.

. **Telephone Exchange Area or District.** — A telephone exchange area ict is the area or district served by a telephone exchange.

. **Central Office (British "Exchange").** — A central office is a switching or inter-connecting lines terminating therein.

. **Toll Central Office.** — A toll central office is one in which toll and long e lines terminate.

. **Local Central Office.** — A local central office is one in which subscriber's rminate.

12206. Private Branch Exchange (Generally Abbreviated "P. B. X."). — A private branch exchange is a telephone system generally installed on the premises of a subscriber, including a switchboard and extension sets, and connected to a central office, affording intercommunication between the extension sets and also between these sets and the central office.

12209. Private Exchange. — A private exchange is one which serves a business organization or individual, and is not connected to a central office.

12210. Private Automatic Exchange. — A private automatic exchange is an automatic exchange which serves one business organization or individual, and not connected to a central office.

12211. Subscriber Set (Often Abbreviated to "Subset"). — A subscriber set is an assembly of apparatus for sending and receiving telephone calls.

12212. Subscriber Station (Often Abbreviated to "Substation"). — A subscriber station is an installed subscriber set connected to a central office for the purpose of sending and receiving telephone calls.

12213. Pay Station (British "Public Call Office"). — A pay station is a subscriber station available for the use of the public on the payment of a fee. The fee may be either deposited in a coin box or paid to an attendant.

12214. Toll Station. — A toll station is a pay station located outside of a local service area and affording toll and long distance service only.

12215. Subscriber Line or Subscriber Loop. — A subscriber line or subscriber loop is the wire connection between a subscriber station and the central office.

12216. Subscriber Line Circuit. — A subscriber line circuit is a subscriber line with its associated individual central office apparatus.

12217. Individual Line (British "Direct Line"). — An individual line is a subscriber line which connects one subscriber station to a central office, though it may have one or more extension sets.

12218. Party Line. — A party line is a subscriber line which connects two or more subscriber stations to a central office.

12219. Tip Side or Tip Wire, Ring Side or Ring Wire. — The tip side or wire, or the ring side or wire, is that conductor of a circuit which is associated with the corresponding member of a jack.

12220. Negative Side or Negative Wire, Positive Side or Positive Wire. — The negative side or wire, or the positive side or wire, is that conductor of a circuit which is normally connected to the corresponding pole of a battery.

12221. Main Distributing Frame. — A main distributing frame is a structure for terminating the permanent inside and outside wires of a central office and effecting flexible junctions between them. It generally carries central office protective devices and functions as a test point between line and office.

12222. Intermediate Distributing Frame. — An intermediate distributing frame is a structure for terminating permanent inside wires of a central office and for effecting flexible junctions between them.

12223. Switchboard. — A switchboard is an assemblage of apparatus for coordinate structure for switching talking and signaling circuits.

12224. Switchboard Section. — A switchboard section is an element or unit one or more of which constitutes a complete manual switchboard.

12225. Operating Room. — An operating room is a room which contains a manual switchboard and associated apparatus.

12226. Combination Current. — A combination current consists of two or more currents of different characteristics in the same circuit. As ordinarily used the term refers to currents whose characteristics are steadily maintained, as for example, a combination of direct current and an alternating current.

12227. Manual Ringing. — Manual ringing is ringing which is effected and continues with the operation of a key.

12228. Machine Ringing. — Machine ringing is intermittent and is caused to act periodically by the apparatus itself.

Digitized by Google

12229. Superimposed Ringing Current. — A superimposed ringing current is a mbination current for ringing, consisting of a direct and an alternating current.

12230. Pulsating Ringing Current. — A pulsating ringing current is a current r ringing in which the succeeding impulses are separated by intervals approxi- tely equal to those of the impulses themselves.

12231. Harmonic Selective Signaling. — Harmonic selective signaling employs vices tuned mechanically or electrically to the frequency of the ringing current, that each device will not operate when receiving current intended to operate other device.

12232. Multiple Harmonic Signaling. — Multiple harmonic signaling employs quencies which are integral multiples of the lowest frequency.

12233. Non-multiple Harmonic Signaling. — Non-multiple harmonic signal- employs frequencies which are not integral multiples of the lowest frequency.

12234. "To Call." — "To call" is to originate a telephone call.

12235. "To Dial." — "To dial" a number is to use a dial type of calling vice in order to control automatic switches.

12236. "To Set Up." — "To set up" a number is to use a key type or multiple r type of calling device in order to control automatic switches.

12237. Calling Device. — A calling device is an apparatus by means of which omatic switches are controlled for the purpose of establishing a connection.

12238. Calling Party. — A calling party is a person who originates a telephone

12239. Called Party. — A called party is the person who answers when a tion is called.

12240. Reverting Call. — A reverting call is one between two stations on the ne subscriber line.

12241. Telephone Traffic. — Telephone traffic is the aggregate volume of nmunication handled in a given time.

12242. "Busy." — "Busy" is the condition of a line or an apparatus when n in use.

12243. Free. — Free is the condition of a line or an apparatus when it is not se. Free is the opposite of busy.

12244. "To Make Busy." — "To make busy" is to cause a line or an appa- us to appear to be busy.

12245. "To Release" or to "Disconnect." — "To release" or "to discon- t" is to terminate a telephone connection by disengaging the apparatus.

12246. "To Clear." — "To clear" is to restore a line or an apparatus to the t condition.

12247. Trunk. — A trunk is the wire connection between switching devices central offices.

12248. Trunk Circuit. — A trunk circuit is a trunk with its associated indi- ual apparatus.

12249. Trunked Call. — A trunked call is one which employs an inter-office nk or a trunk between two switchboard positions.

12250. Relay. — A relay is a device by means of which contacts in one circuit operated by a change in conditions in the same circuit or in one or more ociated circuits. (See Rule 7016.)

12251. Polar Relay. — A polar relay is a relay which operates in response to hange in the direction of the current in the controlling circuit.

12252. Quick Operating Relay. — A quick operating relay is one which erates its contacts within a specified brief time limit.

12253. Quick Release Relay. — A quick release relay is one which releases contacts within a specified brief time limit.

12254. Quick Acting Relay. — A quick acting relay is one which has the roperties of both a quick operating and a quick release relay.

12255. Slow Operating Relay. — A slow operating relay is one which does not operate until after a specified delay.

12256. Slow Release Relay. — A slow release relay is one which when operated will not release until after a specified delay.

12257. Slow Acting Relay. — A slow acting relay is one which has the properties of both a slow operating and a slow release relay.

12258. Line Relay. — A line relay is one whose coil is normally in the line circuit.

12259. Cut-off Relay. — A cut-off relay is one which when operated disconnects from a line apparatus normally connected to it.

12260. Relay Coil Section. — A relay coil section is one of two or more windings of a coil on one and the same core. The several sections may be concentric or placed side by side on the core.

12261. Tension Spring. — A tension spring is one which functions through mechanical pressure but does not carry an electrical current.

12262. Contact Spring. — A contact spring is one which takes an electrical part in switching a circuit.

12263. Main Contact Spring. — A main contact spring is one which directly switch a circuit between two or more other contact springs.

12264. Armature Spring. — An armature spring is the first of a group to be moved by the armature. It may or may not be a main contact spring.

12265. Plunger Spring. — A plunger spring is the first of a group to be moved by the plunger.

12266. Impulse Springs. — Impulse springs are those which act to make and break a circuit for the purpose of sending impulses.

12267. Make-Before-Break Contact Springs (Abbreviation "M. B. B." — Make-before-break contact springs are those in which the main spring touches the front contact before it breaks away from the back contact. Also called continuity preserving contact.

12268. Back Contact Spring. — A back contact spring is one against which the main contact spring rests when in the normal position.

12269. Front Contact Spring. — A front contact spring is one against which the main contact spring rests when in the operated position.

12270. Automatic Signaling. — Automatic signaling is effected without the aid of an operator.

12271. Automatic Switch. — An automatic switch is a remote control device for controlling talking or signaling circuits.

12272. Finder Switch. — A finder switch is a switch connected to one of a smaller number of circuits and which finds automatically a circuit out of a larger number of circuits from whence the signal comes.

12273. Line Switch. — A line switch is a switch connected to one of a larger number of circuits from which a signal comes and which finds automatically the circuit out of a smaller number of circuits.

12274. Selector Switch. — A selector switch is a switch whose duty is to select a particular group of trunks and one trunk of the group selected. In particular cases, one of these functions may be omitted.

12275. Connector Switch or Final Selector. — A connector switch or final selector is a switch whose duty is to establish a connection with the called line. It is usually operated by the last digit or digits of the call number.

12276. Switch Frame. — A switch frame is a structure for mounting the assembly of switching apparatus which may be integral therewith.

12277. Section of Switches. — A section of switches, considered from a mounting standpoint, is a group of adjacent switches whose banks are multiplied together.

12278. Switchroom. — A switchroom is a room which contains an assembly of automatic switches and associated apparatus.

Bank Wires. — Bank wires are those wires which multiple adjacent banks to each other.

Bank Cable. — A bank cable is one which connects a switch bank to a rack.

Multiple Cable. — A multiple cable is one which multiples together more sections of switch banks by connecting together their terminals.

Impulse. — An impulse is any sudden change of brief duration pro- the current of a circuit.

Make Impulse. — A make impulse is an impulse due to a temporary current.

Break Impulse. — A break impulse is an impulse due to a temporary tion of current.

Impulse Frequency. — The impulse frequency is the number of occurring per second. The reciprocal of this is the impulse period.

Impulse Period. — The impulse period is the period of time included the corresponding points in periodically recording impulses. It thus ds to the period of alternating current.

Impulse Ratio. — Impulse ratio is the ratio of duration of an impulse pulse period.

Impulse Circuit. — An impulse circuit is one through which impulses mitted.

Telephone Impulse Repeater. — A telephone impulse repeater is a r repeating impulses from one line circuit into another and for perform- r duties.

Supervisory Signal. — A supervisory signal is a device for attracting a of an attendant to a duty in connection with switching apparatus or sories. This includes cord supervisory lamps on a manual switchboard supervisory lamps in an automatic exchange which indicates that a as been occupied but has not completed its function.

Tell-tale Signal. — A tell-tale signal is a device for locating the f some apparatus; for example, the blowing of a fuse, the continued of heavy current by apparatus intended to receive only momentary etc.

Alarm Signal. — An alarm signal is a sound-producing device for g attention to either a supervisory or a tell-tale signal.

Amplifier. — See § 13040.

Telephone Repeater. — A telephone repeater is a device for ampli- oice current from one line circuit into another line circuit.

Telephone Receiver. — A telephone receiver is an electrically oper- ice designed to produce sound waves or vibrations which correspond to romagnetic waves or vibrations actuating it.

Microphone. — A contact device designed to have its electrical resist- ectly and materially altered by slight differences in mechanical pressure.

Telephone Transmitter. — A telephone transmitter is a sound-wave- or vibration-operated device designed to produce electromagnetic vibrations which correspond to the sound waves or vibrations actuat-

* **Coefficient of Coupling of a Transformer.** — The coefficient of coup- transformer at a given frequency is the ratio of the mutual impedance the primary and secondary of the transformer, to the square root of uct of the self-impedances of the primary and of the secondary.

Repeating Coil. — A term used in telephone practice meaning the transformer, and ordinarily a transformer of unity ratio.

Single-frequency voltages and currents are here supposed to be represented ex numbers. Their ratio is therefore a complex number.

Google

12305.* **Retardation Coil.** — A retardation coil is a reactor (reactance coil) used in a circuit for the purpose of selectively reacting on currents which flow at different rates.

12306. Manual Switchboard. — A manual switchboard is one in which switching operations are performed by hand.

12307. Multi Office Exchange (British "Multi Exchange System"). — A multi office exchange is one which is composed of more than one office.

12308. Trunk Hunting. — Trunk hunting is the operation of an automatic switch in moving its wipers or brushes to an idle set of terminals or contacts in a chosen group of terminals or contacts.

12309. Wiper. — A wiper is that portion of the moving member of a switch which engages with a bank contact.

12310. Bank. — A bank is an assembly of fixed contacts with which the moving members of a selector engage. Banks are usually multiplied.

Telegraphy

12500. Relay. — A relay is a device by means of which contacts in one circuit are operated by a change in conditions in the same circuit or in one or more associated circuits.

12501. Polar Relay. — A polar relay is a relay which operates in response to a change in the direction of the current in the controlling circuit.

12502. Non-polar Relay, or Neutral Relay. — A non-polar relay is a relay which operates in response to a change in the strength of the current in the controlling circuit, irrespective of the direction of the current.

12503. Neutral Relay. — See non-polar relay.

12504. Selector. — A selector is a device which performs certain functions such as causing an electric lamp to light, or an electric bell to sound, in response to a definite signal or group of successive signals received over a control circuit.

12505. Direct-point Repeater. — A direct-point repeater is a repeater in which the receiving relay controlled by the signals received over a line repeats these signals into another line or lines without the interposition of any telegraph repeating or transmitting apparatus.

12506. Concentrator. — A concentrator is a traffic distributing device by means of which a number of telegraph or telephone lines, and connected operating instruments are brought together at one point to facilitate their interconnection at such times as signals or messages are to be transmitted from one to the other.

12507. Transmitter. — A transmitter is a device for effecting electrical changes in a controlled circuit. The term transmitter is commonly applied principally to devices which in response to a controlling means effects in a main line telegraph circuit electrical changes necessary to send signals over the line.

12508. Synchronous System. — A synchronous system of telegraphy is one in which the proper transmission and reception of signals is dependent upon the synchronous operation of similar commutators or other devices located at the sending and receiving stations of a circuit.

12509. Differential Duplex. — A differential duplex is a duplex system in which at each station one of two portions of the receiving instrument is connected in series with the line wire and the other in series with an artificial line of such electrical characteristics that the effects upon the receiver of currents passing through the main and artificial lines, as a result of outgoing signals, are neutralized.

12510. Bridge Duplex. — A bridge duplex is a duplex system in which the receiving instruments at each station are connected across two impedances

---

(12305) In telephone and telegraph usage, the terms "impedance coil," "inductance coil," "choke coil" and "reactance coil" are sometimes used in place of the term "retardation coil."

ies with the line wire and the other in series with the artificial line in such ner that no electrical change in the receiver circuit is effected by outgoing ls.

111. **Half-set Repeater.** — A half-set repeater is a repeater used for con- ng together a simplex circuit and a duplexed circuit converting them into quivalent of a single simplex circuit.

112. **Intermediate Current Supply.** — An intermediate current supply is an anded source of current connected in series with a line wire at a station than a terminal on a ground return telegraph circuit.

113. **Phantoplex Circuit.** — A phantoplex circuit is a superposed circuit ated by alternating current over a simplex, duplex or quadruplex circuit ated from direct-current sources.

114. **Spark Condenser.** — A spark condenser is a condenser, with or without ated non-inductive resistance, connected with a pair of instrument contact s for the purpose of diminishing sparking at these points.

115. **Current Margin.** — In a non-polar simplex system, the difference en the current flowing through a receiving instrument when operated, to lo- ing when not operated.

116. **Margin Ratio.** — In a non-polar simplex system, the ratio of the cur- lowing through a receiving instrument when operated, to that flowing when perated.

117. **Percentage Margin.** — In a non-polar simplex, the current margin ured as a percentage of the current flowing through the relay when operated.

118. **Main Circuit.** — A main circuit is a major electrical circuit of a tele- system and includes both transmitting and receiving devices.

119. **Local Circuit.** — A local circuit is a circuit, within the limits of the n, usually controlled by a receiving instrument in a main circuit or con- ng a transmitter effecting changes in a main line circuit.

CHAPTER XIII

STANDARDS FOR RADIO COMMUNICATION

General

s chapter has been mainly abstracted from the report of the Standardisa- Committee of the Institute of Radio Engineers, and is here included by ssion, until further revised. For full particulars, see the I. R. E. Stand- ion Committee report.

120. **Acoustic Resonance Device.** — One which utilizes, in its operation, nce to the audio frequency of the received signals.

121. **Antenna.** — A system of conductors designed for radiating or absorb- f energy of electromagnetic waves.

122. **Atmospheric Absorption.** — That portion of the total loss of radiated due to atmospheric conductivity.

123. **Audio Frequencies.** — Frequencies corresponding to the normally e vibrations. These are assumed to lie below 10,000 cycles per second.

124. **Capacitive Coupler.** — An apparatus which, by electric fields, joins rs of two radio-frequency circuits, and which is used to transfer electrical between these circuits through the action of electric forces.

125. **Coefficient of Coupling (Inductive).** — The ratio of the effective l inductance of two circuits to the square root of the product of the ve self-inductances of each of these circuits.

126. **Direct Coupler.** — A coupler which magnetically joins two circuits a common conductive portion.

18007. Counterpoise. — A system of electrical conductors forming a portion of a radiating oscillator, the other portion of which is the antenna. In land stations a counterpoise forms a capacitive connection to ground.

18008. Damped Alternating Current. — A damped alternating current is an alternating current whose amplitude progressively diminishes.

18009. Damping Factor. — The damping factor of an exponentially damped alternating current is the product of the logarithmic decrement and the frequency.

Let I_0 = initial amplitude,
I_t = amplitude at the time t,
e = base of Napierian logarithms,
a = damping factor.

Then $I_t = I_0 e^{-at}$.

18010. Detector. — That portion of the receiving apparatus which, connected to a circuit carrying currents of radio frequency, and in conjunction with a source contained or separate indicator, translates the radio-frequency energy into a form suitable for operation of the indicator. This translation may be effected either by the conversion of the radio-frequency energy, or by means of the control of local energy by the energy received.

18015. Electromagnetic Wave. — A periodic electromagnetic disturbance progressing through space.

18016. Forced Alternating Current. — A current, the frequency and damping of which are equal to the frequency and damping of the exciting electromotive force.

18017. Free Alternating Current. — The current following any electromagnetic disturbance in a circuit having capacitance, inductance, and less than the critical resistance.

18018. Critical Resistance of a Circuit. — That resistance which determines the limiting condition at which the oscillatory discharge of a circuit passes into an aperiodic discharge.

18019. Group Frequency. — The number per second of periodic changes of amplitude or frequency of an alternating current.

Note 1. Where there is more than one periodically recurrent change of amplitude or frequency, there is more than one group frequency present.

Note 2. The term "group frequency" replaces the term "spark frequency."

18020. Inductive Coupler. — An apparatus which, by magnetic forces, links portions of two radio-frequency circuits and is used to transfer electrical energy between these circuits, through the action of these magnetic forces.

18025. Logarithmic Decrement. — The logarithmic decrement of an exponentially damped alternating current is the logarithm of the ratio of successive current amplitudes in the same direction.

Note: Logarithmic decrements are standard for a complete period or cycle.

Let: I_n and I_{n+1} be successive current amplitudes in the same direction.

d = logarithmic decrement.

Then: $$d = \log_e \frac{I_n}{I_{n+1}}.$$

18026. Radio Frequencies. — The frequencies higher than those corresponding to the normally audible vibrations, which are generally taken as 10,000 cycles per second. See also Audio Frequencies.

Note: It is not implied that radiation cannot be secured at lower frequencies and the distinction from audio frequencies is merely one of definition based on convenience.

18027. Resonance. — Resonance of a circuit to a given exciting alternating e.m.f. is that condition due to variation of the inductance or capacity in which the resulting effective current (or voltage) in that circuit is a maximum.

1935. Standard Resonance Curve. — A standard resonance curve is a curve ordinates of which are the ratios of the square of the current at any frequency he square of the resonant current, and the abscissas are the ratios of the corponding wave length to the resonant wave length; the abscissas and ordis having the same scale.

1936. Sustained Radiation. — Sustained radiation consists of waves radiated n a conductor in which an alternating current flows.

1936. Tuning. — The process of securing the maximum indication by nting the time period of a driven element. (See Resonance.)

1938. Wave-Meter. — A wave-meter is a radio-frequency measuring instrut, calibrated to read wave lengths.

1934. Decremeter. — An instrument for measuring the logarithmic decret of a circuit or of a train of electromagnetic waves.

1937. Attenuation, Radio. — The decrease with distance from the radiating ce, of the amplitude of the electric and magnetic forces accompanying (and ituting) an electromagnetic wave.

1938. Attenuation, Coefficient of (Radio). — The coefficient which, when tiplied by the distance of transmission through a uniform medium, gives the ral logarithm of the ratio of the amplitude of the electric or magnetic forces ial distance, to the initial value of the corresponding quantities.

1939. Coupler. — An apparatus which is used to transfer radio-frequency gy from one circuit to another by associating portions of these circuits.

1940. Amplifier. — An amplifier is an instrument which modifies the effect local source of energy in substantial accordance with the wave-form of the ived energy, and gives out a wave of greater amplitude than that which it ives.

1941. Phase Angle Defect. — The phase angle defect of a condenser is the arture from quadrature of the phase difference between potential and current erminals. This is sometimes called the phase angle of a condenser: although ctly speaking the phase angle of a condenser is 90° less the phase angle defect, is therefore exactly 90° when the phase angle defect is zero.

1942. Impulse E.m.f. — An e.m.f. the effective value of which becomes small pared with its maximum value in a time which is short compared with the ition of the current which it causes.

1944. Directive Coefficient. — The directive coefficient of a transmitting nna at a given distance therefrom on the surface of the earth or sea, for a n wave length, is the ratio of average field intensity within an angle of stated es centered about the direction of maximum radiation, to the average field sity in all directions.

1945. Directional Selectivity. — The directional selectivity of a receiving nna at a given wave length is the ratio of the average e.m.f. induced in that nna for waves of equal intensity coming from directions comprised within an e of stated degrees centered about the direction of best reception, to the age e.m.f. induced in the antenna for waves of equal intensity coming from irections.

1946. Radiation Efficiency. — The radiation efficiency of an antenna at a n wave length is the ratio of radiation resistance to the antenna resistance.

1947. Selectivity. — The (overall) selectivity of a receiving system is the uct of the several selectivities of that system.

1948. Average Selectivity. — The average selectivity of a receiving system e nth root of the product of the n selectivities of that system.

1949.* Radio-Frequency Selectivity. — The radio-frequency selectivity of a le element * of a receiving system is the ratio of resonant response (in terms fective voltage or current measured at the indicator) to the non-resonant

Digitized by Google

CHAPTER XIV

STANDARDS FOR PRIME MOVERS AND GENERATOR UNITS

General

14000. Regulation of Steam Engines, Steam Turbines and Internal Combustion Engines. — In steam engines, steam turbines and internal combustion engines, the percentage speed regulation is usually expressed as the percentage ratio of the maximum variation of speed, to the rated-load speed in passing slowly from rated-load to no-load (with constant conditions at the supply).

14001. Fluctuation of Steam Engines, Steam Turbines and Internal Combustion Engines. — The percentage fluctuation of a steam engine, steam turbine or internal combustion engine, is the immediate percentage speed regulation corresponding to a sudden change from rated-load to no-load.

14002. Regulation of Hydraulic Turbines. — In a hydraulic turbine or other water motor, the percentage speed regulation is expressed as the percentage ratio of the maximum variation in speed in passing slowly from rated-load to no-load (at constant head of water), to the rated-load speed.

14003. Regulation of Generator Units. — In a generator unit, consisting of a generator combined with a prime mover, the speed or voltage regulation shall be based upon constant conditions of the prime mover; *i.e.*, constant steam-pressure, head, etc. It includes the inherent speed variations of the prime mover. For this reason, the regulation of a generator unit is to be distinguished from the regulation of either the prime mover, or of the generator combined with it, when taken separately.

14010.* Variation in Prime Movers. — The variation in prime movers which do not give an absolutely uniform rate of rotation or speed, as in reciprocating steam engines, is the maximum angular displacement in position of the revolving member expressed in degrees, from the position it would occupy with uniform rotation, and with one revolution taken as 360 degrees. See § 4088.

14011. Pulsation in a Prime Mover, or in the Alternator Connected Thereto. — The pulsation in a prime mover, or in the alternator connected thereto, is the ratio of the difference between the maximum and minimum velocities in an engine-cycle to the average velocity.

BIBLIOGRAPHY

United States

American Society of Mechanical Engineers: Boiler Code.

Foreign

British Engineering Standards Association: Standard Electrical Pressures for New Systems and Installations (Low and Medium Pressures); Steam Turbines for Electrical Plants; Report on Reciprocating Steam Engines for Electrical Purposes.

(14010) If p is the number of pairs of poles, the variation of an alternator is p times the variation of its prime mover, if direct connected, and p n times the variation of the prime mover if rigidly connected thereto in such a manner that the angular speed of the alternator is n times that of the prime mover.

CHAPTER XV

STANDARDS FOR TRANSMISSION LINES AND DISTRIBUTION LINES

Note: For flash-over tests of insulators, see foot-note to § 2361.

General

§ 2360. **Regulation of Transmission Lines, Feeders, etc.** — The regulation of transmission lines, feeders, etc., is the change in the voltage at the receiving end between rated non-inductive load and no-load, with constant impressed voltage at the sending end. The percentage regulation is the percentage change in voltage to the normal rated voltage at the receiving end.

CHAPTER XVI

MISCELLANEOUS STANDARDS

HEATING DEVICES

§ 2361. **Value of A-C. Test Voltage for Household Devices.** — Heating devices taking not over 660 watts, intended solely for operation on supply circuits not exceeding 275 volts, shall be tested with 500 volts at operating temperature.

INTERNATIONAL ELECTROTECHNICAL COMMISSION

I. E. C. RULES FOR ELECTRICAL MACHINERY

VOLUME I

(Adopted at the Plenary Meeting, held in London, October, 1919)

These rules apply to rotating machines of which the terminal pressure do not exceed 5000 volts or of which the rated output does not exceed 750 kv or of which the stator cores do not exceed 50 cm. in length axially, and t transformers which are not water-cooled.

PART I. GENERAL

I. Scope of Rules

1. *Rotating Machines.* — The rules of the I. E. C. contained in this publicat apply to rotating machines, of which the terminal pressure does not exce 5000 volts or of which the rated output does not exceed 750 kv.-a., or of wh the stator cores do not exceed 50 cm. in length axially.

2. *Transformers.* — These rules also apply to all transformers which are n water-cooled. (For water-cooled transformers, *see* Appendix II.)

3. *Altitude.* — In the absence of any information in regard to the heig above sea level at which the machine is intended to work in ordinary servi this height is assumed not to exceed 1000 meters. If the machine is intend to work at an altitude above 1000 meters a correction to the temperature s should be applied. The value for this correction has not yet been fixed by t I. E. C.

4. *Temperature.* — In the absence of any information to the contrary, it i assumed that the temperature of the cooling air shall not exceed 40° C.

II. Definitions

5. *Rating.* — (See Appendix IV.)

6. *Use of the Term "Machine."* — The term "machine" is used in the rules in its most general sense, so as to avoid the constant repetition of th words "machines, transformers and other electromagnetic induction apparatus"

7. *Use of the Term "Power."* — It is usual to speak of a machine by i *power*. It is necessary to note that the term "power" should be used in th following way:

(a) For direct-current generators, the electric power at the terminals expres in watts (w.) or kilowatts (kw.).

(b) For alternators, the apparent power at the terminals, expressed in volt amperes (v.-a.) or kilovolt-amperes (kv.-a.).

(c) For motors, the mechanical power available at the shaft, expressed i watts (w.) or kilowatts (kw.).

(d) For transformers, apparent output at the secondary terminals, expresse in volt-amperes (v.-a.) or kilovolt-amperes (kv.-a.).

III. I. E. C. Rating

8. *Test Rating.* — The I. E. C. rating has been established as a *test* rating which will enable an exact comparison to be made between machines of differe makes.

9. *Classes of Rating.* — There are two classes of I. E. C. rating:

(a) The I. E. C. continuous rating (*see* Clause 10).

(b) The I. E. C. short-time rating or limited-time rating (*see* Clause 12).

Google

o. *Continuous Rating.*—The I. E. C. continuous rating is the load which be carried on test, under the conditions of that rating, for an unlimited iod without the limits of the I. E. C. rules, as regards temperature rise, ig exceeded.

1. *Service Thermally Equivalent to the Continuous Rating.* — Any machine nded for continuous service on fluctuating load may be given for test pur- es a thermally equivalent I. E. C. continuous rating, provided that the rice for which it is intended shall not cause, in any of its parts, temperatures temperature rises in excess of those allowed by the I. E. C. rules when the chine is tested under the conditions of its continuous rating.

General Note re Classes of Fluctuating Load Service, inserted by the Editing mittee. — It is desirable to distinguish between two kinds of fluctuating load ice:

(i) *That in which the overload peaks can be sustained by a machine of ordinary construction, without modification, and without exceeding the limits of temperature rise allowed by these rules for the machine when tested under its I. E. C. continuous rating.*

(ii) *That in which the overload peaks involve special provisions in design or construction either for mechanical or for electrical reasons.*

To designate this second class of service it is customary in Great Britain and the United States of America to employ the term "duty cycle rating," and the word "cycle" in this case signifies a period of time sufficiently long to include all the variations of load which might influence either the electrical construction or the mechanical construction of the machine.

12. *Short-time Rating.*—The I. E. C. short-time rating is the load which can carried on test for the time specified in the rating, the test being started with machine cold and carried out under all the conditions of the rating, without limits fixed by these I. E. C. rules, as regards temperature rise, being exceeded.

13. *Service Thermally Equivalent to the Short-time Rating.* — Any machine ended for service on loads which vary considerably may be given for test rposes a thermally equivalent I. E. C. short-time rating, provided that the vice for which it is intended shall not occasion, in any of its parts, tem- ratures or temperature rises in excess of those allowed by these rules when machine is tested under the conditions of its short-time rating.

PART II. INFORMATION TO BE GIVEN WITH ENQUIRIES AND ORDERS FOR ELECTRICAL MACHINES

IV. General Information

Note. — The term *machine* is used in these rules in its most general sense so to avoid the constant repetition of the words *machines, transformers* and other *tromagnetic induction apparatus.*

14. *General Information.* — The enquiry or order for an electrical machine ould give the following general information:

(a) The service output.

(b) The class of service required.

In the absence of any indication to the contrary, continuous service is understood.

(c) The maximum temperature of the cooling air in which the machine is ended to work when it exceeds 40° C.

In the absence of any definite information, it is understood that the temperature of the cooling air will not exceed 40° C.

(d) The altitude of the place where the machine is intended to work, if it ceeds 1000 meters. In regard to altitude, *see* Clause 3.

(e) Any special requirements, if necessary, with regard to windings, methods connection, neutral points and special tapping points, etc.

Digitized by Google

(f) When the apparatus is intended to operate in parallel with other apparatus, the fact should be stated.

(g) Any special requirements in regard to electrical and mechanical details such as protective devices, cooling arrangements, etc.

(Specific recommendations regarding these details will be made at a later date by the I. E. C.)

V. Supplementary Information

15. *Supplementary Information.* — The above general information should be completed by the following supplementary information in regard to the particular machine forming the subject of the order:

16. *Direct-current Generator.*
- Output at the terminals, in watts (w.) or kilowatts (kw.).
- Pressure between terminals, in volts.
- Current, in amperes.
- Speed, in revolutions per minute.
- Method of excitation.

17. *Direct-current Motor.*
- Output at the shaft, in watts (w.) or in kilowatts (kw.).
- Pressure between terminals, in volts.
- Current, approximate, in amperes.
- Speed at rated output, approximate, in revolutions per minute.
- Method of excitation.

18. *Alternating-current Transformer.*
- Frequency, in periods per second.
- Number of phases.
- Output, in voltamperes (v.-a.), or in kilovoltamperes (kv.-a.).
- Primary pressure between terminals, in volts.
- Secondary pressure between terminals, in volts, at no-load and at rated output with statement as to the power factor of the circuit fed by the secondary. If the power factor is not specified it shall be taken as 0.8.
- Secondary current, in amperes.
- For transformers intended to work in parallel, the primary pressure, current, and power factor on short-circuit test, shall also be stated.
- For three-phase transformers the method of connection shall also be indicated in accordance with the vector diagrams (*see* Appendix I).
- Any special requirements as to the accessibility of neutral points or special tapping points shall be indicated.

Note. — Whatever may be the nature of the transformers (step-up or step-down) the primary terminals are those which are connected to the source of electrical energy and the secondary terminals those which receive the electrical energy.

19. *Synchronous Alternator for Alternating Currents, Single or Polyphase.*
- Frequency, in periods per second.
- Number of phases.
- Output between terminals, in volt-amperes (v.-a.) or kilovolt-amperes (kv.-a.).
- Pressure between terminals, in volts, corresponding to the rated output.
- Power factor of the system to be supplied. If this is not specified it shall be taken as 0.8.
- Current, in amperes.
- Speed, in revolutions per minute.
- Excitation pressure, in volts (if the alternator is not provided with a special exciter).
- Maximum exciting current available, in amperes (if the alternator is not provided with a special exciter).

20. *Synchronous Motor for Alternating Currents, Single or Polyphase.*
Frequency, in periods per second.
Number of phases.
Mechanical output at the shaft, in watts (w.) or in kilowatts (kw.).
Current, approximate, in amperes.
Pressure, in volts, of supply available.
Speed, in revolutions per minute.
Unless otherwise specified, the motor must be capable of giving its rated mechanical output at unity power factor.
If the motor is required to act as a device for improving the power factor, the value of the reactive power required shall be stated.
Excitation pressure, in volts (if the motor is not provided with a special exciter).
Method of starting to be employed and source of power available for this purpose.
Maximum exciting current available, if limited.

21. *Non-synchronous Motor for Alternating Currents, Single or Polyphase.*
Frequency, in periods per second.
Number of phases.
Mechanical power at the shaft, in watts (w.) or in kilowatts (kw.).
Pressure between terminals, in volts.
Current, approximate, in amperes.
Speed, in revolutions per minute, approximate, at the rated output.
Rotor, whether wound or squirrel cage.
Method of starting.
Unless otherwise specified it is assumed that the stator receives the supply current.
Starting torque in kilograms at one meter.
Ratio of the starting current to the current corresponding to the rated output.
Ratio of the starting torque to the torque corresponding to the rated output.
The last three items are to be stated for the motor with its starting accessories.

PART III. CONDITIONS TO BE FULFILLED BY ELECTRICAL MACHINERY

VI. General Remarks

22. *General.* — This section deals with the conditions to be fulfilled by a machine purporting to comply with the I. E. C. Rules.

VII. Limits of Temperature and Temperature Rise

Temperature Limits

23. *Table of Temperature Limits.* — The following table gives the limits for the observable temperatures and temperature rises of windings and of certain parts of machines.

The permissible temperature limits are indicated in Column 1 of the table. The permissible limits of temperature rise are given in Column 2. The temperature rises measured on any machine which has worked for the specified time at the output corresponding with its I. E. C. rating shall not exceed in any of its parts the limiting values given in Column 2 of the table. The highest permissible temperature given in Column 1 and the temperature rises given in column 2 of the table should never be exceeded by a machine operating in service. (For exception *see* Clause 27.)

Temperature Limits

Item No.	Nature of the insulation of the winding or name of part.	Column 1 Highest permissible observable temperature	Column 2 Highest permissible observable temperature rise for the purpose of fixing the international rating
		Degrees C.	Degrees C.
1	Cotton, paper or silk, non-impregnated	80	40
2	Cotton, paper or silk, impregnated (*see* Clause 24)	95	55
3	Cotton, paper or silk, immersed in oil	95	55
4	Enamelled wire (*see* Clause 25)	95	55
5	Mica, asbestos, glass, porcelain, micanite and similar compositions	115	75
6	Insulated windings permanently short-circuited	100	60
7	Non-insulated windings permanently short-circuited	110	70
8	Oil (for temperature limits, *see* Appendix II).	..	..
9	Commutators, slip rings (*see* Cl. 27)	90	50
10	Bearings	80	40
11	Iron core immersed in oil	95	55
12	Iron core in contact with windings	Same as the windings	
13	Iron core not in contact with windings nor immersed in oil. The temperature and temperature rise shall not exceed that allowed for the windings themselves, and in no case shall the temperature and temperature rise exceed 110° C. and 70° C. respectively.		
14	Single layer windings: An increase of 5° C. above the temperatures given for items 1, 2 and 4 shall be permitted in the case of coils, revolving or stationary, with single layer windings when not immersed in oil.		

24. *Impregnated Cotton, Paper or Silk.*—An insulation is considered to be "impregnated" when a suitable substance replaces the air between its fibers, even if this substance does not completely fill the spaces between the insulated conductors. The impregnating substance, in order to be considered suitable, must have good insulating properties; must entirely cover the fibers and render them adherent to each other and to the conductor; must not produce interstices within itself as a consequence of evaporation of the solvent or through any other cause; must not flow during the operation of the machine at full working load at the temperature limit specified; must not deteriorate under prolonged action of heat.

25. *Enamelled Wire.* — When employing the temperature limits in the table for enamelled wire the maker must satisfy himself that the enamel employed is of good quality.

26. *Compound Insulations Made Up of Different Materials.* — When the insulation consists of layers of several different materials, the lowest of the temperatures permitted for the different insulating materials employed (see Clause 23) is to be adopted as the limiting temperature. The insulating material, even when forming the support, shall always be assumed as forming part of the winding.

27. *Commutators and Slip Rings.* — The observable temperature and temperature rise of commutators and slip rings may exceed the values given in Item 9 of the table, provided that the above [illegible]

a) The temperatures of the insulating materials in the commutator and the adjoining windings shall not exceed those allowed in the table for the ılating materials of those parts.
b) The manufacturer shall give a special guarantee that the high temature attained shall not impair the commutation.
c) The temperature shall not be so high as to affect the quality of the soldered ıts and the connections.

Reference Temperature of Cooling Medium

8. *Reference Temperature of Cooling Medium.* — (a) *Temperate Climates.* — the absence of any indication to the contrary the maximum temperature of air in which the machine is intended to operate in service shall be deemed e 40° C.
) *Cold Climates.* — In cold climates, when the actual temperature of the in which the machine is intended to operate in service is not much different n 40° C. it is recommended that this conventional reference temperature of C. should be adopted.
) *Tropical Climates.* — The question of a reference temperature for cooling for machines intended to operate in service in tropical climates will be dealt ı by the I. E. C. at a later date.
l) *Water Cooling* (*see* Appendix II).

Permissible Limits for Temperature Rise

9. *Permissible Limits for Temperature Rise.* — The limits permitted for perature rise are deduced from the values allowed for the highest permissible ervable temperature (*see* Clauses 23–27) by subtracting therefrom 40° C. : value assumed as that of the maximum cooling air temperature of the e in which the machine may be required to work in service (*see* Clause 28).

Temperature Measurements

). *Value of Temperature of Cooling Medium.* — A machine may be tested ny convenient cooling air temperature less than 40° C., but whatever be the ıe of this cooling air temperature the permissible rises of temperature shall exceed those given in Column 2 of the table (*see* Clause 23).
orrections for variations in the cooling air temperature are not considered ssary within the limits of cooling air temperature obtaining in general tise.
ı the case of cooling by means of forced ventilation, the temperature of the measured where it enters the machine, shall be considered as the cooling air perature.
or all machines cooled by other means, special rules will be necessary. (For er cooling, *see* Appendix II).

r. *Measurement of Cooling Air Temperature During Tests.* — The cooling temperature shall be measured by means of several thermometers placed lifferent points around and half-way up the machine at a distance of one to meters, and protected from all heat radiation and draughts.
he value to be adopted for the temperature of the cooling air during a shall be the mean of the readings of the thermometers (placed as mentioned ve), taken at equal intervals of time during the last quarter of the duration he test.
n order to avoid errors due to the time lag between the temperature of e machines and the variations in the cooling air, all reasonable precautions ll be taken to reduce these variations and the errors arising therefrom.

Methods of Measurement of the Temperatures of Machines

2. *Measurement of the Temperatures of Machines.* — Two methods of deterıing the temperature of windings and other parts of machines are recogıd:

Digitized by Google

(a) Thermometer method.
(b) Resistance method.*

33. *Thermometer Method.* — In this method the temperature is determined by thermometers applied to the accessible surfaces of the completed machine. The term "thermometer" also includes thermocouples and resistance-thermometers.

34. *Resistance Method.* — In this method the temperature rise of the winding is determined by the increase in the resistance of the windings themselves as checked by thermometers applied to the accessible surfaces of the windings to ascertain whether there is any higher local temperature. The highest of the temperatures thus found shall be taken as the observable temperature.

35. *Temperature of Windings.* — The temperature of windings, as a rule, shall be measured by the resistance method. The thermometer method also is permitted in the following cases:

(a) When it is not practicable to determine the temperature rise by the resistance method, as for example with low resistance commutating coil and compensating windings, and in general in the case of low resistance windings, especially when the resistance of joints and connections forms a considerable portion of the total resistance. In this case the temperature limits given in the table apply without correction.

(b) Single layer windings, revolving or stationary, when not immersed in oil. In this case an increase of 5° C. above the limits of temperature and of temperature rise given in the table is permitted.

(c) When, for reasons of manufacturing in quantity, the thermometer method is used alone, although the resistance method would be possible. In this case the value of the highest permissible observable temperature and temperature rise given in the table shall be reduced by five degrees except in the case of stationary field coils, when the values given in the table shall be reduced by the difference between resistance and thermometer measurements as determined on similar machines, but in no case shall such reduction be less than 5° C.

36. *Corrections of Measurements Taken after the Machine Has Shut Down.* — If the temperature is measured only after shut-down, the highest temperature attained while running shall be deduced by extrapolation on the time-temperature curve.

37. *Measuring Temperature of Direct-current Generators and Motors.* — The temperature of field windings shall be measured in the manner described in Clauses 35 and 36.

The temperature of the armature shall be determined as a rule by thermometers placed on the windings at the hottest accessible parts, and when this method is employed the value of the highest permissible observable temperature and temperature rise shown in the table shall be reduced by 5° C.

38. *Measuring Temperature of Transformers.* — The temperature of transformer windings shall always be ascertained by resistance.

39. *Measuring Temperature of Synchronous Alternators and Motors.* — The temperature of the field windings shall always be ascertained by resistance. The temperature of stator windings shall be ascertained either by resistance or by thermometer in the manner described in the preceding clauses.

40. *Measuring Temperature of Non-synchronous Motors without Commutators.* — The temperatures of the stator and rotor shall be ascertained in the same manner as those of the stator of a synchronous alternator (*see* Clause 39), except in the case of a permanently short-circuited winding, when the thermometer method shall be employed.

41. *Coefficients of Variation of Resistance of Copper with Temperature.* — In the case of resistance measurements, the temperature coefficient of copper shall be taken from the values stated in the accompanying table, which have been

* Note. — With a view to brevity, the expression "method of variation of resistance of the winding" is replaced by the term "resistance method," or simply "by resistance."

Digitized by Google

duced from the formula $1/(234.5+t)$. Thus, at an initial temperature $t = 30°$ C. e temperature coefficient or increase in resistance per degree Centigrade rise $1/(264.5) = 0.00378$.

Temperature of the windings in degrees C., at which the initial resistance is measured.	Copper—increase in resistance per ohm per degree C.
0	0.00427
5	0.00418
10	0.00409
15	0.00401
20	0.00393
25	0.00385
30	0.00378
35	0.00371
40	0.00364

42. When the temperature of a winding is to be determined by resistance, e temperature of the winding before the test measured by thermometer shall ot differ much from that of the cooling air.

43. *Duration of Temperature Test for Continuous Rating.* — For machines ith I. E. C. continuous rating, the temperature test shall be continued until is evident that the maximum temperature rise attained would not exceed the mits given in the table (*see* Clause 23), if the test were to be prolonged until ie final steady temperature were attained. If possible, the temperature hall be measured both while running and after shut-down.

44. *Duration of Temperature Test for Short-time Rating.* — For machines ith I. E. C. short-time rating the duration of the temperature test shall be iat corresponding to the short-time test rating as indicated upon the rating late.

At the commencement of the test the temperature of the machine must be actically that of the cooling air.

VII. Dielectric Tests

(*See* Appendix III for proposals.)

IX. Mechanical Tests

(Not yet prepared.)

X. Commutation

(Not yet prepared.)

PART IV. MARKINGS

XI. Rating Plates

45. *Rating Plate.* — Every machine shall bear the information necessary define the limitations of the service for which it is intended.

For this purpose it shall have, in all cases, a rating plate and also ich diagrams and terminal markings as may be necessary.

46. *Information on Rating Plate.* — The rating plate of a machine complying ith the I. E. C. rules shall have a distinctive special sign and give the following formation:

(a) The name of the maker.
(b) The maker's machine number.

Digitized by Google

(c) The class of rating or the necessary information if the machine is intended to operate under more than one class of rating.

(d) The altitude at which the machine is intended to work if such altitude exceeds 1000 meters.

(e) The following technical information, according to the character of the machine:

In the absence of any indication in regard to the class of rating it is understood that the machine is intended for continuous service.

47. *Direct-current Generator.*

Generator — Direct-current.
Output, in watts (w.) or in kilowatts (kw.), with statement as to the class of rating.
Pressure between terminals, in volts.
Current, in amperes.
Speed, in revolutions per minute.

48. *Direct-current Motor.*

Motor — Direct-current.
Output, in watts (w.) or in kilowatts (kw.), with statement as to the class of rating.
Pressure between terminals, in volts.
Current, approximate, in amperes.
Speed, in revolutions per minute.

49. *Transformer.*

Frequency, in periods per second.
Number of phases.
Apparent output at the secondary, in volt-amperes (v.-a.) or in kilovolt-amperes (kv.-a.), with statement as to the class of rating.
Primary pressure between terminals, in volts.
Secondary pressure, in volts, at no load and at rated load, with statement as to the power factor.
Short-circuit pressure, in volts.
Secondary current, in amperes.
In addition, for three-phase transformers, a vector diagram indicating the method of connection of the windings in accordance with the figures. (*See* Appendix I.)

50. *Alternator.*

Frequency, in periods per second.
Number of phases.
Apparent output, in volt-amperes (v.-a.) or kilovolt-amperes (kv.-a.), with statement as to the class of rating.
Pressure between terminals, in volts, corresponding to the rated output.
Current, in amperes.
Power factor corresponding to the rated output.
Speed, in revolutions per minute.
Excitation pressure, in volts.
Maximum exciting current, in amperes.

51. *Synchronous Motor.*

Frequency, in periods per second.
Number of phases.
Mechanical output, in watts (w.) or in kilowatts (kw.), with statement as to the class of rating.
Pressure between terminals, in volts, corresponding to the rated output.
Current, approximate, in amperes.
If the motor is intended to work with a power factor different from unity, the necessary information to be given.
Speed, in revolutions per minute.
Excitation pressure, in volts.
Maximum exciting current, in amperes.

Digitized by Google

2. *Non-synchronous Motor.*

Frequency, in periods per second.
Number of phases.
Mechanical output, in watts (w.) or in kilowatts (kw.), with statement as to the class of rating.
Pressure between terminals, in volts.
Current, approximate, in amperes.
Speed, in revolutions per minute, at rated output.
Maximum pressure between slip rings, in volts.

APPENDIX I

t the meeting of the Advisory Committee on Rating held in September,), the question of terminal marking and vector diagrams was referred to srs. Everest and la Cour. The following rules were forwarded to the tral Office, but as they have not been submitted to the National Committees, Editing Committee decided to include them as an Appendix only. They therefore, be submitted to the next Plenary Meeting for ratification.

Terminal Markings for Transformers

Single-phase Transformers. — The terminals of all single-phase transers shall be marked with the letter T for the high-pressure side and *t* for the pressure side.

The neutral terminal, if provided, shall be marked by N or *n*.

The letters T and *t* should be accompanied by subscripts 0, 1, 2, etc., arranged in order of progression in the same direction as the electromotive force in each circuit at the same instant, as shown in the diagram.

If the transformer has two or more windings intended to be coupled in series or in parallel, the subscripts shall be single numbers for the first of such windings (1, 2, etc.), double numbers for the second windings (11, 22, etc.), and so on.

Polyphase Transformers. — The terminals of all polyphase transformers be marked as follows:

) Phase Identification. The terminals of the high-pressure and low-ure windings of any one phase shall be marked with the same letter, using al letters on the high-pressure terminals and small type letters on the low-ure terminals.

The letters A, B, C, *a*, *b*, *c* shall be used.

The neutral terminal, if provided, shall be marked N or *n*.

) Polarity Identification. The relative polarity of the corresponding pressure and low-pressure windings in each phase shall be indicated by the ion of subscripts (0) and (1) after the phase letters, so placed that at the nt when (in, for instance, phase A) the high-pressure terminal marked A_1 itive to terminal A_0, the low-pressure terminal a_1 shall be simultaneously ive to that marked a_0.

Vector Diagrams for Polyphase Transformers

Polyphase Transformers Connected Together. — When two or more polyphase formers are to be grouped together with their windings connected to the primary and secondary systems, it is essential that the transformers shall spond, not only as regards the pressures for which they are intended, lso as regards the exact phase relation of the secondary winding to the ary winding.

Scope of Vector Diagrams. — All polyphase transformers shall bear a vector am which shows accurately the phase relation between primary and dary terminals. To secure the correctness of such a diagram the following rements shall be complied with:

The identification of each phase of the secondary winding with the corre-ling phase of the primary winding shall be clearly indicated by the same inal marks (*see* Paragraph 2 above).

Digitized by Google

(b) To avoid error arising from differences in methods of winding, the relative instantaneous polarity of primary and secondary windings in each phase shall be indicated at the terminals of the various phase windings (*see* Paragraph 3 above).

5. *Vector Diagrams.* — The vector diagram of connections shall show the phase letter and the polarity marking for each phase of the windings, and shall show correctly how the various phases are connected together. Because to avoid the complexity of marking both phase letter and polarity mark at each end of every winding vector, it shall be sufficient to show the phase letter connected together with an arrow head to indicate polarity, the arrow head in every case pointing away from that end of the phase which has the polarity mark (or at its terminal.

6. The following are some typical vector diagrams which embody the principles laid down in these rules:

APPENDIX II

This Appendix contains proposals prepared by the Advisory Committee on Rating for submission to the National Committees, but not yet presented to a Plenary Meeting for ratification.

1. *Temperature Limits for Oil.*

Temperature limit for oil (measured by thermometer)...	90° C.
Temperature limit for the windings (measured by the increase of resistance) and other parts immersed in oil..	95° C.

Note. — The adoption of these temperatures implies the employment of a good oil of which the quality may be verified by ascertaining the flash point and measuring the deposit produced by heating.

The I. E. C. has not yet sufficient data to fix limiting values for the flash point or to prescribe the methods of measurement of the deposit.

2. *Reference Temperature of Cooling Water.* — For water-cooled apparatus in the absence of any indication to the contrary, the maximum temperature of the cooling water in service shall be deemed to be 25° C. at the point of entry.

3. *Temperature Limits for Water-cooled Transformers.* — In the case of oil immersed water-cooled transformers, the limits of highest permissible observed temperature given in the table are to be reduced by 10° C.; therefore the corresponding limits of temperature rise shown in the table may be increased by

APPENDIX III

Dielectric Tests

This Appendix contains proposals in regard to Dielectric Tests prepared by the Advisory Committee on Rating, for submission to the National Committees but not yet presented to the Plenary Meeting for ratification.

Dielectric Tests. — The high-pressure test shall be applied between the winding and the frame, with the core connected to the frame and to the windings not under test, and shall be applied only to a new and completed machine with all its parts in place under conditions equivalent to normal working conditions and, unless otherwise specified, the test shall be carried out at the maker's works at the conclusion of the temperature test of the machine.

The test pressure shall be alternating, preferably of sine wave form.

The test shall be commenced at a pressure of less than one-third the test pressure and shall be increased to the full test pressure as rapidly as is consistent with its value being correctly indicated by the measuring instrument. The full test pressure shall then be maintained for one minute in accordance with the values as indicated in the following table:

Digitized by Google

Machine or part	Test pressure (R. M. S.)
Rotating machines of size less than 1 kw.	500 volts + twice the rated pressure.
Rotating machines of size 1 kw. to 3 kw.	1000 volts + twice the rated pressure.
Rotating machines of size above 3 kv.-a.	1000 volts + twice the rated pressure with minimum, 2000 volts.
Field windings for synchronous generators when the excitation pressure does not exceed 750 volts.	10 times the excitation pressure. Minimum, 2000 volts. Maximum, 3500 volts.
Field windings for synchronous motors:	
(a) When intended to be started up with the field windings short-circuited.	10 times the excitation pressure. Minimum, 2000 volts. Maximum, 3500 volts.
(b) When intended to be started up with the field windings separated by a break-up switch.	5000 volts.
(c) When intended to be started up with the fields on open circuit and without a break-up switch.	5000 volts when the excitation pressure is less than 275 volts. 8000 volts when the excitation pressure is equal to or exceeds 275 volts.
Exciter	Not yet decided.
Transformers in general	1000 volts + twice the rated pressure.
Transformers for primary pressures over 550 volts, the secondaries of which are for direct connection to public or private distribution systems or public or private consumers (i.e., secondary pressures less than 550 volts).	Primary windings: 1000 volts + twice the rated primary pressure with minimum, 10,000 volts (adopted as a protection to human life). Secondary windings: 1000 volts + twice the rated secondary pressure.
Secondary (rotor) windings of induction motors not permanently short-circuited.	For non-reversing motors: 1000 volts + twice the maximum pressure which could be induced between the slip rings. For reversing motors: 1000 volts + 4 times the pressure between the slip rings at standstill on open circuit with full primary pressure applied to stator windings.
Alternating-current apparatus connected to a single-phase system of more than 300 volts pressure permanently earthed.	Not yet decided.
Assembled apparatus	When the test is made on an assembled group of several pieces of new apparatus each one of which has previously passed its high pressure test, the test on such assembled group shall not exceed 85 per cent. of the lowest test pressure appropriate for any part of the group.

Digitized by Google

APPENDIX IV

Definitions dealing with the subject of "Rating":

Great Britain. — The rating of an electrical machine is the output assigned to it by the maker, together with the associated conditions, all of which are marked on the Rating Plate.

Note. — A machine may have a test rating or a service rating, or both assigned to it, and marked on the rating plate.

United States of America. — The rating of a machine is the output marked on the Rating Plate and shall be based on, but shall not exceed the maximum load which can be taken from the machine under prescribed conditions of test. This is also called the Rated Output.

(The term "maximum load" does not refer to loads applied solely for mechanical, commutation, or similar tests.)

France. — The rating of a machine is determined by the conditions of working such as speed, pressure, current, power factor, etc., as indicated on the Rating Plate.

Italy. — The output of a machine is the normal or average output, that is to say, the load at which the machine can work under normal conditions.
