

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

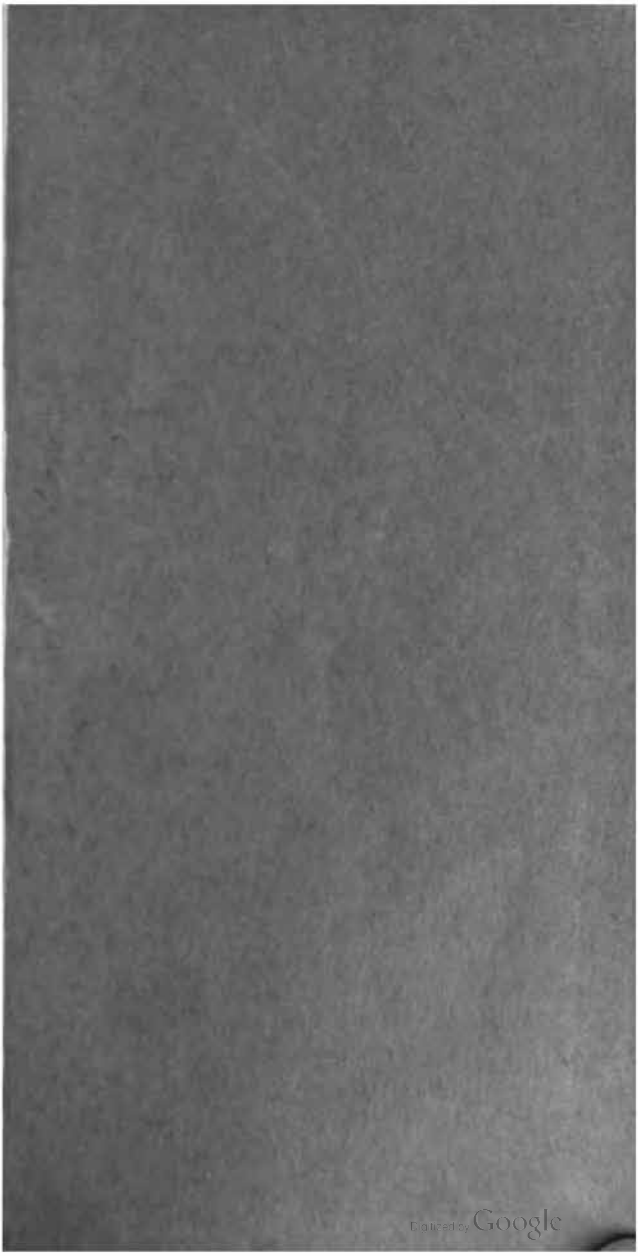
Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.



+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

The Publishers and the Editor-in-Chief will be grateful to reader this volume who will kindly call attention to any errors of omissio commission therein. It is intended to make our publications stand works of study and reference, and, to that end, the greatest accurac sought. It rarely happens that the early editions of books are free fr errors; but it is the endeavor of the Publishers to have them remov and it is therefore desired that the Editor-in-Chief may be aided in task of revision, from time to time, by the kindly criticism of read

PREFACE TO SECOND EDITION

THE steady demand for this book since its first appearance in 1914 has shown conclusively that an encyclopedic handbook of Electrical Engineering is an indispensable tool to the engineer. Its use in a number of large universities has also shown that the encyclopedic arrangement is well adapted to the purposes of the class room.

Although in many respects electrical engineering practice to-day is much the same as it was in 1914, there have nevertheless been noteworthy developments in several branches of the industry, for example, in radio-communication, electric welding, electric ship propulsion, etc. Electrical science has also made considerable progress, especially in the development of the electron theory and its application to engineering.

In order to keep this Handbook abreast of the times, the publishers requested the editor in 1920 to undertake a thorough revision of the book. In line with this request, each article was submitted to the orginal contributor or other qualified person with the request that he go over it carefully, add new matter where the development of the art warranted, and bring the article up to date.

The result of this review was that nearly every article in the book has been revised, the amount of revision varying from a few lines to the entire article, according to the desires of the authors. While the greater part of the revisions appear in paragraphs interspersed throughout the book, new articles have been added on the following subjects:

Frequency Changers.
Ignition, Electric.
Phase Converters and Balancers.
Ships, Electric Propulsion of.
Starting and Lighting Systems for Automobiles.
Welding, Electric.

The following articles have been completely rewritten:

Ammeters.
Ampere-hour Meters.
Corona, Electric.
Dams.
Demand Meters.
Depreciation.
Electron Theory.
Heating and Cooking by Electricity.
Hydraulics.
Hydrology.
Insulating Materials.
Lighting of Trains by Electricity.
Oil, transformer.
Radio Communication (replacing the articles on Detectors, Electric Wave; Waves, Electromagnetic; Wave meters; Wireless Telegraphy and Wireless Telephony.
Standarization Rules and Standard Specifications.
Water Wheels and their Settings.
Water Wheels, Speed regulation of.

In addition to the above, extensive changes have been made in the following articles:

Alloys.
Buildings, Allowable Unit Stresses in.
Cross-Arms.

Digitized by Google

Electrolysis.
Frequency Indicators.
Generators, Alternating Current.
Grounding for Electric Circuits.
Heat and Thermal Properties.
Insulators, Overhead.
Lamps and Illumination.
Motors, Alternating-current Commutator.
Oscillographs.
Power Factor Indicators and Reactive Volt-ampere Indicators.
Resistance and Conductance.
Rubber.
Signalling, Railway.
Synchronizers and Synchroscopes.
Transformers, Instrument.
Voltmeters.
Watt-hour Meters.
Wattmeters.
Wires and Cables, Bare.
Wires and Cables, Insulated.
Wiring of Buildings.

The Standards of the American Institute of Electrical Engineers (formerly known as the Standardization Rules) are given in full at the end of the book. These standards are a verbatim copy of the 1922 edition and are reproduced with the permission of the Board of Directors of the Institute. It is the plan of the publishers to revise these Standards whenever a new edition is published by the Institute, which in the past has been about every two years.

While the encyclopedic arrangement of the book especially commends it for reference purposes, no difficulty attends its use for consecutive study, if the order given in the *Topical List of Articles* is followed. This list is arranged in the order usually followed in the course of class studies. Some teachers may prefer to vary the order of reading, and will find it easier to do so by the aid of such a list, than where the text itself is arranged in some arbitrary order.

Care has been taken to make each article a readable compendium on its subject and not merely a series of disconnected paragraphs containing miscellaneous data, a too common fault in books of this class.

In the preparation of the Second Edition, the editor has been fortunate in having associated with him, as Associate Editor-in-Chief, Mr. William A. Del Mar. Mr. Del Mar has supervised all articles dealing with Electric Railways, Wires and Cables, Transmission and Distribution, Switch Gear and Control Apparatus, Electric Meters and Instruments for commercial use, Mathematics, and Mathematical Tables. These articles make up about one-third of the entire book.

A glance at the make-up of the "Editorial Staff" will show the care with which experts in each line have been selected. In several cases men were selected because of notable investigations or researches which they were conducting at the time along the lines of the articles assigned to them.

The editor takes this opportunity to express his sincere appreciation of the earnest effort of all members of the Editorial Staff to make this new edition of the Handbook throughly representative of modern engineering practice.

HAROLD PENDER

PHILADELPHIA, PA.,
September 1, 1922.

FROM THE PREFACE TO THE FIRST EDITION

1. This Handbook has been prepared primarily for the practicing engineer. With this end in view the matter has been so arranged as to be most readily found, and all *theoretical discussions have been segregated into separate articles.* Fundamental or "theoretical" principles are fully but concisely treated in articles dealing with such matters and nothing else, e.g., such article as *Electricity and Magnetism, Principles of; Alternating Currents; Electrochemistry, Principles of; Mechanics, Principles of; Hydraulics; etc.* Therefore, in articles dealing with practical matters only enough is said of theory to indicate the general principle of which the matter in hand may be a specific application.

2. This book is primarily for Electrical Engineers, but the general arrangement of the subject matter and the method of treatment adopted will make the book a useful reference book for mechanical, civil, mining and other engineers who have occasion to utilize any of the numerous applications of electricity in their special fields. Considerable space has been devoted to those matters pertaining to the applications of motors in all branches of modern industry; see the article on *Motors, Industrial Applications of*, and the numerous cross references there given.

3. Although this book deals primarily with electrotechnical matters, a large amount of space has been devoted to those mechanical and civil engineering subjects which are closely related to electrical engineering practice.

4. Numerous mathematical tables and relations are given. Among these may be mentioned the articles on *Logarithms, Trigonometric Functions, Hyperbolic Functions, Exponential Functions, Derivatives, Integrals, Indeterminate Forms, Equations*, etc.

5. In spite of the fact that this book contains upwards of 2000 pages, many of the articles have been greatly condensed. However, it has been the consistent endeavor of the editorial staff to make each article sufficiently complete so that the information given therein should be of the greatest practical value.

6. Although this book has been prepared primarily for the practicing engineer, it is believed that the method of treatment adopted will render many of the articles suitable as the bases for courses of lectures in technical schools. A teacher usually has his own method of presenting a subject, and sometimes a textbook proves more of a handicap than a help; yet every teacher recognizes the desirability of putting in the hands of his students some sort of synopsis or syllabus which will serve as a general guide.

7. Experience has shown that the alphabetical arrangement is eminently fitted for an encyclopedia of general information; a like arrangement is equally applicable to a reference book dealing only with engineering topics. The subject matter of this book has therefore been disposed in 266 articles alphabetically arranged. The user of the book will undoubtediy find it more convenient at first to refer directly to this detailed index, but as soon as he becomes acquainted with the main article headings, he will be able to turn directly to the article containing the information he may be seeking without referring to the index.

8. One feature of this Handbook which should prove particularly helpful is that the same plan of treatment has been consistently followed in all the articles, at least wherever possible. This applies particularly to articles dealing with apparatus or machinery, the plan of treatment being:

Digitized by Google

a. General Description and Definitions.
b. Brief Statement of Application.
c. Principle of Operation.
d. Design.
e. Testing.
f. Performance.
g. Specifications.
h. Installation.
i. Operation.
j. Dimensions, Weights and Costs.
k. Bibliography.

In some instances it was found advisable to vary this scheme more or less, but the general sequence of topics was adhered to as closely as possible. At the beginning of each article occupying more than fifteen pages is given a brief table of contents.

9. It is believed that the cost data given in the various articles will prove particularly valuable when properly used. These data in most instances are given as unit costs, and usually the ordinary *range* of cost is given. It has been the experience of the writer that students and recent technical graduates are sadly lacking in even the roughest idea of the cost of apparatus and structures. It is primarily to supply a rough idea of such costs that the cost curves and figures are given in the various articles. The cost data given will also be found suitable for preliminary estimates; but for close estimating, current prices should of course be obtained from the makers of the apparatus, or, in the case of construction work, some one having personal experience in similar work should be consulted.

10. The bibliography given at the end of each article is intended to direct the reader to more extended information in treatises and current periodicals. The space available for these bibliographies has made it necessary to omit many important works and technical articles. The references are usually those in which the writer of the article in question is most familiar and which he has found most useful. They are therefore in no sense complete, but will be found a very useful guide in the search for additional information. In many instances a blank space of a half page or more is left after the bibliography; this space may be advantageously utilized by the insertion of references to new books and articles as they appear.

11. The articles in this Handbook have been prepared by an editorial staff of experts; this staff is given on pp. iii and iv.

The Editor-in-Chief wishes to take this opportunity of expressing his sincere appreciation of the hearty coöperation of the entire editorial staff and of the spirit of coöperation and generosity shown by the publishers throughout the preparation of this book.

HAROLD PENDER.

East Bluehill, Me.,
September 5, 1914.

TOPICAL LIST OF ARTICLES

The articles listed under each main heading, except those of a statistical nature, are in an order appropriate for consecutive reading or assignment for class-room instruction.

General and Miscellaneous

Associate Editors: W. A. Del Mar (a)
H. M. Goodwin (b)
R. G. Hudson (c)
P. G. Agnew (d)

	Pages
Shock, Electric (c)	1402–1403
Standardization Rules and Standard Specifications (d)	1446–1451
Standards of the A.I.E.E.	2083–2183
Specifications and Contracts (a)	1442–1445
Depreciation (a)	351–358
Interest, Annuities and Sinking Fund (a)	881–882
Elements, Chemical (b)	526

Units, Abbreviations and Symbols

Associate Editors: Harold Pender (a)
R. G. Hudson (b)

Abbreviations and Symbols (a)	5
Units, Practical Electric (a)	1876–1877
Units and Conversion Factors (a) and (b)	1853–1875

Mathematics

Associate Editor: W. A. Del Mar

Greek Alphabet	710
Decimal Equivalents	343
Pi (π), Value of	1129
Interest, Annuities and Sinking Fund	881

ABBREVIATIONS AND SYMBOLS.—(*See also Units and Conversion Factors.*) At the meeting of the International Electrotechnical Commission in Berlin, in 1913, a list of abbreviations for electrotechnical and related quantities was adopted. The American Institute of Electrical Engineers has also adopted (1918) a list of such symbols, which for the most part is in agreement with the list of the I.E.C., but contains certain additional symbols not included in the I.E.C. list. In the following table both lists are given. See the *Standardization Rules of the A.I.E.E.* for symbols for photometric quantities.

STANDARD SYMBOLS AND ABBREVIATIONS

Name of quantity	Symbol for the quantity		Name of Unit, adopted by A.I.E.E.	Abbreviation for the unit to be used only after numerical values	
	Adopted by I.E.C. (*See Note 1*)	Adopted by A.I.E.E.		Adopted by I.E.C.	Adopted by A.I.E.E.
Acceleration due to gravity	g	g	centimeter per second per second	—	cm. per sec. per sec.
Acceleration due to gravity, Standard (=980.665 cm. per sec. per sec.) (*Note 5*)	—	g_n	centimeter per second per second	—	cm. per sec. per sec.
Admittance	—	Y, y	mho	—	—
Angles	α, β, γ, etc.	—	—	—	—
Angular velocity ($2\pi f$)	ω	ω	radian per second	—	—
Capacity (Capacitance)	C	C	farad	F	—
Conductance	G	g	mho	—	—
Conductivity (*Note 6*)	—	γ	mho per centimeter	—	mho per cm.
Current	I	I, i	ampere	A	—
Dielectric constant	ϵ	ϵ or k	—	—	—
Dielectric field intensity or electric force	—	F	—	—	—
Dielectric flux	—	ψ	—	—	—
Dielectric flux density	D	D	—	—	—
Efficiency	η	η	per cent	—	(*Note 7*)
Electromotive force (e.m.f.)	E	E, e	volt	V	—
Energy	W (U)	U or W	joule or watt-hour	—	—
Frequency	$f(\nu)$	f	cycle per second	—	~
Impedance	Z $(\mathfrak{Z})$	Z, z	ohm	(*Note 2*)	—
Inductance (or coefficient of self-induction)	L $(\mathfrak{L})$	L	henry	H	—

Digitized by Google

STANDARD SYMBOLS AND ABBREVIATIONS (*Continued*)

Name of quantity	Symbol for the quantity: Adopted by I.E.C. (*See Note 1*)	Symbol for the quantity: Adopted by A.I.E.E.	Name of unit adopted by A.I.E.E.	Abbreviations for the unit to be used only after numerical values: Adopted by I.E.C.	Abbreviations for the unit to be used only after numerical values: Adopted by A.I.E.E.
Inductance, mutual (or coefficient of mutual induction)	M ($\mathfrak{M}$)	M	henry	H	—
Length	l (*Note 3*)	l	centimeter	cm.	cm.
Magnetic flux (*Note 4*)	Φ ($\mathcal{F}$)	Φ, ϕ	maxwell	—	—
Magnetic flux density	B ($\mathfrak{B}$)	B, $\mathfrak{B}$	gauss (*Note 4*)	—	—
Magnetization, intensity of	J ($\mathcal{J}$)	J	—	—	—
Magnetizing force or magnetic field intensity	H ($\mathcal{H}$)	H, $\mathcal{H}$	gilbert per centimeter or gauss	—	gilbert per cm.
Magnetomotive force (m.m.f.)	—	$\mathcal{F}$	gilbert (*Note 4*)	—	—
Mass	m (*Note 3*)	m	gram	—	g.
Period	T	—	—	—	—
Permeability	μ	μ	—	—	—
Phase displacement (or phase angle)	ϕ	θ, ϕ	degree or radian	—	(*Note 5*)
Potential difference (p.d.)	—	V, v or E, e	volt	V	—
Power	P	P, p	watt	W	—
Quantity of electricity	Q	Q, q	coulomb or ampere-hour	C	—
Reactance	X ($\mathfrak{X}$)	X, x	ohm	(*Note 2*)	—
Reluctance	S ($\mathfrak{R}$)	$\mathcal{R}$	—	—	—
Resistance	R	R, r	ohm	(*Note 2*)	—
Resistivity (*Note 6*)	ρ	ρ	ohm-centimeter	—	ohm-cm.
Revolutions per unit time	n	n	revolution per second	—	rev. per sec.
Susceptance	—	b	mho	—	—
Susceptibility	κ	κ	—	—	—
Temperature, absolute	T, Θ	—	degree centigrade	—	—
Temperature, centigrade	t(θ, ϑ)	T, t, θ	degree centigrade	—	deg.cent. (*Note 8*)
Time	t (*Note 3*)	t	second	—	sec.
Turns or number of conductors	—	N	convolution or turn	—	—
Voltage	—	E, e or V, v	volt	V	—
Work, mechanical	A (W)	W or A	joule or watt-hour	—	—

Digitized by Google

NOTES. — (1) The symbols in brackets are recommended in case the principal symbol is unsuitable; instead of the script letters heavy-faced or other special type may be used. (2) One or other of the symbols O and Ω is recommended provisionally to represent the ohm. The symbol Ω should no longer be employed for the megohm. (3) In dimensional equations the capital letters *L*, *M* and *T* for length, mass and time respectively are to be employed. (4) An additional unit for m.m.f. is the "ampere-turn", for flux the "line", and for magnetic flux density "maxwell per sq. in." (5) This has been the accepted standard value for many years and was formerly considered to correspond accurately to 45° latitude and sea level. Later researches, however, have shown that the most reliable value for 45° and sea-level is slightly different; but this does not affect the standard value given above. (6) The numerical values of these quantities are *ohms resistance* and *mhos conductance* between two opposite faces of a cm. cube of the material in question, but the correct names are as given, not ohms and mhos per cm. cube as commonly stated. (7) The symbol % is commonly used for per cent, but is not recommended by the A.I.E.E. (8) The symbol ° is commonly used for degree, ° C. for degree centigrade and ° F. for degree Fahrenheit; these symbols are not recommended by the A.I.E.E.

In addition to the symbols for the units given in the above table, the I.E.C. adopted (1913) the following signs to be used only after numerical values.

Volt-coulomb	VC	Kilovolt-ampere	kVA
Watt-hour	Wh	Kilowatt-hour	kWh
Volt-ampere	VA	Sign for milli-	m
Ampere-hour	Ah	Sign for kilo-	k
Milliampere	mA	Sign for micro- or micr-	μ
Kilowatt	kW	Sign for mega- or meg-	M

SPECIAL RULES IN REGARD TO SYMBOLS. — The following rules were also adopted at the Berlin meeting (1913) of I.E.C., and are concurred in by the Standards Committee of the A.I.E.E. The latter committee also recommends that vector quantities be printed in bold-face capitals.

Instantaneous values of electrical quantities which vary with the time to be represented by small letters. In case of ambiguity they may be followed by the subscript "t."

Virtual (*i.e., effective or r.m.s.*) or constant values of electrical quantities to be represented by capital letters.

Maximum values of periodic electrical and magnetic quantities to be represented by capital letters followed by the subscript "m."

In cases where it is desirable to distinguish magnetic quantities from electric quantities, magnetic quantities should be represented by capital letters of either script, heavy-faced or other special type. Script letters should not be used except for magnetic quantities.

Angles should be represented by small Greek letters.

Dimensionless and specific quantities should be represented wherever possible by small Greek letters.

Ordinary numerals as exponentials shall exclusively be employed to represent powers. (In consequence, it is desirable that the expression $\sin^{-1}x$, $\tan^{-1}x$, employed in certain countries, be expressed by arc sin x, arc tan x.)

The comma and the full-stop shall be employed for separating decimals according to the custom of the country, but the separation between any three digits constituting a whole number shall be indicated by a space and not by a full-stop or a comma(1 000 000).

For the multiplication of numbers and geometric quantities indicated by two letters, it is recommended to use the sign × and the full-stop only when there is no possible ambiguity.

To indicate division in a formula it is recommended that the horizontal bar and the colon be employed. Nevertheless the oblique line may be used when

there is no possibility of ambiguity; when necessary, ordinary brackets ( ), square brackets [ ], and braces { } may be employed to obtain clearness.

INSTITUTE (A.I.E.E.) STYLE. — The Editing Committee of the American Institute of Electrical Engineers issues a little pamphlet called "Suggestions to Authors," in which are given the rules of the Institute in regard to manuscript submitted for publication. The following list of abbreviations is taken from the last edition (1919) of these rules.

Name	A.I.E.E. style	Name	A.I.E.E. style
Alternating current	spell out, or a-c. as adjective.	Kilowatts	kw.
Amperes	spell out	Kilowatt-hours	kw-hr.
Brake horse power	b.h.p.	Magnetomotive force	m.m.f.
Boiler horse power	boiler h.p.	Mean effective pressure	spell out
British thermal units	B.t.u.	Miles	mi.
Candle power	c.p.	Miles per hour per second	mi. per hr. per sec.
Centigrade	cent.	Millimeters	mm.
Centimeters	cm.	Milligrams	mg.
Circular mils	cir. mils	Minutes	min.
Counter electromotive force	counter e.m.f.	Meters	m.
Cubic	cu.	Meter-kilograms	m-kg.
Diameter	spell out	Microfarad	spell out
Direct current	spell out, or d-c. as adjective.	Ohms	spell out
Electric horse power	e.h.p.	Per	spell out
Electromotive force	e.m.f.	Percentage	per cent, or % in tabular matter.
Fahrenheit	fahr.	Pounds	lb.
Feet	ft.	Power-factor	spell out
Foot-pounds	ft-lb.	Revolutions per minute	rev. per min., or r. p. m. in tabular matter.
Gallons	gal.	Seconds	sec.
Grains	gr.	Square	sq.
Grams	g.	Square-root-of-mean-square	effective, or r.m.s.
Gram-calories	g-cal.	Ton-mile	spell out
High-pressure cylinder	spell out	Tons	spell out
Hours	hr.	Volts	spell out
Inches	in.	Volt-amperes	spell out
Indicated horse power	i.h.p.	Watts	spell out
Kilogram	kg.	Watt-hours	watt-hr.
Kilogram-meters	kg-m.	Watts per candle power	watts per c.p.
Kilogram-calories	kg-cal.	Yards	yd.
Kilometers	km.		
Kilovolts	kv.		
Kilovolt-amperes	kv-a.		

Digitized by Google

1. Use "Fig.," not "Figure." Example: "Fig. 3" and not "Figure 3."

2. In all decimal numbers having no units, a cipher should be placed before the decimal point. Example: "0.32 lb." not ".32 lb."

3. Use the word "*by*" instead of "x" in giving dimensions. Example: "8 by 12 in." not "8x12 in."

4. Never use the characters (') and (") to indicate either feet and inches, or minutes and seconds as period of time.

5. Do not use the expression "rotary" or "rotary converter"; use "converter" or "synchronous converter."

6. Do not use a descriptive adjective as a synonym for the noun described. Example: a "spare transformer," not a "spare"; a "portable instrument," not a "portable"; "automatic apparatus," not "automatics"; a "short circuit," not a "short."

7. Do not use the words "primary" and "secondary" in connection with transformer windings. Use instead "high-tension" and "low-tension."

8. Avoid dividing mathematical expressions into two or more parts if possible. If division is necessary, divide *after* a plus, minus or equality sign.

9. Use the English plural where there is a choice. For example: abscissas, not abscissae; formulas, not formulae.

10. Data is the plural form and takes plural verb, etc.

11. Make compounds of two-word adjectives, as direct-current motor, three-phase circuit, etc.

ACIDS. — The properties of some of the more important acids used in the arts are given in the following paragraphs.

Aqua Regia is a mixture of one part of nitric acid and three parts of hydrochloric acid. It obtains its name from the fact that it will dissolve gold. It is used as an oxidizing agent and for dissolving metals, such as platinum, gold, etc., which are insoluble in other acids. It should be used as soon as possible after being prepared since it loses its characteristic properties after standing a short time. It is distinguished by its reddish yellow color and its chlorine-like odor.

Hydrochloric Acid or Muriatic Acid (HCl) is an aqueous solution of hydrogen chloride, a colorless, pungent gas. While the pure acid is colorless, the commercial acid is a yellowish liquid, the color being due to impurities. The concentrated acid has a specific gravity of 1.16 and contains 32 per cent of HCl. The dilute acid has a specific gravity of 1.09 and contains 18.4 per cent of HCl. Hydrochloric acid is used extensively in the manufacture of chlorine, hydrogen and bleaching powder and is prepared as a by-product of the soda manufacture. The acid is recognized by its odor and by the dense fumes it makes with ammonia.

Hydrofluoric Acid (HF) is an aqueous solution of anhydrous hydrogen fluoride, a colorless, fuming liquid. The acid, when saturated, has a specific gravity of 1.25. Its gas is poisonous if inhaled and causes swellings and pain if applied to the skin. It readily dissolves glass and must be kept in platinum, lead, rubber or wax vessels. The acid is most commonly used for etching glass.

Nitric Acid (HNO_3) is a colorless fuming liquid with a specific gravity of 1.55 at 0° C. Commercial nitric acid has a specific gravity of 1.414 at 15° C. and contains 68 per cent of the pure acid. The commercial acid is yellowish in color and the pure acid becomes yellow if exposed to the light. Nitric acid is a powerful oxidizing agent and decomposes organic substances. The acid is used in the manufacture of many chemical substances. Concentrated nitric acid is best recognized by the red fumes, which are given off when the acid is acting upon a metal.

Sulphuric Acid or Oil of Vitriol (H_2SO_4) is a colorless oily liquid. The concentrated acid has a specific gravity of 1.854 at 0° C. and contains 1.5 per cent of water. Commercial sulphuric acid, sometimes known as "brown acid," has a specific gravity of 1.720 and usually contains arsenic as an impurity. Sulphuric acid boils at 290° C., the temperature increasing to 338° C. as the boiling continues. The acid has a strong affinity for water and is frequently used as a drying agent. When diluted with water, the mixing should be performed gradually as great heat is evolved. The acid should be added to the water as the addition of water to the acid may produce violent explosions due to the ebullition of the water.

Sulphuric acid is used in the manufacture of many chemical substances, in dyeing and in refining petroleum. It is a fairly good conductor of electricity and is used in the lead type of storage batteries (q.v.). The acid is recognized by its weight, by its carbonizing action upon organic bodies and by the white precipitate formed by the addition of barium chloride.

ALLOYS — (*See also Wires, Resistor.*) In this article is given a brief description of some of the more common alloys used in engineering work, together with specific data on some of their more important properties. It should be noted that there may be a considerable departure from the quantitative values given. Traces are not included in the chemical compositions given. The various alloys are listed alphabetically. Additional data on their various physical properties will be found in the articles on *Heat and Thermal Properties; Resistance and Conductance; Strength and Elasticity; Weight of Materials, etc.*

Acid-resisting Alloys. — Alloys of iron and chromium and of iron and silicon are used for containers, partly replacing stoneware, in the manufacture of acids. Ferro-chrome is not attacked by sulphuric or nitric acid, but is readily attacked by hydrochloric acid. Silicon-iron containing 14 to 15 per cent silicon (with a small amount of Mn) is likewise not attacked by sulphuric or nitric acid. Such an alloy has a specific gravity of about 7, a melting point of about 2500° F., a tensile strength of about 15,000 pounds per square inch, and a compressive strength of about 70,000 pounds per square inch. Acid-resisting silicon irons are sold under various trade names, such as "duriron," "tantiron," etc. (*W. C. Cornell, Chem. News, 116, p. 92, Aug. 24, 1917.*)

Aluminum Brass (70.5 Cu, 26.4 Zn, 3.1 Al). — The tensile strength is about 21 tons per square inch, the elastic limit 8.5 tons per square inch and the elongation 50 per cent. Aluminum brass is used when very accurate castings are desired, e.g., for pumps, valves, pinions and propellers. It can be rolled and forged while hot but is not easily worked when the aluminum content exceeds 4 per cent.

Aluminum Bronze (95 Cu, 5 Al). — The tensile strength is about 28 tons per square inch, the elastic limit 12 tons per square inch and the elongation 75 per cent. Aluminum bronze containing less than 7.5 per cent Al is very ductile. With more than 7.5 per cent Al the alloy becomes brittle but increases in tensile strength. Tubes, propellers and propeller shafts are sometimes made of aluminum bronze. It has not been found to withstand intense heat for any length of time without fracturing. It is sometimes drawn into wire for use as an electrical resistance.

Amalgams are alloys of mercury and other metals. When newly made amalgams are plastic but harden in a short time without appreciable expansion or contraction. The common metals combined with mercury to form amalgams are tin, copper, cadmium, bismuth, silver and gold. Amalgams are used for silvering glass and as a cement for metals and porcelain.

Anti-friction Metals are alloys of copper, tin, zinc, lead and antimony in various combinations. These alloys are commonly used in bearings for revolving shafts and for valve packings. See *Babbitt and Bearing Metals* below.

Babbitt Metal (4 Cu, 69 Zn, 19 Sn, 5 Pb, 3 Sb) is used extensively for bearings, the composition stated being that used for car bearings of the Pennsylvania Railroad. See also the article on *Bearings.*

Bearing Metals for use in specific cases are illustrated by the following examples: Locomotive (82 Cu, 8 Zn, 10 Sn), railway car (90 Cu, 10 Sn), low-speed bearing (16 Sn, 84 Pb). There are a large number of anti-friction metals in use, the object in the composition of each of them being to procure a metal which is as hard as possible but plastic enough to be moulded by the shaft into a shape offering a minimum friction.

Brass is an alloy of copper and zinc and often contains small percentages of lead, tin, arsenic, antimony, bismuth and iron. *Cast brass* usually consists of 66 per cent of copper and 34 per cent of zinc. *Low brasses,* suitable for hot

rolling contain from 55 per cent to 63 per cent of copper. *High brasses*, suitable for cold rolling and drawing, contain from 60 per cent to 70 per cent of copper. In drawing brass it must be annealed and cleaned in acid at frequent intervals to prevent fracture. The ductility of brass is impaired if the lead content exceeds 0.1 per cent, but in the case of brasses intended for turning about 2 per cent of lead is often added so that the brass may be turned at higher speed and possess a better finish. Brass is made harder by the addition of about 1 per cent of tin and is found to better withstand corrosion due to salt water. The presence of small quantities of arsenic, antimony or bismuth in brass is liable to cause it to crack when rolled. The addition of 1 per cent to 3 per cent of iron to brass produces a harder and stronger alloy. The tensile strength of commercial brass ranges from 15 to 40 tons per square inch and the elongation varies from 10 per cent to 40 per cent depending upon the composition.

Bronze is a name used to designate various alloys of copper and tin with other metals. Ordinary bronze is an alloy of copper. tin, and zinc, and melts about 980° C. See also *Aluminum Bronze*, *Manganese Bronze*, and *Phosphor Bronze* in this article.

Duralumin is an alloy whose composition varies between the limits Cu, 3 to 4.5 per cent; Mg, 0.4 to 1.0 per cent; Mn, 0 to 0.7 per cent; Fe, 0.4 to 10 per cent; Si, 0.3 to 0.6 per cent; and the balance aluminum. It has a specific gravity of 2.85 and possesses the remarkable property of being appreciably hardened by quenching from temperatures below its melting point and subsequent ageing. (*Amer. Inst. Min. Eng., Bull. No. 150, 1919.*)

Ferro-Alloys. — See above under *Acid-resisting Alloys* and the article on *Steel*.

Fusible (Low Melting Point) Metals consist of various alloys of bismuth, lead, tin and cadmium. The chemical composition of the common fusible metals and their melting points are given in the following table:

Alloy	Composition				Melting point °C.
	Bi	Pb	Sn	Cd	
Newton's alloy	50.0	31.25	18.75	.....	95
Rose's alloy	50.0	26.00	24.00	.....	100
Darcet's alloy	50.0	25.00	25.00	.....	93
Wood's alloy	50.0	24.00	14.00	12.00	66–71
Lipowitz' alloy	50.0	27.00	13.00	10.00	60

Lower melting points are obtained by the addition of mercury.

German Silver is an alloy of copper, nickel and zinc in various combinations. It is sometimes called nickel silver, argentan, packfong, silveroid, silverite or electrum. German silver is extensively used because of its ductility; it can be readily rolled, hammered and drawn. It is hard, tough and not easily corroded. Its composition varies from (50 Cu, 30 Ni, 20 Zn) to (57 Cu, 7 Ni 36 Zn), the nickel content decreasing as the zinc increases. The usual impurities found in German silver are iron, lead and tin. The presence of iron in the alloy makes it stronger, harder and more elastic. Tin makes the alloy brittle. Lead is sometimes added to render the alloy more workable but should not be added when the alloy is to be rolled. German silver is drawn into wires for use as a

ectrical resistance and has been drawn into tubes for use in locomotive boilers. e *Wires, Resistor*.

Gun Metal is a bronze consisting of about 90 per cent of copper and 10 per nt of tin. The tensile strength varies from 12 to 16 tons per square inch, pending upon the method of working. Melting point 980 to 995° C. It is echanically strong and elastic and withstands severe shocks without fracture. A small amount of lead is added to gun metal, the alloy is more easily turned filed. Better castings are made by the addition of a small amount of zinc d the alloy is made harder by adding a small percentage of iron.

Manganese Bronze is an alloy containing copper, tin, zinc, lead, iron and manganese in various combinations. Alloys containing from 4 per cent to 6 per nt of manganese possess high tensile strength at high temperatures and are before used for fire-box stays. High tensile strength at ordinary temperatures is obtained, however, by the addition of very small quantities of manganese. The composition of manganese bronze for certain specific uses is as ws. For hydraulic machinery (82 Cu, 8 Sn, 5 Zn, 3Pb, 2Mn); for forging 5 Cu, 38.4 Zn, 1.6 Fe, 0.02 Mn). The tensile strength ranges from 27 to tons per square inch but if the alloy is cold-rolled, a tensile strength of 50 tons square inch may be obtained. Manganese bronze is often used in place of or copper, when a higher tensile strength is required. It is not easily ed and may be bent when hot or cold.

Magnetic Alloys. — See the article on *Magnetic Properties of Iron and er Metals*.

Monel Metal is described in the article on *Wires, Resistance*. It has a sile strength of 40 tons per square inch at air temperature and 29 tons per are inch at 500° C. It is used for pump rods and valves as well as for resistor wires. (*J. Arnott, Engineering, 106, p. 451, Oct. 25, 1918.*)

Non-expansive Alloys are composed of iron, nickel and carbon. *Platinite* ains 46 per cent of nickel and 0.15 per cent of carbon. *Invar* contains 36 per nt of nickel and 0.2 per cent of carbon. Its coefficient of expansion ranges om 8×10^{-7} to 25×10^{-7} per degree centigrade. These alloys are used extensively in scientific instruments for standard measures of length and in candescent lamps where the wire connections fused into the glass must not small enough to fracture the glass.

Phosphor Bronze consists of copper, tin and phosphorus in various proportions, the phosphorus content rarely exceeding 2 per cent. The most useful property of phosphor bronze is its hardness and resistance to wear. Phosphor bronzes containing (A) 8 to 10 per cent of tin and 0.5 to 0.7 per cent of phosphorus are used for valves, pumps, propellers and boiler fittings, (B) 10 to 12 per nt of tin and 0.7 to 1 per cent of phosphorus are used for worms and gears nd (C) 10 to 12 per cent of tin and 1 to 1.5 per cent of phosphorus are used for ars, gears and bearings where the wear is excessive. The tensile strength ges from 10 to 15 tons per square inch, the elastic limit from 5 to 7 tons per uare inch and the percentage elongation from 2 to 6 per cent.

Platinum Substitutes. — Alloys of gold and silver with palladium have en recently developed as a substitute for platinum for contacts and sparking ints in magnetos.

Pyrophoric Alloys are certain alloys of rare earths, especially ferrocrium, which give a shower of sparks when filed or struck. Sb and Bi are added per cent) to harden the alloy and copper (5 per cent) to produce a low melting int and a smooth casting product. (*Engineering and Mining Journ., p. 212, 17.*)

Digitized by Google

Resistance Alloys. — See article on *Wires, Resistor*.

Solder is an alloy of tin and lead. Cadmium may be used as a substitute fo part of the tin, 80 Pb, 10 Sn, 10 Cd being a satisfactory solder. *Hard* or ti solder contains 50 per cent of tin and 50 per cent of lead and melts at 370° F *Soft* or plumber's solder contains 33.3 per cent of tin and 66.6 per cent of lea and melts at 441° F.

ALTERNATING CURRENTS. — (*See also Electricity and Magnetism, Principles of; Generators, Alternating-current; Motors, Alternating-current; Resistance and Conductance, Electric; Skin Effect; Transformers; Wave Analysis, &c.*).

GENERAL DEFINITIONS. — (*See also Standardisation Rules of the A.I.E.E.*). To avoid repetition the following definitions are given in terms of electric current; they also apply to electromotive forces, potential differences or to any other functions of time.

An alternating current is defined as a current which varies continuously with time from a constant maximum value in one direction to an equal maximum value in the opposite direction and back again to the same maximum in the first direction, repeating this cycle of values over and over again in *equal* intervals of time.

Period, Frequency and Alternations. — The period of an alternating current is the time taken for the current to pass through a complete cycle of positive and negative values.

The frequency or number of cycles per second is the number of periods per second.

The number of alternations per minute is the total number of times per minute that the current changes in direction, from positive to negative and from negative to positive. In engineering practice the number of cycles is usually referred to the second as the unit of time and the number of alternations is referred to the minute as the unit of time.

Let T be the period, f the frequency or number of cycles per second and a the number of alternations per minute, then

$$f = \frac{1}{T} \qquad \text{and} \qquad a = 120f = \frac{120}{T}. \tag{1}$$

The constant

$$\omega = 2\pi f = \frac{2\pi}{T} \tag{1a}$$

is sometimes called the angular velocity or angular frequency of the current. The name periodicity for this quantity is not recommended.

Instantaneous, Maximum and Average Values. — The instantaneous value of an alternating current is the value of the current at any instant. Instantaneous values of current, potential difference and electromotive force will be designated by small letters throughout this article, viz., i, v and e.

The maximum value of an alternating current is the numerical value of its maximum instantaneous value. Maximum values will be designated by capital letters with the subscript "m."

The average value of an alternating current for which the positive and negative half cycles are equal, which is usually the case, is defined as the numerical value of the average of its instantaneous values for a half cycle; the average over a complete cycle is of course zero. The general expression for the average value of a symmetrical current wave over a half cycle is

$$I_{\text{aver.}} = \frac{2}{T}\int_{t_1}^{t_1+\frac{1}{2}T} i\,dt, \tag{2}$$

where t_1 is a value of t at which $i = 0$; similarly for a voltage wave.

R.M.S. or Effective Values. — The square root of the mean of the squares of the instantaneous values of an alternating current over a complete period is called the r.m.s., or effective, value of the alternating current. In specifying the value of an alternating current as so many amperes this r.m.s. value is always meant unless specifically stated otherwise. In the same manner the square root of the mean of the squares of the instantaneous values of an alternating

potential difference over a complete period is called the r.m.s. value of the alternating potential difference. When the value of an alternating potential difference is specified as so many volts, this r.m.s. value is always meant unless specifically stated otherwise.

The reason for selecting this particular function of the instantaneous values of an alternating current or potential difference as the measure of the current or potential difference is that the deflection of all instruments used in alternating-current measurements is a function of this r.m.s. value. See *Ammeters, Electrodynamometers, Voltmeters, etc.* Moreover, the average power dissipated as heat in a resistance, r, when an alternating current of r.m.s. value I flows through it, is rI^2.

R.m.s. values will be designated throughout this article by capital letters without subscripts.

The general expression for the r.m.s. value of an alternating current is]

$$I = \sqrt{\frac{1}{T}\int_0^T i^2\,dt}, \tag{3}$$

and similarly for an alternating potential difference.

Form Factor. — The form factor of an alternating current is defined as the ratio of its r.m.s. to its average value, viz.,

$$\text{Form factor} = \frac{I}{I_{aver.}}, \tag{4}$$

and similarly for an alternating potential difference.

Crest or Peak Factor. — The crest factor, also called the peak factor or amplitude factor, of an alternating current is defined as the ratio of its maximum to its r.m.s. value, viz.,

$$\text{Crest factor} = \frac{I_m}{I}. \tag{5}$$

Instantaneous and Average Power. — Let v be the value at any instant of the potential drop from any point 1 to any other point 2, and let i be the instantaneous value of the current from 1 to 2 at this same instant; then the power input at this instant is

$$p = vi. \tag{6}$$

When v and i are *both* positive (i.e., in the direction from 1 to 2, say) or when they are *both* negative, the power input is positive, but when v is positive and i negative or vice versa, the power input is negative, i. e., there is an actual power output.

The average value of the product vi over a complete period for both v and i (or over any whole number of periods) is the average power input or output, usually called simply the power input or output (input when the average of vi is positive, output when the average of vi is negative), the word average being understood. That is, the average power input is

$$P = \frac{1}{T}\int_0^T p\,dt = \frac{1}{T}\int_0^T vi\,dt, \tag{7}$$

T being a complete period. For the actual measurement of alternating-current power see *Wattmeters*.

Power Factor. — Only in certain special cases (*see below*) is the average power input P equal to the product of the r.m.s. value V of the potential difference by the r.m.s. value I of the current; it can never be greater and as a rule is less. The ratio of the average power P to the product of the r.m.s. value V of the

potential difference by the r.m.s. value I of the current is called the power factor of the circuit between the terminals considered, i.e.,

$$\text{Power factor} = \frac{P}{VI}. \tag{8}$$

When V is expressed in volts and I in amperes then P must be in watts; when V is expressed in kilovolts and I in amperes P must be in kilowatts.

Volt-Amperes, Kilovolt-Amperes (kv-a.) — The product of the r.m.s. volts across the terminals of a circuit by the r.m.s. amperes through it is called the volt-amperes taken by the circuit; this product divided by 1000 is called the kilovolt-ampere input. Or, when V is in volts and I in amperes

$$\text{volt-amperes} = VI, \tag{9}$$

$$\text{kilovolt-amperes} = \frac{VI}{1000}. \tag{9a}$$

Kilovolt-amperes are usually abbreviated kv-a. or K.V.A., the former abbreviation being that recommended by the American Institute of Electrical Engineers and used in this book.

Effective Resistance (r) **and Conductance** (g). — The effective resistance of any portion of a circuit to an alternating current is the quotient of the average rate P_h at which heat is developed by this current, either directly in the substance through which it passes or indirectly as a consequence of the hysteresis and eddy-current losses produced by its magnetic field (*see Magnetic Properties of Iron*), divided by the square of the r.m.s. value I of the total current (conduction plus displacement or charging current) through this portion of the circuit, viz.,

$$r = \frac{P_h}{I^2}. \tag{10}$$

Similarly, calling V the r.m.s. value of the potential difference across the given portion of the circuit the effective conductance g of this portion of the circuit is defined by the relation

$$g = \frac{P_h}{V^2}. \tag{11}$$

In general, both r and g depend upon both the frequency and the wave-shape (*see below*) of the current and voltage but in many instances they may be considered as practically constant irrespective of the frequency or wave-shape. See the articles on *Resistance and Conductance* and *Skin Effect* for further discussion.

Impedance (z) **and Admittance** (y). — Let V be the r.m.s. value of the potential drop through any portion of a circuit due to its effective resistance, self-inductance and capacity (*see Electricity and Magnetism, Principles of*), i.e., if there is any other source of e.m.f. in the given portion of circuit (e.g., a generator or motor) V is the r.m.s. value of the potential drop which the same current would produce through this portion of circuit were this external source of e.m.f. removed. Then the quotient of the potential drop V by the r.m.s. value of the current I in this portion of the circuit, viz.,

$$z = \frac{V}{I}, \tag{12}$$

is defined as the impedance of this portion of the circuit.

Digitized by Google

The reciprocal of the impedance, viz.,

$$y = \frac{1}{z} = \frac{I}{V}, \tag{13}$$

is defined as the admittance of the given portion of the circuit.

Impedance and admittance, as thus defined, both depend upon the frequency and wave-shape. Impedance is expressed in the same units as resistance (e.g. ohms), and admittance in the same units as conductance (e.g. mhos); see *Units and Conversion Factors*.

Reactance (x) and Susceptance (b). — The square root of the difference between the square of the impedance and the square of the effective resistance of a given portion of an electric circuit is defined as the reactance x of this portion of the circuit, viz.,

$$x = \sqrt{z^2 - r^2}. \tag{14}$$

The reactance of a coil of inductance L to a sine-wave current of frequency f is

$$x = 2\pi fL. \tag{14a}$$

Similarly, the susceptance b of the given portion of the circuit is defined by the relation

$$b = \sqrt{y^2 - g^2}. \tag{15}$$

The susceptance of a condenser of capacity C to a sine-wave voltage of frequency f is

$$b = 2\pi fC. \tag{15a}$$

The simple relations expressed by (14a) and (15a) hold only for *sine-wave* currents and voltages; see Pender, H., *Electricity and Magnetism for Engineers, Part II*, N. Y., 1919. See also the articles in this book on *Capacity and Charging Current* and *Inductance and Inductive Reactance*.

Inductive and Condensive (or Capacity) Reactance and Susceptance. — The reactance of a circuit may be due either to the back e.m.f. set up as a consequence of the varying magnetic field of the current or to a back e.m.f. set up by a condenser or its equivalent, or to both. In the first case the reactance and susceptance are said to be "inductive" and in the second case "condensive." A condensive reactance or susceptance is equivalent to a *negative* inductive reactance or susceptance; e.g., the inductive susceptance of a condenser to a sine-wave voltage is $-2\pi fC$.

Equivalent* Resistance, Impedance and Reactance. — Sometimes in calculating alternating-current circuits it is convenient to consider a motor or other load developing a back e.m.f. as equivalent to a single resistance and reactance. Let P be the total power taken by the load, V the voltage between its terminals, I the current; then the equivalent resistance is defined as

$$R = \frac{P}{I^2}, \tag{16}$$

the equivalent impedance as

$$Z = \frac{V}{I} \tag{16a}$$

and the equivalent reactance as

$$X = \sqrt{Z^2 - R^2}. \tag{16b}$$

The difference between the *effective* resistance and the *equivalent** resistance is

* The distinction here made between equivalent and effective is not always observed; the term equivalent resistance is frequently used in the same sense as effective resistance.

Digitized by Google

that the first takes into account only the power dissipated as heat, whereas the latter takes into account the total power, of which only a part is heat, the rest being converted into some other form, e.g. mechanical power.

SIMPLE HARMONIC OR SINE-WAVE CURRENTS AND VOLTAGES. — A simple harmonic or sine-wave current is one which varies with time according to the sine formula

$$i = I_m \sin(\omega t + \theta),$$

where t represents time in seconds, measured from any arbitrarily chosen instant, I_m the maximum value of the current, $\omega = 2\pi f = \frac{2\pi}{T}$, where f is the frequency in cycles per second and T the period as a fraction of a second, and θ a constant, called the "phase angle," which depends upon the instant chosen as the zero of time. See the section on *Harmonic Motion* in the article on *Mechanics, Principles of*, for a full discussion of this equation and its physical significance.

Difference in Phase Between a Sine-wave Current and a Sine-wave Voltage of the Same Frequency. — In general, when a sine-wave electromotive force is impressed on a circuit the resulting current is likewise a sine function of time (after a very brief interval, see *Transient Electric Phenomena and Oscillations*) having the same frequency, but the e.m.f. and current do not reach their maximum values simultaneously. Let the current and the potential drop in the direction of the current be represented respectively by the two equations

$$i = I_m \sin \omega t,$$
$$v = V_m \sin(\omega t + \theta),$$

where t is the time measured from the instant when $i = 0$ and is increasing in the *positive* direction. The current reaches its maximum value when $t = \frac{\pi}{2\omega}$, while the potential drop reaches its maximum value when $t = \frac{\pi}{2\omega} - \frac{\theta}{\omega}$. Hence when θ is positive the potential drop reaches its maximum value $\frac{\theta}{\omega}$ seconds *before* the current reaches its maximum, or the current reaches its maximum value $\frac{\theta}{\omega}$ seconds *after* the potential drop reaches its maximum; when θ is negative the current reaches its maximum value $\frac{\theta}{\omega}$ seconds *before* the potential drop reaches its maximum. In the first case the current is said to "lag" the potential drop, and in the second case the current is said to "lead" the potential drop. The angle θ is called the "difference in phase," or simply the phase angle, between the current and potential drop.

In general, when i and v are expressed by the formulas

$$i = I_m \sin(\omega t + \theta_i),$$
$$v = V_m \sin(\omega t + \theta_v),$$

i reaches its first maximum at an interval of time $\frac{1}{\omega}(\theta_i - \theta_v)$ ahead of v, and therefore i leads v by the angle $\theta_i - \theta_v$. Note the order of the subscripts: *i leads v* by the angle $\theta_i - \theta_v$; or *v leads i* by $\theta_v - \theta_i$. A negative lead is of course equivalent to an actual lag, and a negative lag is equivalent to an actual lead.

Currents and Voltages in Phase, in Quadrature and in Opposition. — When the phase difference is zero the current and potential drop are said to be "in phase"; when the phase difference is $\frac{\pi}{2}$ radians or 90° the current and potential drop are said to be "in quadrature"; when the phase difference is π radians or 180° the current and potential drop are said to be "in opposition."

R.M.S. and Average Values, Form Factor and Crest Factor. — For a *sine wave*:

$$\text{R.m.s. value} = \frac{\text{Maximum value}}{\sqrt{2}}; \tag{17}$$

$$\text{Average value} = \frac{2}{\pi} \times (\text{maximum value}); \tag{17a}$$

$$\text{Form factor} = \frac{\pi}{2\sqrt{2}} = 1.11; \tag{17b}$$

$$\text{Crest factor} = \sqrt{2} = 1.414. \tag{17c}$$

For any other relation between the instantaneous values of the current or voltage and time, i.e., for any other shape of current or voltage wave, *these relations do not hold*. The form factor of a rectangle is 1.00; of an isosceles triangle, 1.15; of a semi-circle or semi-ellipse, 1.04. The corresponding crest factors are 1.00, 1.73 and 1.22. See also article on *Wave Analysis*.

Power and Power Factor for Sine-wave Current and Voltage. — Let the voltage drop from terminal No. 1 to terminal No. 2 through any piece of apparatus be $v = \sqrt{2}\,V \sin(\omega t + \theta_v)$ and the current from terminal No. 1 to terminal No. 2 be $i = \sqrt{2}\,I \sin(\omega t + \theta_i)$, where V and I are the r.m.s. values and therefore $\sqrt{2}\,V$ and $\sqrt{2}\,I$ are the maximum values. Then the *instantaneous* power input is

$$p = vi = VI[\cos(\theta_v - \theta_i) - \cos(2\omega t + \theta_v + \theta_i)]. \tag{18}$$

A study of Fig. 1 will show the physical meaning of this expression. The *average* power input is

$$P = VI \cos(\theta_v - \theta_i), \tag{18a}$$

where $(\theta_v - \theta_i)$ is the difference in phase between the current and voltage. Putting θ for this difference in phase, viz., $\theta = \theta_v - \theta_i$, equation (18a) may be written

$$P = VI \cos\theta. \tag{18b}$$

Whence the power factor of the load supplied to the apparatus is, from equation (8),

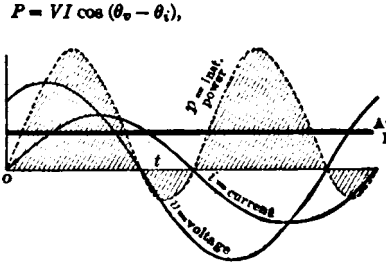

Fig. 1.

$$\cos\theta = \frac{P}{VI}. \tag{19}$$

Power-factor Angle. — Since in the case of sine-wave currents and voltages the power factor is equal to the cosine of the angle which expresses the difference in phase between them, this difference in phase is frequently called the "power-factor angle." When the wave shape is not a pure sine

Digitized by Google

urve, the power factor cannot be interpreted as the cosine of the phase difference, for phase difference has no definite meaning except in reference to sine waves; see definitions above. A non-sinusoidal voltage and current may both reach their zero values at the same instant, as in the case of an arc (*see Arc, Electric*), and in a sense may be said to be "in phase," but the power factor as defined by equation (8) may be far from unity.

Leading and Lagging Power Factor. — The power factor is always a positive quantity, but the power-factor angle may be either positive or negative, i.e., the current may lag or lead the voltage drop by any angle between 0° and 90°, or lag or lead the potential drop by any angle between 0° and 90°.* When the current lags the reference voltage by an angle between 0° and 90° the power factor is stated as such a fraction or percentage, *lagging*, e.g., a power factor of 80% lagging, and when the current leads the power factor is stated as such a fraction or per cent, *leading*. In the first case the power-factor angle is taken as positive, and in the second case negative.

Equivalent Sine-wave Currents and Voltages. — In very few instances are the actual currents and voltages in a circuit pure sine-waves, but many of the ordinary calculations of alternating-current circuits may be made with sufficient accuracy by assuming them as sine-waves of the same r.m.s. values as the actual waves, and differing in phase by the angle whose cosine is equal to the actual power factor, i.e., by the angle

$$\theta = \cos^{-1} \frac{P}{VI}, \qquad (19a)$$

where P is the average power, V the r.m.s. value of the actual voltage and I the r.m.s. value of the actual current.

Vector Representation of Sine-wave Currents and Voltages. — Consider any sine function

$$i = I_m \sin \omega t.$$

The value of i at any instant may be represented graphically, see Fig. 2, by the vertical projection (i.e., the vertical distance from P_1 to OX) of a point P_1 at the end of a radius $OP_1 = I_m$ which revolves† at an angular speed ω about a fixed point O, the angle ωt being measured from the horizontal fixed line OX. Similarly, any other sine function

$$v = V_m \sin (\omega t + \theta)$$

may be represented by the vertical projection of the point P_2 at the end of a radius $OP_2 = V_m$ also revolving about O with an angular speed ω, the angle between OP_1 and OP_2, *when the frequency of both i and*

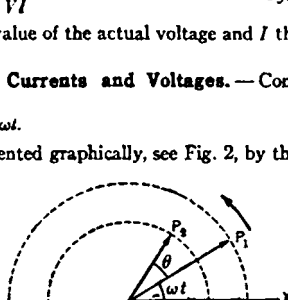

Fig. 2.

* When there is an actual power input into a portion of a circuit (e.g., a motor) it is most convenient to refer the current to the voltage *drop* through this portion of circuit in the direction of the current; when there is an actual power output (e.g., a generator) it is most convenient to refer the current to the voltage *rise* through this portion of the circuit, i.e., to the electromotive force in this portion of the circuit, in the direction of the current. When the potential *rise* is used as the reference, then for a power-factor angle between $-90°$ and 0° and between 0° and $+90°$, the apparatus gives out power, and for a power-factor angle between $-90°$ and $-180°$ and between $+90°$ and $+180°$ the apparatus absorbs power.

† Counter-clockwise rotation has been adopted (1911) as standard by the International Electrotechnical Commission.

Digitized by Google

v is the same, remaining fixed in value and equal to the difference in phase θ between v and i. That is, v and i may be represented by rotating vectors (*see article on Vectors*) and when of the same frequency the relative position of the two vectors remains fixed. Similarly any number of currents and voltages of the same frequency may be represented by rotating vectors which remain fixed with respect to one another.

Instead of referring the various rotating vectors to a *fixed* line OX, this line of reference may also be considered as rotating with the same speed ω as the various vectors, or any one of the vectors may be chosen as the line of reference, for example, the vector OP_1 in Fig. 2. The rotating vectors referred to this rotating line of reference are then fixed with respect to this line of reference, and the entire diagram may be considered as fixed, as in Fig. 3, the originally chosen fixed line of reference OX rotating in the opposite direction with an angular speed ω.

Instead of making the vectors equal in length to the maximum values of the sine functions they may be chosen equal in length to their r.m.s. values. This merely introduces a factor $\sqrt{2}$ so that when any vector is considered as rotating the instantaneous value of the quantity which it represents is equal to $\sqrt{2}$ times the perpendicular distance from its end to the fixed line of reference.

Addition of Sine-wave Currents or of Sine-wave Voltages. — Since the r.m.s. values and phase relations of sine-wave currents and voltages may be represented by vectors, sine-wave currents are added in exactly the same manner as vectors, or forces, are added, and similarly for sine-wave voltages. The addition of vectors is fully treated in the article on *Vectors*, q.v. To add any two sine-wave currents or voltages not only must their effective values be known but also their phase relation; *the resultant of two alternating voltages of r.m.s. values V_1 and V_2 is never the arithmetical sum of V_1 and V_2*, except when the two voltages are exactly in phase, and similarly for alternating currents.

In-phase and Quadrature Components. — In Fig. 3, considering OP_1 as equal to the r.m.s. value I of the current and OP_2 as representing the r.m.s. value V of the voltage, the voltage V may be considered as made up of two components, viz.:

$V_1 = V \cos\theta$ in phase with I,

$V_2 = V \sin\theta$ in quadrature with I.

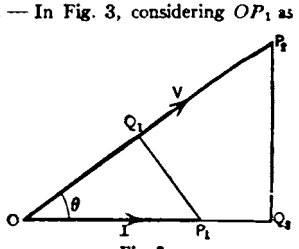

Fig. 3.

The average power corresponding to the component $V_1 = V \cos\theta$ is, from equation (18b), $IV_1 = IV \cos\theta$, and is equal to the total power corresponding to V and I. The average power corresponding to the component $V_2 = V \sin\theta$, since the angle between the current and this component of the voltage is 90°, is equal to zero. The voltage component $V_1 = V \cos\theta$ is therefore frequently called the "power" component of the voltage, and the component $V_2 = V \sin\theta$ is frequently called the "wattless" component of the voltage. These terms, however, are not recommended. It is preferable to refer to these two components as the in-phase and quadrature components respectively. The terms active and reactive components are also used.

Similarly, the current I may be considered as made up of two components, viz.:

$I_1 = I \cos\theta$ in phase with V,

$I_2 = I \sin\theta$ in quadrature with V.

Digitized by Google

The first component is called the in-phase component of the current and the second the quadrature component of the current.

Resistance Drop and Reactance Drop. — When a sine-wave current of r.m.s. value I is established in a coil which has an effective * resistance r and inductance L, the drop of voltage V through the coil is represented by the vector diagram shown in Fig. 4. The reactance of such a coil, from the definition given by equation (14a), is then $x = 2\pi fL$. The voltage drop rI, due to the resistance of the coil, is in phase with the current I, whereas the voltage drop $2\pi fLI = xI$, due to the reactance of the coil, is 90° ahead of the current. A "resistance drop" i.e., the drop of potential due to a current through a resistance, is always in phase with the current which causes it, and an *inductive* reactance drop is always 90° ahead of the current which produces it. (A *condensive* reactive drop is always 90° behind the current which causes it, and is therefore directly opposite in phase to an inductive reactance drop produced by the same current.)

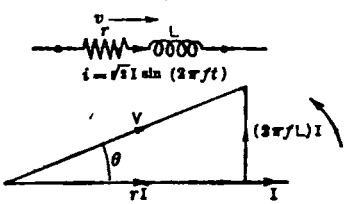

Fig. 4.

Impedance of a Coil to a Sine-wave Current. — From Fig. 4 and the definition of impedance, equation (12), it is evident that the impedance of a coil of resistance r and inductance L is

$$z = \sqrt{r^2 + (2\pi fL)^2}. \qquad (20)$$

Leakage Current and Charging Current of a Condenser. — When a sine-wave voltage of r.m.s. value V is established across a condenser which has an effective† conductance g and capacity C, the total current I through it is represented by the vector diagram shown in Fig. 5. The *condensive* susceptance of a condenser from the definition given in equation (15a) is then $b = 2\pi fC$, or the *inductive* susceptance is $b' = -b = -2\pi fC$. The conduction or leakage current gV is in phase with the voltage drop through the condenser, whereas the charging or capacity current (or displacement current) $2\pi fCV = bV$ is 90° ahead of the voltage.

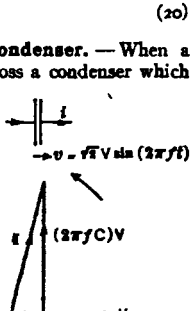

Fig. 5.

Admittance, Impedance, Effective Resistance and Reactance of a Condenser. — From Fig. 5 and the definitions given by equations (12) to (15) it follows that the admittance of a condenser to a sine-wave voltage is

$$y = \sqrt{g^2 + (2\pi fC)^2}; \qquad (21)$$

the impedance is

$$z = \frac{1}{y} = \frac{1}{\sqrt{g^2 + (2\pi fC)^2}}; \qquad (21a)$$

* When the coil has a non-magnetic core and the frequency is low, say 60 cycles or less, the effective resistance is practically equal to its ohmic or d-c. resistance; see article on *Skin Effect*.

† Even for moderate frequencies, 25 cycles or more, the effective conductance of a condenser is in general many times its ohmic conductance; see article on *Condensers, Electric*.

Digitized by Google

the effective resistance is

$$r = \frac{g}{g^2 + (2\pi fC)^2}; \tag{21b}$$

and the effective *condensive* reactance is

$$x_c = \frac{2\pi fC}{g^2 + (2\pi fC)^2}, \tag{21c}$$

which is equivalent to an *inductive* reactance of

$$x = -x_c = \frac{-2\pi fC}{g^2 + (2\pi fC)^2}. \tag{21d}$$

Only when the effective conductance g is zero is the reactance of a condenser equal to $-\frac{1}{2\pi fC}$, but in many instances the value of g is so small compared with $2\pi fC$ that the inductive reactance may be taken as $-\frac{1}{2\pi fC}$; the error in this approximate expression is less than 1 per cent for g less than 10 per cent of $2\pi fC$.

Relations between Effective Resistance, Reactance and Impedance and Effective Conductance, Susceptance and Admittance for Sine-wave Currents and Voltages. — From the definitions given above, equations (12) to (15), it may be shown that for sine-wave currents and voltages of a given frequency the following relations hold for any portion of a circuit:

$$\left.\begin{array}{ll} z = \sqrt{r^2 + x^2}, & y = \sqrt{g^2 + b^2}, \\ z = \frac{1}{y}, & y = \frac{1}{z}, \\ r = \frac{g}{y^2}, & g = \frac{r}{z^2}, \\ x = \frac{b}{y^2}, & b = \frac{x}{z^2}, \end{array}\right\} \tag{22}$$

where r = effective resistance, x = reactance (taken positive when inductive), z = impedance, g = effective conductance, b = susceptance (taken positive when inductive) and y = admittance, all for the given portion of circuit. Equations (20) to (21d) are special cases of equation (22).

Impedances in Series. — Let z_1, z_2, z_3, etc., be the impedances of the several portions of a circuit all connected in series (same current through each). Then the resultant impedance is

$$\left.\begin{array}{ll} & Z = \sqrt{R^2 + X^2}, \\ \text{where} & R = r_1 + r_2 + r_3 + \text{etc.}, \\ \text{and} & X = x_1 + x_2 + x_3 + \text{etc.}, \end{array}\right\} \tag{23}$$

where r_1, r_2, r_3, etc., are the effective resistances and x_1, x_2, x_3, etc., the reactances (condensive reactances to be considered as negative) of the several impedances. When there is no external source of e.m.f. in any portion of the circuit, then the resultant power factor is $\cos\theta$ where

$$\tan\theta = \frac{x_1 + x_2 + x_3 + \text{etc.}}{r_1 + r_2 + r_3 + \text{etc.}}. \tag{23a}$$

Example. — An alternating current of 100 amperes is to be supplied to a receiver which has an equivalent resistance r_1 of 2 ohms and an equivalent

reactance x_1 of 0.5 ohm. The line has a resistance r_1 of 0.1 ohm and an inductive reactance x_2 of 1.5 ohms. The equivalent resistance of the line and receiver is then $R = 2 + 0.1 = 2.1$ ohms and the equivalent reactance of the line and receiver is $X = 0.5 + 1.5 = 2.0$ ohms. Hence the equivalent impedance of the line and receiver is $Z = \sqrt{(2.1)^2 + (2.0)^2} = 2.90$ ohms. The impedance of the receiver alone is $z_1 = \sqrt{(2)^2 + (0.5)^2} = 2.06$ ohms and the impedance of the line alone is $z_2 = \sqrt{(0.1)^2 + (1.5)^2} = 1.50$ ohms. The arithmetical sum of z_1 and z_2 is 3.56, which is 23 per cent greater than the true impedance of the line and receiver.

When the current supplied to the receiver is 100 amperes, the voltage at the receiver is $V = 100 \times z_1 = 100 \times 2.06 = 206$ volts and the voltage at the generator is $V_0 = 100 \times Z = 100 \times 2.90 = 290$ volts, see Fig. 6, that is, the voltage at the receiver is 290 — 206 = 84 volts less than at the generator. The total potential drop in the two wires forming the line, however, is $100 \times z_2 = 100 \times 1.50 = 150$ volts, which is 79 per cent greater than the true difference between the potential drops across the generator and across the receiver terminals.

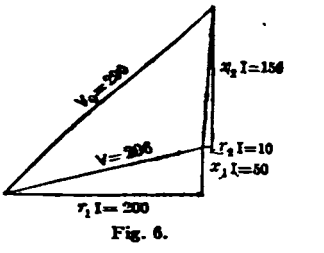

Fig. 6.

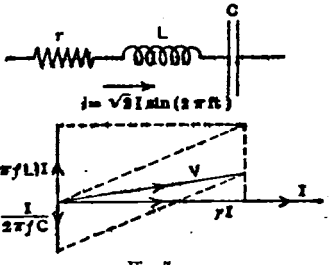

Fig. 7.

Resonance of a Coil and Condenser in Series. — Consider the circuit shown in Fig. 7. When a sine-wave current of effective value I is established in such a circuit the voltage drop across the resistance is $V_r = rI$ and is in phase with I. The voltage drop across the inductance is $V_L = (2\pi fL)\, I$ and *leads* I by 90°. The voltage drop across the capacity (a condenser with *negligible* conductance) is $V_C = \frac{I}{2\pi fc}$ and *lags* I by 90°. Hence the resultant voltage across the entire circuit is

$$V = \sqrt{V_r + V_L + V_C} = I\sqrt{r^2 + \left(2\pi fL - \frac{1}{2\pi fC}\right)^2}. \qquad (24)$$

The reactance is therefore

$$x = \sqrt{z^2 - r^2} = \left(2\pi fL - \frac{1}{2\pi fC}\right).$$

When the inductance L, capacity C and frequency f are so related that

$$f = \frac{1}{2\pi\sqrt{LC}} \qquad (25)$$

the reactance of the circuit is zero, the impedance is equal to the resistance, the power factor is unity and the current corresponding to a given voltage V is $I = \frac{V}{r}$; that is, the current is a maximum and depends only upon the resistance

Digitized by Google

of the circuit. The frequency corresponding to this condition is the same as the frequency with which the current and p.d. would oscillate were the condenser short-circuited by the inductance; i.e., this frequency corresponds* to the free period of such a circuit (*see Transient Electric Phenomena and Oscillations*). In general, a condenser and coil in series are said to be in resonance with the impressed frequency when the current for a given impressed voltage is a maximum, and the power factor therefore unity. When the conductance of the condenser is negligible the resonant frequency is given by equation (25).

When resonance obtains in a series circuit the voltage across the coil and that across the condenser may be many times the impressed voltage. For example, when the inductance L is 1 henry, the capacity C is 7.04 microfarads, and the frequency is 60 cycles, the inductive reactance is $x_L = 2\pi \times 60 \times 1 = 377$ ohms, the condensive reactance is $x_c = \frac{1}{2\pi \times 60 \times 7.04 \times 10^{-6}} = 377$ ohms, and the circuit is in resonance. For a resistance of 1 ohm in the coil and an impressed e.m.f. of 100 volts, the voltage across the coil is $\sqrt{(100)^2 + (377 \times 100)^2} = 37{,}700$ volts and the voltage across the condenser is $377 \times 100 = 37{,}700$ volts.

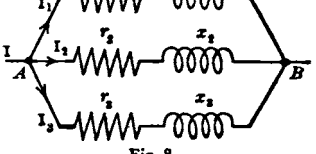

Fig. 8.

Impedances in Parallel.— Let z_1, z_2, z_3, etc., be the impedances of several branch circuits as shown in Fig. 8, and let the resistances and reactances constituting these impedances be r_1, r_2, r_3, etc., and x_1, x_2, x_3, etc., respectively.† First calculate the corresponding conductances g_1, g_2, g_3, etc., and susceptances b_1, b_2, b_3, etc., using equations (22). Then the resultant admittance, *provided there are no external sources of e.m.f. in any of the branches*, is

$$\left.\begin{aligned} Y &= \sqrt{G^2 + B^2}, \\ G &= g_1 + g_2 + g_3 + \text{etc.}, \\ B &= b_1 + b_2 + b_3 + \text{etc.}, \end{aligned}\right\} \quad (26)$$

where

and the resultant power factor is $\cos\theta$ where

$$\tan\theta = \frac{b_1 + b_2 + b_3 + \text{etc.}}{g_1 + g_2 + g_3 + \text{etc.}}. \quad (26a)$$

Resonance of a Coil and Condenser in Parallel. — When a coil of negligible resistance and a condenser of negligible conductance are connected in parallel, the resultant current established through the circuit by a given impressed voltage will be *zero* (infinite impedance) when the inductance L, capacity C and frequency f bear the following relation:

$$f = \frac{1}{2\pi\sqrt{LC}}. \quad (27)$$

Compare with equation (25). Under these conditions the coil and condenser are said to be in resonance with the impressed frequency. When the coil has an appreciable resistance and the condenser an appreciable conductance they are said to be in resonance when the resultant current is a minimum for a given impressed voltage, and the power factor therefore unity.

* Approximately only when r is large; see *Transient Electric Phenomena and Oscillations*.

† Condensive reactances to be considered negative.

NON-SINUSOIDAL CURRENTS AND VOLTAGES. — The general expression for any alternating current, or in fact of any continuous periodic function, is

$$i = \sqrt{2}\, I_1 \sin(\omega t + \theta_1) + \sqrt{2}\, I_2 \sin(2\,\omega t + \theta_2) + \sqrt{2}\, I_3 \sin(3\,\omega t + \theta_3) + \ldots,$$

where I_1, I_2, I_3, etc., represent the r.m.s. values of each of the terms. That is any current or voltage wave may be considered as made up of a "fundamental" sine-wave, having the same frequency as that of the actual wave, and "harmonic" sine-waves having frequencies which are integral multiples of the frequency of the fundamental. Alternating currents and voltages in practice usually contain one or more of the *odd* harmonics; *even* harmonics practically never occur in ordinary electric circuits supplied from commercial forms of generators. However, as noted above, it is permissible in most instances to assume sine-wave currents and voltages, since the harmonics present are usually relatively weak compared with the fundamental. In certain instances, however, it is necessary to analyze a wave into its fundamental and harmonics. For methods of experimentally determining the shape of current and voltage waves see the articles on *Oscillographs* and *Braun Tube;* for the analysis of the curves themselves see the article on *Wave Analysis*.

R.M.S. Value of a Non-sinusoidal Wave. — The r.m.s. value of such a wave can be obtained directly from equation (3), or if the r.m.s. values I_1, I_2, I_3, etc., of the harmonic and fundamentals are known the r.m.s. value of the resultant wave is

$$I = \sqrt{I_1^2 + I_2^2 + I_3^2 + \ldots} \qquad (28)$$

A like relation holds for the r.m.s. value of a voltage wave. Similarly, if for example a 25-cycle e.m.f., say E_{25}, and a direct e.m.f., say E_d, are acting in series in the same circuit, the resultant e.m.f. of the combination is

$$E = \sqrt{E_{25}^2 + E_d^2}.$$

Power Corresponding to Non-sinusoidal Currents and Voltages. — Let I_1 be the r.m.s. value of the fundamental (first harmonic) of the current, V_1 the r.m.s. value of the fundamental of the voltage and θ_1 the difference in phase between these two fundamentals, both being of the same frequency; let I_2, V_2 and θ_2 be the corresponding quantities for the second harmonic; let I_3, V_3 and θ_3 be the corresponding values for the third harmonic, etc. Then the average power is

$$P = V_1 I_1 \cos\theta_1 + V_2 I_2 \cos\theta_2 + V_3 I_3 \cos\theta_3 + \text{etc.}$$

That is, each harmonic contributes an amount to the total power equal to the power it would develop were the other harmonics not present. If, for example, the third harmonic is not present in the current wave, then this harmonic contributes nothing to the average power even though there may be a large third harmonic in the voltage wave. Again, when a 25-cycle alternating electromotive force E_{25} and a direct electromotive force E_d are acting in series on the same circuit the power developed is the sum of the powers which each would develop if they acted separately, but the resultant e.m.f. of the combination is not $E_{25} + E_d$, but, as noted above, is $\sqrt{E_{25}^2 + E_d^2}$.

Calculation of Networks when the Currents and Voltages are Non-sinusoidal. — See below under *Symbolic Notation*, equations (31) and (32)), and the accompanying text.

SYMBOLIC NOTATION FOR EXPRESSING SINE-WAVE CURRENTS AND VOLTAGES. — Since sine-wave currents and voltages may be represented by vectors equal in length to the r.m.s. values of these quan-

Digitized by Google

tities and making definite constant angles with one another, two mutually perpendicular axes of references may be chosen, and each current and voltage resolved into two components, one along the X-axis or horizontal axis and one along the Y-axis or vertical axis. The component along the X-axis may be expressed as an ordinary algebraic quantity, and the component along the Y-axis may also be expressed as an algebraic quantity with the symbol "j" written in front of it to indicate that it is perpendicular to the X-component. That is, any current may be written

$$\underline{I} = I_1 + jI_2,$$

where I_1 is the horizontal or X-component of the current and I_2 the vertical or Y-component. Until one gets familiar with this notation it is best to indicate the symbolic nature of the currents, voltages, impedances, etc., by writing dots under them; but these dots may be dispensed with in the actual solution of problems by this method when one keeps clearly in mind that in all operations the various quantities are to be treated as *complex* quantities throughout.

A voltage drop in symbolic notation is expressed in a similar manner, viz.,

$$\underline{V} = V_1 + jV_2,$$

and an electromotive force as

$$\underline{E} = E_1 + jE_2,$$

the *same* axis of reference being used for the currents, voltage drops and electromotive forces.

Impedance and Admittance in Symbolic Notation. — In this notation an impedance of resistance r and reactance* x is represented by the complex quantity

$$\underline{z} = r + jx, \qquad (29)$$

and an admittance of conductance g and susceptance* b by the complex quantity

$$\underline{y} = g - jb. \qquad (29a)$$

These expressions are independent of the axes of reference chosen.

Currents, Voltages, Impedances and Admittances as Complex Numbers. — In all operations involving the addition or subtraction of currents or voltages and in all operations involving products of currents and impedances or products of voltages and admittances, these quantities when written in symbolic notation may be treated as complex quantities (*see article on Complex Quantities*), *provided all the currents and voltages are referred to the same axis of references*. In all such operations the symbol "j" may be considered as mathematically equivalent to $\sqrt{-1}$. Hence when a term of the form $A_1 + jA_2$ occurs in the denominator of any fraction, the fraction may be "rationalized" by multiplying numerator and denominator by $A_1 - jA_2$, which gives

$$\frac{1}{A_1 + jA_2} = \frac{A_1 - jA_2}{A_1^2 + A_2^2}. \qquad (30)$$

In any resulting expression for a current or voltage when thus rationalized the "real" part represents the actual component of the current or voltage in the direction of the X-axis and the "j" part, i.e., the sum of the terms which are multiplied by j, represents the actual component of the current or voltage along the Y-axis.

* Taken positive when inductive, negative when condensive, e.g., the admittance of a condenser is $g + j\,(2\pi fC)$.

Digitized by Google

Solution of Alternating-current Networks. — When all the currents, voltages, impedances and admittances are expressed in symbolic notation, the following relations hold:*

1. The sum of all the currents flowing to any point in any network of conductors is zero. That is, at any point

$$\dot{I} + \dot{I}' + \dot{I}'' + \ldots = 0, \tag{31}$$

where the currents are all expressed in symbolic notation and are all referred to the *same* line of reference.

2. The sum of all the impedance drops in a given direction around any closed loop in any network of conductors is equal to the sum of all the *externally induced e.m.f.'s* acting in this loop in this direction. That is, around any closed loop

$$\dot{z}\dot{I} + \dot{z}'\dot{I}' + \dot{z}''\dot{I}'' + \ldots = \dot{E} + \dot{E}' + \dot{E}'' + \ldots, \tag{32}$$

where the currents, impedances and electromotive forces are all expressed in symbolic notation, and the *currents and e.m.f.'s are all referred to the same axis of reference*. That is, the currents are to be expressed as $\dot{I} = I_1 + jI_2$, $\dot{I}' = I_1' + jI_2'$, etc., and the e.m.f.'s as $\dot{E} = E_1 + jE_2$, $\dot{E}' = E_1' + jE_2'$, etc., where all the components of the currents and e.m.f.'s with the subscript 1 are parallel to one another and all those with the subscript 2 are parallel to one another and lead the first set of components by 90 degrees.

The electromotive forces due to inductance and capacity are taken account of by the impedance; the electromotive forces represented by the $\dot{E}$'s in equation (32) are the externally induced electromotive forces such as those due to generators or motors or to the mutual inductance of the two windings of a transformer.

In applying equations (31) and (32) to the calculation of the currents and potential drops in any network of circuits, care must be taken to designate clearly the sense of the vectors representing the currents and e.m.f.'s. This is most conveniently done by numbering all the junction points in the network, and designating each current and e.m.f. by a double subscript written in the order corresponding to the assumed direction of the current or e.m.f. vector. For example, in Fig. 9, the e.m.f. from 0 to 1 is represented by $\dot{E}_{01}$ while the e.m.f. from 1 to 0, which is equal to $-\dot{E}_{01}$, is represented by $\dot{E}_{10}$. In the figure, then, the net electromotive force from 1 to 2 is

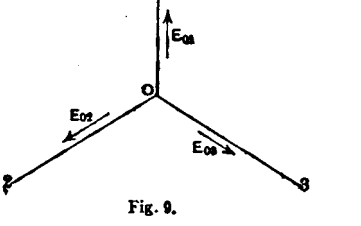

Fig. 9.

$$\dot{E}_{12} = \dot{E}_{10} + \dot{E}_{02},$$

or

$$\dot{E}_{12} = -\dot{E}_{01} + \dot{E}_{02}.$$

Each equation of the form (31) or (32) is in reality equivalent to two equations, since the sum of all the "real" terms on one side must be equal to the sum of all the real terms on the other side, and similarly, the sum of all the "j" terms on one side must be equal to the sum of all the "j" terms on the other side, the denominators of all fractions having been cleared of "j" terms by the transformation given by equation (30). This is merely another way of stating the fact that the component in any direction of the *resultant* of any number of vectors

* These relations are simply Kirchhoff's Laws (*see Electricity and Magnetism, Principles of*) expressed in a convenient form for alternating currents.

Digitized by Google

must be equal to the algebraic sum of the components in this direction of all the individual vectors. Applying these two laws to any network enables one, therefore, to calculate both components of every p.d. and every current, when the impedances and the electromotive forces are known.

These equations hold only when *the currents and e.m.f.'s are all simple harmonic functions* of the *same* frequency *and the resistances and reactances are constant.* When, however, the resistances, inductances and capacities are constant, a similar set of equations holds for each frequency that may be present. Since the equations are all linear in the I's and E's, the currents and e.m.f.'s of any given frequency will be uninfluenced by the presence of currents or e.m.f.'s of any other frequency. Hence, when the harmonics present in each e.m.f. are known, the harmonics present in each current may be calculated by solving the equations corresponding to the frequency of this particular harmonic, these equations being exactly the same as would hold were all the other harmonics absent.

Network problems can often be simplified by various expedients, see for example, *Analytical Solutions of Power-Circuit Network Problems*, by R. D. Evans, in the *Electric Journal, Vol. 16, pp. 345–349, 1919.*

Difference in Phase between a Current and Voltage in Symbolic Notation. — Let the current be represented by

$$\underline{I} = I_1 + jI_2$$

and the voltage drop in the same sense as the current be represented by

$$\underline{V} = V_1 + jV_2.$$

Then the current lags behind the voltage drop by the angle θ, where

$$\tan\theta = \frac{V_2I_1 - V_1I_2}{V_1I_1 + V_2I_2}. \qquad (33)$$

Power Corresponding to a Current and Voltage in Symbolic Notation. — Let the current and voltage drop be represented by the same expressions as in the preceding paragraphs. Then the average power is

$$P = V_1I_1 + V_2I_2. \qquad (34)$$

Note that this expression is equal to the real part of the product of the complex numbers $V_1 + jV_2$ and $I_1 + jI_2$ *with the sign between the two terms reversed.*

Example of the Use of the Symbolic Method. — An impedance z_1 has a resistance of 3 ohms and an inductive reactance of 4 ohms; a second impedance z_2 has a resistance of 8 ohms and a condensive reactance of 6 ohms. z_1 is then represented symbolically as $z_1 = 3 + j4$ and z_2 as $z_2 = 8 - j6$.

Let these two impedances be connected in series, and let an e.m.f. of 100 volts be impressed across them. Choosing the vector representing the over-all potential drop as the axis of reference, and calling the current I, then $(3 + j4 + 8 - j6)\,\underline{I} = 100 + j0$, whence

$$\underline{I} = \frac{100}{11 - 2j} = \frac{1100 + j200}{121 + 4} = 8.8 + j1.6.$$

Hence the effective value of the current is

$$I = \sqrt{(8.8)^2 + (1.6)^2} = 8.94 \text{ amperes}$$

and the current leads the over-all potential drop by the angle

$$\tan^{-1}\frac{1.6}{8.8} = 10.3°.$$

The potential drop across the first impedance is

$$\underline{V}' = (3 + j4)\,(8.8 + j1.6) = 26.4 - 6.4 + j\,(35.2 + 4.8) = 20 + j40,$$

Digitized by Google

which has the effective value

$$V' = \sqrt{(20)^2 + (40)^2} = 44.7 \text{ volts},$$

and leads the over-all potential drop $\mathfrak{V}$ by the angle

$$\tan^{-1}\frac{40}{20} = 63.5°.$$

The potential drop across the second impedance is

$$\mathfrak{V}'' = (8 - j6)(8.8 + j1.6) = 70.4 + 9.6 - j(52.8 - 12.8) = 80 - j40,$$

which has the effective value

$$V'' = \sqrt{(80)^2 + (40)^2} = 89.4 \text{ volts},$$

and lags behind the over-all potential drop $\mathfrak{V}$ by the angle

$$\tan^{-1}\frac{40}{80} = 26.5°.$$

The power input into the first impedance is

$$W' = 8.8 \times 20 + 1.6 \times 40 = 240 \text{ watts}.$$

The power input into the second impedance is

$$W'' = 8.8 \times 80 - 1.6 \times 40 = 640 \text{ watts}.$$

The total power input is

$$W = 8.8 \times 100 + 1.6 \times 0 = 880 \text{ watts},$$

which of course is the sum of W' and W''.

POLYPHASE SYSTEMS. — A polyphase alternating-current system is a network (i.e., combination of circuits) supplied from a generator or generators which develop two or more electromotive forces differing in phase from one another by a constant angle; see *Distribution of Electric Energy; Generators, Alternating-current; Transformers*. The two kinds of polyphase circuits commonly employed are the two-phase and three-phase circuits.

Star and Mesh Connections. — Consider n separate coils or windings, which may be mounted on a common armature or be entirely distinct, as for example n groups of lamps. When these n windings are connected end to end so that they are all in series, forming a closed chain, as in Fig. 10, and terminals

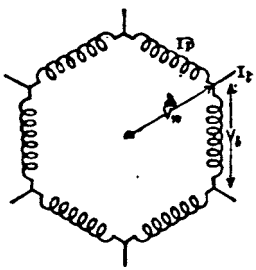

Fig. 10.

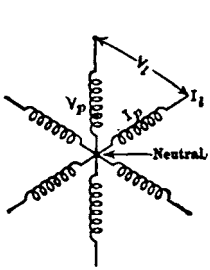

Fig. 11.

are brought out from the n junctions, they are said to be connected in "mesh." When one terminal of each of these windings is connected to a common junction point, as in Fig. 11, and terminals are brought out from the free ends, the windings are said to be connected in "star," and the common point is called the "neutral point."

n-Phase System. — When such a group of n windings, as shown in Fig. 10 or 11, is connected to a generator or other source of e.m.f., having n separate windings and therefore developing n different e.m.f.'s which differ in phase from one another, the system is called an n-phase system, each winding being called a "phase." For example, when there are three separate windings on the generator, three line wires and three windings constituting the load, the system is a three-phase system.

Balanced Systems. — When the e.m.f.'s, if any, in the n-phases of any system of connection are all equal in r.m.s. value and differ successively in phase by $360/n$ degrees and if the currents in these windings are also equal in r.m.s. value and differ successively in phase by $360/n$ degrees, the system is said to be a "balanced" n-phase system. When the e.m.f.'s in the various parts of a system are equal in r.m.s. value and differ successively in phase by $360/n$ degrees, and the impedances in the various windings or phases are all equal, both as regards resistance and reactance, then the currents are necessarily equal in r.m.s. value and differ successively in phase by $360/n$ degrees, and the system is balanced.

Phase and Line Currents and Voltages. — The current in any winding or phase of an n-phase system, see Figs. 10 and 11, is called the "phase current," and the drop (or rise) of potential *through* this winding is called the "phase voltage." The current in the line leaving any terminal of an n-phase system is called the "line current" and the voltage between *adjacent* line wires or terminals is called the "line voltage," except in the special case of a two-phase connection, see below, when the voltage between diametrically opposite terminals is called the line voltage. In the case of a star-connection the voltage between any terminal and the neutral point is called the "voltage to neutral"; in the case of a balanced mesh connection by voltage to neutral is meant the voltage which would exist between any terminal and the neutral of a star-connection connected to the terminals of the actual device, the impedance of all the legs of the star-connection forming this "artificial neutral" being equal and sufficiently large not to take an appreciable current.

The relations between these various currents and voltages for a balanced n-phase system are as follows:

	Mesh	Star
Number of phases	n	n
Line current	I_l	I_l
Line voltage	V_l	V_l
Phase current	$I_p = \frac{1}{2 \sin \frac{\pi}{n}} I_l$	$I_p = I_l$
Phase voltage	$V_p = V_l$	$V_p = \frac{1}{2 \sin \frac{\pi}{n}} V_l$
Voltage to neutral	$V_n = \frac{1}{2 \sin \frac{\pi}{n}} V_p$	$V_n = V_p$
Total volt-amperes	$nV_pI_p = \frac{n}{2 \sin \frac{\pi}{n}} V_lI_l$	$nV_pI_p = \frac{n}{2 \sin \frac{\pi}{n}} V_lI_l$

Two-phase or Quarter-phase System. — Strictly, the so-called single-phase system is a star-connected two-phase system, since the currents *from* the two terminals are in opposite directions at any instant, the current leaving by one and entering by the other. However, in practice the name two-phase system is used for a system supplied from a generator or other source of e.m.f. having two windings in which are developed two e.m.f.'s differing in phase by 90°; i.e., a two-phase system is in reality two distinct single-phase systems each with two terminals. Two of the four terminals may be connected to each other, in which case but three line wires are required. Or, the two single-phase systems may be connected at their middle points; in this case the two-phase system may be considered as a four-phase, or, as it is usually called, a "quarter-phase" system. See the articles on *Distribution of Electric Energy* and *Transformers*.

Three-phase System. — Delta and Y-Connections. — For a three-phase system the generators and motors are designed with three windings or phases which may be connected either in mesh, usually called a "delta-connection" in this case, since the diagram of the three windings forms a Greek delta, or the three windings may be connected in star, usually called a "Y-connection" in this case, since the diagram of the three windings forms a Y. The relations between line and coil currents and voltages for a *balanced* three-phase system are as follows:

	Delta	Y
Line current	I_l	I_l
Line voltage	V_l	V_l
Phase current	$I_p = \frac{I_l}{\sqrt{3}}$	$I_p = I_l$
Phase voltage	$V_p = V_l$	$V_p = \frac{V_l}{\sqrt{3}}$
Voltage to neutral	$V_n = \frac{V_l}{\sqrt{3}}$	$V_n = V_p$
Total volt-amperes	$3V_pI_p = \sqrt{3}V_lI_l$	$3V_pI_p = \sqrt{3}V_lI_l$

Calculation of Balanced Three-phase Circuits. — Any problem in regard to a *balanced* three-phase circuit may be solved by reducing all parts of the circuit to an equivalent Y-connection, provided the currents and e.m.f.'s are sine-waves. The transformations are made as follows:

Any Δ-connected motor or generator is considered as equivalent to a Y-connected generator or motor in which

$$E_y = \frac{E_\Delta}{\sqrt{3}}, \qquad r_y = \frac{r_\Delta}{3}, \qquad x_y = \frac{x_\Delta}{3},$$

where the quantities E_y, r_y and x_y are the e.m.f., resistance and reactance per phase of the Y-connected machine equivalent to the e.m.f., resistance and reactance per phase of the actual Δ-connected machine.

Each of the line wires is in series with a corresponding phase of the equivalent Y-connected machine.

When all parts of the circuit have thus been reduced to equivalent Y's, each of the three-phases may be treated as a single-phase circuit, each circuit considered completed by a wire having *zero* impedance connecting all the neutrals together, since all the neutrals are at the same potential.

Digitized by Google

The voltages thus calculated are the voltages to neutral and the currents are line currents. To find the line voltage multiply the calculated voltage by $\sqrt{3}$; similarly, to find the actual phase current in the Δ-connected generator or load divide the calculated current by $\sqrt{3}$.

Example of Three-phase Calculation. — Energy is supplied from a generating station to a substation 50 miles away at a rate of 20,000 kilowatts. The system is a balanced three-phase system and operates at a frequency of 25 cycles. The transmission line consists of three No. 0000 B. & S. copper wires spaced six feet between centers. It is desired to find (1) the voltage between wires at the generating station when the voltage between wires at the substation is 60,000 volts, and the power factor at the substation is 80 per cent, with the current *lagging*, (2) how much power is lost in the transmission line and (3) what is the power factor at the generating station. The electrostatic capacity of the line may be neglected.

The current per wire is

$$I = \frac{20{,}000{,}000}{\sqrt{3} \times 60{,}000 \times 0.8} = 241 \text{ amperes.}$$

The voltage to neutral at the substation is

$$V_n = \frac{60{,}000}{\sqrt{3}} = 34{,}600.$$

The component of this voltage in phase with the line current is $0.8 \times 34{,}600 = 27{,}700$ volts and the component 90° ahead of the line current is $0.6 \times 34{,}600 = 20{,}800$ volts, since $\cos\theta = 0.8$ and $\sin\theta = 0.6$.

The resistance per mile of a No. 0000 wire is 0.258 ohm; its reactance per mile at 25 cycles is 0.303 ohm. Hence the total resistance of each wire is 12.9 ohms and the total reactance of each wire 15.2 ohms. The resistance drop in each wire is then $12.9 \times 241 = 3110$ volts and is in phase with the line current and the inductive drop in each wire is $15.2 \times 241 = 3660$ volts and is 90° ahead of the line current.

At the generator end the voltage to neutral in phase with the line current is then $27{,}700 + 3110 = 30{,}810$ volts and the voltage to neutral 90° ahead of the current is $20{,}800 + 3660 = 24{,}460$ volts. The resultant voltage to neutral at the generator end is then $\sqrt{(30{,}810)^2 + (24{,}460)^2} = 39{,}300$ volts, and therefore the line voltage at the generating station is

$$V_l' = \sqrt{3} \times 39{,}300 = 68{,}000.$$

The power lost in the line is equal to $3RI_l^2$, where R is the total resistance of each wire and I_l the line current. Hence the power lost in the line is

$$3 \times 12.9 \times (241)^2 \text{ watts} = 2250 \text{ kilowatts.}$$

The total power delivered to the line and substation is then 22,250 kilowatts. Hence the power factor at the generating station is

$$\frac{22{,}250{,}000}{\sqrt{3} \times 68{,}000 \times 241} = 0.784 = 78.4 \text{ per cent.}$$

Measurement of Power in Three-phase Circuits. — See *Wattmeters*.

Calculation of Unbalanced Three-phase Circuits. — When a three-phase system is unbalanced, the currents and voltages can always be calculated by applying Kirchhoff's laws to the junctions and loops formed by the various parts of the system. For example, referring to Fig. 12, what will be the currents in each line wire and what will be the readings of the two watt-meters connected as shown when the three impedances forming the unbalanced star

Digitized by Google

ive the values $z_1 = 1 + j2$, $z_2 = 3 - j4$ and $z_3 = 5 + j6$, and the voltages tween the terminals 1, 2 and 3 are balanced and numerically equal to 100 lts? What is the voltage from each terminal to the neutral?

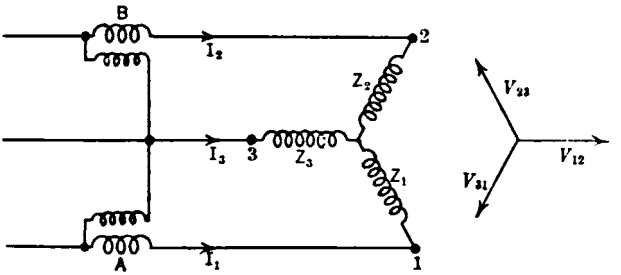

Fig. 12.

The following relations then hold, taking V_{12} as the reference vector:

$$\dot{V}_{12} = 100, \tag{a}$$

$$\dot{V}_{23} = -50 + j86.6 \tag{b}$$

$$\dot{V}_{31} = -50 - j86.6 \tag{c}$$

$$\dot{I}_1 + \dot{I}_2 + \dot{I}_3 = 0 \tag{d}$$

$$100 = (1 + j2)\dot{I}_1 - (3 - j4)\dot{I}_2 \tag{e}$$

$$-50 + j86.6 = (3 - j4)\dot{I}_2 - (5 + j6)\dot{I}_3 \tag{f}$$

Substituting in (f) the value of $\dot{I}_3$ from (d) there results.

$$-50 + j86.6 = (8 + j2)\dot{I}_2 + (5 + j6)\dot{I}_1 \tag{g}$$

Substituting in (g) the value of $\dot{I}_2$ from (e) and solving for $\dot{I}_1$ there results,

$$\dot{I}_1 = 25.36 + j5.90. \tag{h}$$

Substituting this value of $\dot{I}_1$ in (e) there results,

$$\dot{I}_2 = -19.43 - j7.04 \tag{i}$$

Substituting (h) and (i) in (d) there results,

$$\dot{I}_3 = -5.93 + j1.14 \tag{j}$$

The r.m.s. values of these three currents are respectively,

$$I_1 = 26.04; \quad I_2 = 20.64; \quad I_3 = 6.04.$$

Wattmeter A indicates the power P_A corresponding to the voltage V_{13} and the current I_1, and wattmeter B indicates the power P_B corresponding to the voltage V_{23} and the current I_2. Note that from (b) and (c) and (h) and (i),

$$\dot{V}_{13} = 50 + j86.6, \qquad \dot{V}_{23} = -50 + j86.6,$$

$$\dot{I}_1 = 25.36 + j5.90, \qquad \dot{I}_2 = -19.43 - j7.04.$$

Whence, from equation (34),

$$P_A = 1779 \text{ watts} \quad \text{and} \quad P_B = 362 \text{ watts}.$$

Note that $(P_A + P_B)$ is equal to the total power in-put to the three phases, viz., to $(r_1I_1^2 + r_2I_2^2 + r_3I_3^2)$, and compare with the article on *Wattmeters*.

The r.m.s. voltage from each terminal to the neutral is the product of t current in that particular phase of the Y by the impedance of that phase, viz.,

$$V_{10} = 26.04 \times \sqrt{(1)^2 + (2)^2} = 58.23 \text{ volts},$$

$$V_{20} = 20.64 \times \sqrt{(3)^2 + (4)^2} = 103.20 \text{ volts},$$

$$V_{30} = 6.04 \times \sqrt{(5)^2 + (6)^2} = 47.17 \text{ volts}.$$

Unbalanced Polyphase System Equivalent to Two Balanc Polyphase Systems of Opposite Phase-rotation. — In many cases it advantageous, for the purpose of calculation, to consider an unbalanced pol phase system as the superposition of two balanced polyphase systems of opposi phase rotation. The procedure and a number of applications are given b Fortescue in the *A.I.E.E. Proc., June 18, 1918, p. 629.* See also Lyon, W. V *Elec. World, 75, p. 1304, June 5, 1920.*

ALUMINUM. — (*See also Electrochemical Processes, Industrial; Lightning Protectors; Wires and Cables, Bare.*) The method of manufacturing aluminum wire is similar to that employed in making copper wire (*see Copper*).

MECHANICAL PROPERTIES. — The more important mechanical properties of aluminum are discussed below.

Necessity of Stranding Aluminum Wire. — Aluminum wire (i.e., solid wire) is little used for aerial spans owing to the danger of failure where accidental abrasions have occurred. Cables not only reduce the above danger, but have greater breaking load, owing to the superior tensile strength of small wires.

Tensile Strength. — The tensile strength of aluminum has not been studied as thoroughly as that of copper, but it is well known that, like copper, aluminum is much stronger in small, than in large, wires. The following table by H. M. Hobart, which is for solid wires, illustrates this point.

Diameter, inches	0.05	0.10	0.15	0.20	0.25	0.30	0.35
Tensile strength, lb. per sq. in.	33,300	28,800	26,200	24,800	23,800	23,200	23,000

The Standard Electric Co., of California, uses a solid aluminum wire, 0.294 inch diameter, having a tensile strength of 22,800 pounds per square inch, and a conductivity of 59.9 per cent.

Elongation. — The ultimate elongation of hard-drawn aluminum wire varies from 2.0 per cent to 3.7 per cent (in 1 meter length) as the diameter is increased from 1 to 4½ mm. (*H. M. Hobart.*)

Modulus of Elasticity. — Different authorities give values from 9×10^6 to 10×10^6 in pounds per square inch, the former being given by the Aluminum Company of America.

Elastic Limit. — The Aluminum Company of America in their booklet on "Properties of Aluminum," give the following figures for elastic limit in tension, the metal being 99 per cent pure.

	Lb. per sq. in.
Castings	8,500
Sheet	12,500 to 25,000
Wire	16,000 to 33,000
Bars	14,000 to 23,000

Density. — A density of 2.70 grams per cubic centimeter is given by the U. S. Bureau of Standards (*Circ. No. 31*) as a good average value for commercial hard-drawn aluminum. This is equivalent to 0.0975 pound per cubic inch. Hobart gives 2.71 for the density. F. J. Brislee (*Lond. Elec. Review, Jan. 5, 1912*) gives 2.708 as the density of cast aluminum and 2.705 for hard-drawn rod.

THERMAL PROPERTIES. — See article on *Heat and Thermal Properties*.

CONDUCTIVITY AND RESISTIVITY. — The Aluminum Company of America give as the average of many thousands of separate determinations, the figure of 2.828 microhms per centimeter cube at 20° C. as the resistivity of commercial aluminum wire. This corresponds to a conductivity of 61 per cent of the annealed copper standard (see *Resistance and Conductance, Electric*).

Effect of Hardness on Conductivity. — The resistance of aluminum depends upon its hardness; for example, the resistance of aluminum wire of hard-

ness corresponding to a tensile strength of about 20 kg. per mm. is approximately 2 per cent greater than that of the same wire when thoroughly annealed and consequently soft. (*H. M. Hobart.*)

Temperature Coefficient of Resistivity. — From the data given by G. Grassi (*Elletrotecnica, 6, p. 10, Jan. 5, 1919*), the 20° C. temperature coefficient of 61 per cent conductivity annealed aluminum wire is 0.00408, per degree centigrade, corresponding to a 0° C. coefficient of 0.00444. Grassi also found that the temperature coefficient of aluminum is proportional to its per cent conductivity (as is also the case with copper; see article on *Copper*). American investigators have found a lower coefficient, the figure 0.0039 being most commonly used.

COMPARISON OF ALUMINUM AND COPPER. — Aluminum is usually cheaper than copper of the same length and resistance and is said to be cheaper to install (*C. B. Smith, El. W., 1912, Vol. 59, p. 96*). It is, however, subject to the disadvantage of lower tensile strength which often makes it more expensive than copper, except for very high voltages.

The table below compares the various items for wires having the same length and same resistance and is based on the following assumptions:

	Copper	Aluminum
Per cent conductivity	98	61
Tensile strength, lb. per sq. in.	55,000	25,000
Density	8.89	2.70
Price per pound	P	p

COMPARISON OF COPPER AND ALUMINUM WIRES FOR EQUAL RESISTANCES PER UNIT LENGTH

Item	Copper	Aluminum
Cost	1	$0.488 \times \frac{p}{P}$
Cross-section	1	1.63
Diameter	1	1.28
Weight	1	0.488
Breaking strength	1	0.731
Carrying capacity	1	1.13

Disadvantage of Low Tensile Strength. — The lower tensile strength of aluminum for equal length and conductance as compared with copper affects the cost of an aerial line in two ways: 1st, by making it necessary to erect the spans with a greater sag or less length in order to reduce the stresses, thereby either increasing the height or the number of poles, and 2nd, by making it necessary to increase the distance between wires on account of the increased sag. The increase in the height of poles for the same spacing amounts to about 10 per cent. (*C. L. Johnson*). Aluminum cables with steel core are now used and overcome these difficulties. See article on *Wires and Cables, Bare.*

Effect of Large Elongation of Aluminum. — The extraordinarily great elongation of aluminum enables it to withstand severe mechanical overloads by stretching and thus increasing the sag. However, in dealing with a single

solid wire this cannot be relied on, as a scratch or a single imperfection will often cause the wire to break without any appreciable elongation. This is one reason why cables are to be preferred to single-wire conductors.

Effect of Low Melting Point of Aluminum. — The distance between aerial wires is also influenced by the fact that aluminum has a lower melting-point than copper, making it necessary to keep wires at different potentials well separated in order to avoid the danger of short-circuits through foreign bodies. This danger has, perhaps, been exaggerated in the past as the author has the record of a case where a copper wire was thrown across two aluminum cables with 60,000 volts difference of potential between them and an arc was formed between the cables forming an arch 12 to 15 feet high, but with no injury to the cables except the formation of a few minute beads on their surface.

Formation of Sleet. — While for equal length and resistance, aluminum wires are larger than copper wires, they do not necessarily collect a proportionally greater load of sleet, as it is found that a film of grease left over from the drawing process often entirely prevents the adhesion of sleet. Conclusive information on this subject is, however, lacking, especially with regard to wire that has been in use for several years.

Corona Formation. — At very high potentials, such as 100,000 volts, aluminum conductors possess a marked advantage over copper in the lower corona loss due to their greater diameter for the same conductance.

Corrosion. — E. Huber-Stockar gives the results of a number of tests on the corrosion of aluminum in moist air, salt air, salt water, various gases, acids, etc., which indicate that, in respect to its chemical stability, aluminum is in general the equal of copper. There has been much said about the tendency of electrostatic repulsion to reduce impure condensation on aluminum conductors, but this author rejects such statements as unworthy of the slightest credence.

Aluminum wire exposed to the atmosphere increases in resistance. E. Wilson (*Electrician, 75, p. 886, Sept. 17, 1915*), reports a case where commercial aluminum increased in resistance 17.2 per cent in 13 years. Wilson also gives the results of tests on various aluminum alloys.

Bare aluminum conductors laid in the earth have been tried for railway return feeders, with the result that they were rapidly corroded by galvanic action.

Mr. Dusaugey says that aluminum containing over 4 per cent of impurities is very liable to corrode rapidly. This is especially the case if sodium is present.

At ordinary temperatures aluminum is covered with a layer of oxide which protects it against the influence of the weather and of many chemicals.

Example of Relative Cost. — According to the official publications of the Ontario Hydro-Electric Commission on a line consisting of two three-phase circuits, each comprising three 0000 A.W.G. cables, the six cables cost $1450 per mile as compared with $2050 per mile for copper cables (copper being at 16 cents per pound and aluminum at 23.5 cents per pound), showing a saving of nearly 30 per cent on the cables alone. This saving was reduced to 5.6 per cent only on the total cost of the line, partly because the actual towers weighed 1.72 tons against 1.57 tons for towers for an equivalent copper line, and partly because the cost of cables was only 30 per cent of the total cost of the line, including erection but excluding rights-of-way. (*C. L. Johnson.*) Owing to a tariff of 3 ½ cents per pound the price of aluminum is higher in the United States than in Canada and Europe, so that the saving would have been considerably less at United States prices.

SOLDERS FOR ALUMINUM. — (*Bureau of Standards, Circ. No. 78*, Washington, D. C., 1919). Aluminum can be welded in a satisfactory manner by the oxyacetylene blowpipe flame, but soldering is often desirable. Alumi-

num solders consist usually of mixtures in varying proportions of Zn and Sn or of Zn, Sn and Al. The surfaces to be soldered are carefully cleaned and "tinned" or coated with a layer of the solder by heating the surface and rubbing the solder into it. The joint between the tinned surfaces may then be made in the usual way with a soldering iron and the solder, no flux being used. A soldered joint is rapidly attacked when exposed to moisture. The joints should never be made by soldering unless they are to be protected against corrosion by a paint or varnish or unless they are heavy, as in the case of repairs in castings.

The composition of the solder may vary within wide limits. For tin-zinc solders, zinc 15 to 50 per cent, the remainder Sn, is recommended. The higher the temperature at which the tinning is done the better is the adhesion of the tinned layer, therefore the solders high in Zn and Al give better results. The joint between previously tinned surfaces may be made by ordinary methods by ordinary soft solders; only the tinning mixture need be special for Al. The tensile strength of a good solder is about 7000 pounds per square inch. The strength of a joint depends on the type and on the workmanship, but much dependence should not be placed upon it.

SPREE-ALUMINUM. — E. Huber-Stodkar gives considerable data on an aluminum alloy, known under the name of spree-aluminum. It has nearly double the strength of pure aluminum. Its breaking length is 10.7 kilometers, as compared with 10.3 kilometers for steel, 6.7 kilometers for aluminum and 5.1 kilometers for hard copper. The use of spree-aluminum cable shows a saving in cost of about 7.3 per cent as compared with copper cable of equal conductance.

AMMETERS. — (*See also Balances, Current; Electricity and Magnetism, Principles of; Electrodynamometers; Galvanometers; Voltmeters.*) An ammeter is essentially a galvanometer (q.v.) or electrodynamometer (q.v.) of rugged construction, provided with a pointer moving over a scale forming an integral part of the instrument and calibrated to read directly in amperes. The moving element is usually supported in jeweled bearings.

CLASSIFICATION AND USE OF AMMETERS. — Ammeters which have found general commercial application may be classified as follows:

Moving-magnet Type, in which a permanent magnet or polarised vane is caused to move under the influence of a winding which carries the current to be measured. The principle of operation is similar to that of a Thomson galvanometer (*see Galvanometers*). The restoring force is usually a fixed permanent magnet. This type of instrument measures average values and is therefore suitable for direct currents only.

Moving-iron Type, in which there is relative motion between a piece of soft iron and a fixed coil carrying the current to be measured. There are a number of subclasses which are distinguished chiefly by differences of mechanical construction. In the plunger type a soft iron core is drawn into the coil. The core is usually in the form of a rod, and the length of the coil is several times its diameter. In the repulsion type, as usually constructed, a piece of iron is repelled by a fixed piece of iron, both being within the coil carrying the current to be measured. The Weston moving-iron ammeter is of this type. In the Thomson inclined-coil ammeter, the coil is fixed at an angle of about 45° with the shaft which carries one or more iron vanes, the latter also making the same angle with the shaft. As the current through the coil increases the vanes turn so as to approach the condition of parallelism with the magnetic field within the coil. The restoring force of all these forms of ammeter is usually that of a spring. This type of ammeter measures effective (r.m.s.) values * and may be used for either alternating or direct currents, but such ammeters are subject to slight errors in the latter case, due to the tendency of the vane or plunger to hold its magnetism.

Permanent-Magnet Moving-coil Type, in which a permanent magnet maintains a strong field in a fixed location, and the current to be measured is sent through a moving coil, entering or leaving by springs that furnish the restoring force or through auxiliary spirals. The principle of operation is the same as that of a d'Arsonval galvanometer (*see Galvanometers*). This type of instrument measures average values and is suitable for direct currents only. Precision d-c. ammeters are usually of this type.

Electrodynamic Type, in which the operation depends upon the force exerted by one current-carrying circuit upon another, or by a portion of one circuit upon another portion of the same circuit. (See *Electrodynamometers.*) The usual form of construction includes a pivoted coil which moves in the field of a fixed coil or set of coils. The restoring force is usually due to springs, and the current is led into and out of the moving coil through these springs or through flexible conductors constructed to carry relatively large currents and to have a minimum restoring force. This type of instrument measures effective (r.m.s.)

* Moving iron instruments do not measure r.m.s. values exactly, on account of the lack of exact proportionality between the instantaneous torque and the square of the instantaneous current, but by careful attention to details in the design such instruments can be made nearly perfect in this respect, so that all things considered, they are sometimes to be preferred to electrodynamic instruments. For precise work, calibration of such instruments made with direct current should not be used on alternating current.

Internet Archive

values and may be used to measure either alternating or direct currents. Precision a-c. instruments are usually of the electrodynamic type.

Hot-wire Type, in which the expansion of a wire or strip due to the heat developed within it, caused by the current passing through it, is made to move an indicating pointer. The "thermocouple" ammeter, described below, may also be classified as a hot-wire ammeter, although the principle of operation is quite different. Hot-wire ammeters measure effective (r.m.s.) values and are useful for both alternating- and direct-current measurements.

Induction Type, in which a metal cylinder or disk with pointer attached is caused to rotate under the action of a rotating magnetic field, usually produced from a single-phase source by means of a phase-splitting device. The principle of operation is similar to that of an induction watthour meter (*see Watthour Meters*), the motion of the moving element being opposed by a spring. This type of instrument measures effective values of alternating currents only and generally for only a limited range of frequency and wave form.

Thermocouple Ammeters. — For measuring small alternating currents, particularly when the frequency is high (500 cycles per second or more), a thermocouple (*see Pyrometers*) may be used; the current to be measured is passed through a wire resistor (*see Wires, Resistor*) to which is soldered one junction of the thermocouple, the free ends of which are connected to an ammeter (or galvanometer) of any of the types noted above. The heating of the resistor wire sets up a direct current in the thermocouple circuit which, in turn, depends upon the effective value of the current through the heater wire. The limitations and errors in the use of such ammeters are discussed at length in a paper on *High Frequency Ammeters* in Scientific Paper No. 206, Bull. Bur. Stds., 1913, Vol. 10. See also article in the Gen. El. Rev. 17, p. 981, Oct., and p. 1210, Dec., 1914.

Other Types of Ammeters. — Successful instruments for special needs have been made that would not ordinarily be classed under the above headings, and other instruments might be referred to which combine in a single instrument more than one of the subdivisions.

Portable and Switchboard Instruments. — Switchboard instruments are usually of more rugged construction than portable instruments and are somewhat less precise in their indications. Portable instruments are provided with suitable binding posts on their bases and are generally used in a horizontal position. Switchboard instruments are usually provided with back connections and are used in a vertical position. In the so-called "edgewise" instruments the instrument mechanism is horizontal but the pointer is so designed that it indicates on a vertical scale.

Recording (Graphic) Ammeters. — A continuous record of current may be obtained by using an ammeter provided with a clock mechanism which slowly rotates a chart (disk-shaped or mounted on a drum) or a continuous paper ribbon under the end of the pointer which carries a pen kept continuously inked. The moving element is comparatively heavy since the deflecting force must be great enough to overcome the friction of the pen and prevent "sticking."

INSTRUMENT SCALES. — A uniform scale is usually desirable in any kind of instrument, and with permanent-magnet moving-coil types such a scale is readily obtained, since the deflecting torque is proportional to the current. In moving-iron, electrodynamic and other types in which the deflecting torque depends upon the square of the current, very small deflections are obtained for low values of the current and the scale divisions are crowded for low values.

Digitized by Google

DAMPING. — For ordinary purposes it is essential that the pointer of the instrument come quickly to rest. The moving coil of the permanent-magnet moving-coil instrument is usually wound on a light aluminum frame which is mounted between the poles of the permanent magnet, and a soft-iron core fills the air gap between the poles, other than that necessary to allow free motion of the coil. The metal frame moves through a very strong magnetic field and eddy currents are set up in it which effectually damp its motion. Although it is not difficult to make the instruments perfectly aperiodic, a slight underdamping is often preferred because it gives opportunity to observe at all times that the movement of the instrument is perfectly free.

Magnetic (eddy current) damping or air damping by means of light vanes moving in a more or less perfectly closed air chamber is used with the other types of instruments.

ELIMINATION OF EFFECT OF STRAY FIELDS. — Due to the low reluctance of iron compared with air, a soft-iron shield placed around the instrument mechanism will greatly reduce the disturbing effect of an external magnetic field on the readings of the instrument. Many types of switchboard and portable instruments are thus shielded. Permanent-magnet moving-coil instruments are affected by only comparatively strong fields.

Astatic Instruments. — Another means of avoiding errors due to stray fields is by making the moving element astatic. The principle of this construction is to divide the moving element into two parts, so arranged that the deflecting torques acting on the two parts due to the field of the instrument are additive, whereas any stray field will produce equal and opposite torques on these two parts.

Thomson Astatic Instruments. — The Thomson astatic ammeters and voltmeters are unique in that the deflecting torque and the controlling torque are both caused by the same magnetic field. This field is produced by an electromagnet wound for any specified voltage and provided with binding posts separate from the current posts of the instrument, or by means of a permanent magnet. Two moving coils are mounted diametrically opposite each other upon an aluminum disk. The disk and coils cut across the field which is directed parallel to the shaft carrying the disk. Two small pieces of soft iron are rigidly mounted on the shaft, the magnetic field entering these pieces of iron radially tending to hold the shaft and moving coils in their initial position.

When current passes through the coils of the moving element, the lines of force parallel to the shaft produce a torque which tends to turn the shaft and cause the needle to travel across the scale. This action is opposed by the magnetic field at right angles to the shaft acting on the two pieces of soft iron. The instrument has no controlling springs and since both the deflecting and controlling force are due to the same electromagnet, the accuracy is not affected by changes in magnetic strength. These instruments are particularly suited to service where very strong external fields are present.

USE OF SHUNTS AND CURRENT TRANSFORMERS. — *See also articles on Shunts; Transformers, Instrument.*) The current which may be led into the moving element of an ammeter (moving-coil or electrodynamic type) is limited by the current-carrying capacity of the springs or special leading-in wires, which must necessarily be light; this current seldom exceeds 5 or 10 amperes. To increase the range of such instruments, and also to avoid the use of heavy conductors in the instruments, shunts or current transformers (the latter for alternating currents only) are used. Ammeters for use with current transformers are usually designed to take a maximum current of 5 amperes, but

their scales are calibrated to read directly the current in the primary of the transformer.

Millivoltmeter Used as Ammeter. — Direct-current ammeters designed for use with shunts are usually designed to carry but a very small current (about 0.025 ampere). A wire resistor having practically zero temperature coefficient is permanently connected, within the case of the instrument, in series with the moving coil. The combined resistance of the moving coil and resistor is thus made large compared with the resistance of the shunt, and the error, due to resistance variation, is not large for ordinary changes in temperature. The ammeter proper is then essentially a millivoltmeter (*see Voltmeters*) and measures the drop of potential through the shunt to which it is connected; the scale of the ammeter, however, is often calibrated to read directly in amperes for one or more standard shunts designed for use with it.

Voltage Drop Across Shunts. — Shunts for use with switchboard direct-current ammeters of the permanent-magnet moving-coil type are usually designed for a drop of 50 or 60 millivolts at full load, although for some special requirements, where the indicating instrument must be located at a considerable distance from the shunt, double-drop shunts having 120 millivolts are used, and even higher drops are used to meet very special requirements. For precision use with portable instruments the resistance coil is so designed that a drop of 100 or 200 millivolts is required for full-scale reading, the high resistance with zero temperature coefficient practically eliminating temperature errors.

Use of Portion of Bus Bar as Shunt. — Sometimes the shunt is dispensed with altogether and the millivoltmeter is connected directly to a portion of the bus bar or main conductor. This arrangement is usually not desirable, because the variation of temperature in the bus bar due to the current flowing through it causes larger errors than the variation due to changes in room temperatures. Some arrangements have been made to compensate for these, but are not very generally used.

Voltmeter and Shunt for Measuring Alternating Currents. — An a-c. voltmeter with shunt is not in general suitable for measuring an alternating current, since such instruments are not readily constructed to read low voltages and therefore a relatively large drop in the shunt would be required, also the division of current between the shunt and voltmeter depends (1) upon the inductances of the shunt and instrument, (2) upon the "skin effect" (q. v.) in the shunt. However, hot-wire voltmeters with shunts are sometimes used for alternating-current measurements and are satisfactory at commercial frequencies.

PRECAUTIONS IN USE OF PORTABLE AMMETERS. — The following precautions, which in the main also apply to other portable electrical instruments, should be observed:

An ammeter should always be connected in series with the load. Never connect it across the mains.

All contact surfaces of nuts, terminals, etc., must be clean.

Transformers and wires carrying heavy currents should be kept at a safe distance from all instruments.

Portable instruments should be always used in a horizontal position, unless specifically designed for use otherwise.

Tapping an instrument while it is being read is usually unnecessary if it is properly constructed and in good order, but when slight friction is present from any cause its effect can be eliminated by gently tapping the instrument. Hard tapping defeats its object.

Digitized by Google

It is a good plan in testing to place a low-resistance jumper or short-circuit ock * or switch around the terminals of the ammeter and to connect a rheostat series with it and the load. The plug of the short-circuit block should be adually withdrawn, or the switch gradually opened, and the needle of the mmeter watched to be sure that the current is in the right direction and does ot exceed the rated current of the instrument.

A heavy short-circuit in nearby conductors, even though of extremely short uration, is liable to demagnetize the magnet of a permanent-magnet instrument. After such a short-circuit the instrument should be recalibrated, even ough the short-circuit causes no mechanical injury.

When it is desired to measure the average value of a pulsating current (e.g., om a rectifier), permanent-magnet moving-coil instruments should be used. he average value is to be used when the current is used for an electrochemical peration, such as plating, or charging storage batteries. Power measurements a rectified-current circuits should in general be made with an electrodynamic attmeter.

The power of a rectified current in a noninductive circuit, such as incandescent amps or electric heating apparatus, may be correctly determined by multiplying the effective current by the effective voltage, both being measured by electrodynamic or hot-wire ammeter and voltmeter. For a discussion of this subject see article by Todd, Elec. Rev. (Chicago) Vol. 77, p. 683, 1920.

Instruments containing iron should not be used for a frequency differing largely from that for which they are designed. For high-frequency measurements (above 500 cycles per second), some type of hot-wire or thermocouple instrument should be used. Instruments containing iron are also subject to errors due to distorted current waves; for precise work on badly distorted waves they should be compared with an electrodynamic or hot-wire instrument, using the same kind of current in the comparison as that to be measured.

CHECKING OF AMMETERS. — The readings of two or more ammeters may be compared by connecting them in series with a rheostat (q.v.) and suitable source of e.m.f. An ammeter may thus be compared with a standard ammeter, and a curve drawn showing the true amperes corresponding to the dial readings. It is usually more convenient to plot the correction to be made to the reading against the actual reading. Corrections to be added to the readings are usually designated as + and corrections to be subtracted from the readings as −.

Instead of using a standard ammeter, a standard millivoltmeter and a standard resistor (*see Resistors, Standard*) may be employed for direct current. The standard resistor is connected in series with the ammeter to be checked and the millivoltmeter is connected across the potential terminals of the resistor. Let V be the reading of the millivoltmeter in volts, R the resistance of the resistor and r the resistance of the millivoltmeter; then the current measured is

$$I = V/R + V/r.$$

The last term V/r is usually negligible.

An accurate and convenient way of checking an ammeter on direct current is to use a potentiometer (q.v.), when such an instrument is available.

Checking of A.-C. Ammeters. — Alternating-current indicating instruments, whose deflections are independent of frequency and wave form, when calibrated on direct current indicate correctly effective values when used on

* For small currents, two blocks of metal mounted on an insulating base with a tapered slot between the two, into which fits a tapered metal plug, make a convenient short circuit block; for heavy currents a switch should be used.

alternating current. Electrodynamic instruments usually give readings of equal accuracy on alternating or direct current at commercial frequencies and wave forms. Eddy currents in the metal supports and conductors, however, may cause slight errors in some makes, even at commercial frequencies, and for high frequencies errors are liable to occur in all types unless special precautions are taken to avoid eddy currents. Moving-iron and induction-type ammeters should be compared with an electrodynamic ammeter which has been previously calibrated on direct current.

ACCURACY OF AMMETERS AND OTHER ELECTRICAL INSTRUMENTS. — Various methods of expressing the accuracy of electrical instruments have been used. A customary and reasonably satisfactory method is to state that the instrument is correct to within a given percentage of the full scale value. This is understood to apply throughout the scale, and in uniform-scale instruments amounts to saying that no division mark is out of its proper position by more than a certain linear distance.

It is difficult to make general statements of the accuracy of electrical instruments, because this depends on many things, such as operating principle, workmanship, range, and conditions of use. It may be said that 0.1 to 0.2 per cent is about the limit of accuracy attainable in d.-c. instruments, and to get it requires high-grade instruments carefully used in connection with calibration curves obtained by regular and sufficiently frequent comparisons with standards of higher class, such as potentiometers. The accuracy attainable in a.-c. instruments is in general less than in d.-c. instruments.

Portable instruments of high grade are obtainable having a stated accuracy of 0.25 per cent of full scale value; intermediate grade instruments, 0.5 per cent; small portable instruments, 1 per cent. Switchboard instruments of the best grade are usually stated to be accurate to within 1 per cent of full scale value.

The accuracy obtainable in service depends not only on the inherent accuracy of the instrument, but also to a very great extent on the conditions of use. This subject is discussed in detail in a paper on "The Accuracy of Commercial Electrical Measurements" by H. B. Brooks, Trans. A.I.E.E., Vol. 39, 1920.

INSTALLATION OF SWITCHBOARD INSTRUMENTS. — The same general considerations apply to all switchboard instruments, i.e., ammeters, voltmeters, wattmeters, etc. Instruments previous to installation should be kept in a dry, cool place. Switchboard instruments should not be put in place until all the work on the boards or in the vicinity of their location has been done, so that they may not be damaged by violent shocks.

During shipment moving parts, etc., are sometimes blocked and instructions furnished with instruments by makers should be carefully followed in unpacking and assembling.

It is not customary to ground the cases of d-c. instruments or of a-c. instruments above 650 volts; these latter are usually protected by insulated covers. The cases of instruments on secondary circuits below 650 volts are usually grounded.

Determination of Capacity of Instruments. — In providing instrument equipment for switchboard service the relation between ammeters, voltmeters, wattmeters and the circuit conditions should be carefully considered so that proper sizes may be provided. The size should be so chosen that a good indication can be obtained under all ordinary load conditions, and at the same time the highest loads can be accurately indicated.

REPAIRS OF INSTRUMENTS. — Most portable and switchboard instruments in use at the present time are constructed with the idea of having

their parts readily accessible for repair. Instruments, however, are usually very delicate in comparison with other apparatus, particularly with reference to the pivots and jewel bearings. Any extended repairs should, therefore, not be attempted unless equipment and experience suitable for the work in hand are available.

COST OF AMMETERS AND VOLTMETERS. — The following figures are approximate only, and should be used only as a rough guide. Shunts and instrument transformers are not included; see articles on *Shunts* and *Transformers, Instrument*.

COST OF AMMETERS AND VOLTMETERS (1920–21)

Type of instrument	Switchboard instruments	Portable instruments
Permanent-magnet moving-coil type:		
Small instruments	$6–$10	$12–$17
Medium-size instruments	$13–$24	.....
Regular-size instruments, high-grade	$23–$34	$43–$100
Polarized-vane type	$2–$4	.....
Moving-iron type:		
Unshielded, portable, single-range	.....	$25–$48
Shielded, portable, two-range	.....	$54–$100
Round pattern	$20–$29	.....
Horizontal edgewise pattern	$36–$51	.....
Electrodynamic type:		
Medium-size instruments	.....	$33–$42
Regular-size instruments, high-grade	.....	$60–$104
Induction type:		
High-grade	$24–$40	$54–$65
Low-grade	.....	$32
Thermocouple type:		
Small instruments	$16–$19	.....
Regular size instruments	$53–$76	.....

AMPERE-HOUR METERS. — (*See also Ammeters; Wattmeters.*) Ampere-hour or quantity (coulomb) meters may be divided into practically two classes, i.e., electrolytic meters and electromagnetic or motor meters. They are used in this country chiefly for storage-battery work; small capacity ampere-hour meters are also used, particularly abroad, as watthour meters, being calibrated in this case to read directly in kilowatt-hours at some definite voltage.

ELECTROLYTIC METERS. — This type of meter is used extensively in Europe, but is rarely used in this country. The meter generally consists of some form of glass container or "U" tube containing an electrolyte, such as water, or an aqueous solution of a salt of mercury, or of caustic soda. The action of the current passing through the solution decomposes it and since the rate of decomposition is proportional to the strength of the current, the deposit of metal or the number of cubic centimeters of gas evolved can be calibrated to measure the quantity of current. (*See Electrochemistry, Principles of.*) Such meters can also be used as watthour meters (q.v.) in which case they are usually calibrated to read directly in kilowatt-hours at some assumed voltage. In some types the entire current to be measured is passed through the electrolyte and in others the main current passes through a shunt and only a very small part of the current passes through the electrolyte. In a satisfactory design of electrolytic meter the drop at full load does not exceed 1½ to 2 per cent on a 200-volt circuit, and the meter is accurate to within 2 per cent or better (depending on the design) at all loads between 10 per cent and 150 per cent load.

MOTOR METERS. — The essential parts of the motor ampere-hour meter are the motor element, the brake or speed-regulating device and the register or gear train which records the integrated current passed through the meter. The motor consists of an armature rotating in a magnetic field produced either by a permanent magnet or by an electromagnet. The meters are generally arranged so that only a shunted portion of the current flows through the armature and when electromagnet fields are used they are connected *in series* with the armature. The construction of these motors is otherwise similar to that of a watthour meter (q.v.). The commutator and other electromagnetic types of motor meters are all designed with the idea of producing a device which will be cheaper and if possible more rugged than the ordinary watthour meter. The absence of a constantly excited potential circuit in the meter also avoids the constant loss of energy which takes place in such a circuit irrespective of the load. In the motor meter the drop across the shunt varies in meters of different manufacture from about 50 to 100 millivolts in the mercury meter, and from 0.8 to 1.5 volts in the commutator meter.

Commutator Ampere-hour Meter. — The commutator type of meter in its simplest form usually consists of one or two permanent magnets which provide a driving field within which rotates an armature with three coils and a three-part commutator. In some designs the armature coils are mounted flat on an aluminum disk which in addition to supporting the armature coils produces the retarding or braking action in connection with the field magnet. In another design there is a stationary iron core between the poles of the field magnet and a drum armature rotating in the gap between the stationary iron core and the pole faces of the field magnet. No braking device is used in this latter type, and the motor runs at a speed proportional to the impressed e.m.f., taking only sufficient power to overcome the friction in the bearings and in the gear train.

To compensate for friction at light loads a slight auxiliary potential difference is sometimes maintained across the brushes by placing the armature in series with a high resistance across the line. This arrangement is adjusted so that the meter will not run with no current through the main shunt, but at light load the

extra potential difference at the brushes will be sufficient to provide a torque which will compensate for the frictional torque of the moving parts. In a recent type of A.E.G. ampere-hour meter the light-load compensation is effected by movable brushes automatically controlled (*Elekt. Zeits. 40 p. 213, May 8, 1919*).

Oscillating Motor Ampere-hour Meter. — A special form of the electromagnetic motor meter differing from all other designs is the oscillating meter. In principle, this meter is a clock which is controlled by the current. The hair spring of the clock is replaced by a disk carrying a few small iron wires. This special balance wheel is supported between two coils which carry the current to be measured or a shunted portion of it. The magnetic field from the coils magnetizes the iron wires and in conjunction with the main spring of the clock causes the special balance wheel to oscillate at a rate proportional to the strength of the magnetic field and therefore proportional to the current passing through the meter. The movement of the clock is transferred to a registering mechanism geared to register ampere-hours, or kilowatt-hours at a constant voltage.

Mercury Ampere-hour Meter. — The motor meter of the mercury type utilizes mercury to carry current to the armature, the mercury really taking the place of the brushes and commutator of the ordinary direct-current motor. One form of the meter consists in principle of a copper disk or copper thimble armature mounted in jeweled bearings and immersed in the mercury. The current is led into the mercury chamber through suitable terminals and since mercury has about fifty-five times the resistance of copper, the greater part of this current goes through the copper (approximately diametrically across the disk) and out the other terminal by way of the mercury. This arrangement applies to meters with permanent-magnet fields. In case electromagnet fields are used, the driving torque is approximately proportional to the square of the current, hence a braking system must be used to produce a retarding force varying with the square of the speed, such as air or fluid friction. When this is done the rate of revolution of the armature when running at a constant speed is proportional to the current passed through the meter. When permanent-magnet fields are used, a device is sometimes used to compensate for the increase of fluid friction with increase of speed; this device takes some such form as an auxiliary coil, in series with the motor element, which produces a flux which augments the flux cutting the driving disk.

The mercury motor meters utilize iron or in some cases moulded compound for the mercury well, and in the design care must be taken to provide non-spillable joints at the point where the spindle of the armature enters the mercury chamber. All metal in the meters should be of such composition as not to be readily affected by mercury even though not in direct contact with it.

SPECIAL FEATURES. — Ampere-hour meters used for showing the state of charge of storage batteries are sometimes provided with special features. For example, a "compensation for overcharge" causes the meter to run more slowly on a given value of charging current than on the same value of current during discharge. The percentage difference in the two cases is chosen to provide for the excess that must be put into the battery because it is not 100 per cent efficient. This is accomplished by a "variable resistor element" in parallel with the main mercury chamber. A pivoted copper bar in this element is immersed in mercury, and is cut by some of the flux from the driving magnets. It will thus change its position with the reversal of current direction, and will vary the resistance of the element. The "compensation for light-load accuracy and internal battery losses" consists of a thermocouple heated by a potential winding and delivering a small current continually to the motor element in the direction corresponding to battery discharge. This action may be adjusted to cause the meter to record the loss of charge when the battery is not in use. The "thermal

shunt method" of compensation for high discharge rates consists in making the shunt to the motor element of iron or other material of high temperature coefficient, and so designing it that it will heat up at the heavier loads. This causes the ampere-hour meter to have a higher percentage registration as the load increases.

Ampere-hour meters are sometimes provided with contacts which actuate auxiliary devices, such as circuit breakers, bells, or other signaling devices. This feature is used in connection with battery charging and electro-plating.

CALIBRATION OF AMPERE-HOUR METERS.— Ampere-hour meters are adjusted and calibrated as follows:

Electrolytic Meters.— As noted above, in the modern types of electrolytic meters mercury is deposited in a glass tube or water is decomposed, the gases passing off into the atmosphere. In the first type a marked scale is placed beside the registering tube into which the electrolyzed mercury falls. This mercury is run back into the mercury reservoir after the reading is taken, by tipping up the cell which is hinged at the top and held vertical by a removable clip at the bottom. To calibrate the instrument an ordinary ammeter may be placed in series with it and the time that the current passes noted on a watch. In testing the types in which gases are evolved and pass off into the atmosphere, it is only necessary to obtain the number of cubic centimeters of liquid per division of the scale, which can be done with a graduated burette. Only the water is decomposed by the passage of the current. To renew the electrolyte after the reading is taken at the end of a period, it is only necessary to add water.

Motor Meters.— In testing ampere-hour meters several adjustments are necessary, since a shunt, a series adjusting resistance and the gear train are involved. In addition, care must be taken to see that there is no excessive friction in any of the moving parts. The general method is to pass a measured constant current through the meter and to determine the time with a stop watch for a certain number of revolutions. Knowing the shunt constant (ratio of total to shunt current) and the register or gear-train ratio the correct speed at a certain current can be calculated and the shunt or adjusting resistance in series with the motor element adjusted to give the correct speed. To determine the accuracy for any set of readings the following formula can be used.

$$\frac{\text{(No. of rev.)} \times \text{(meter constant)}}{\text{No. of seconds}} = \text{current.}$$

The "meter constant" is marked on each meter; it is the number of ampere-seconds per revolution of the disk

WEIGHTS AND COSTS.— Mercury ampere-hour meters of American manufacture are made in different sizes for different types of services. Exclusive of shunts, the larger meter weighs about 16 lb. and the smaller meter 8 to 10 lb. In small capacities with self-contained shunt, the larger meter sells for $30 to $40, and the smaller meter for $12 to $20. External shunts are furnished with the larger meter above 100 amperes, and above 40 amperes with the smaller meter. These shunts range in price from $25 to $30 for 300 amperes and from $65 to $75 for 3000 or 4000 amperes. These prices are only approximate, and should be used only as a rough guide.

ANGLES. — (*See also Trigonometric Functions; Trigonometry.*) Plane angles may be expressed in degrees or in radians. The degree is arbitrarily taken as $\frac{1}{360}$th of the plane angle about a point; the radian is defined as the angle subtended by an arc of unit length in the circumference of a circle having unit radius. The angle in radians subtended by any arc of any circle is

$$\text{Angle in radians} = \frac{\text{arc}}{\text{radius}}.$$

The relation between radians and degrees is

1 radian = 57.30 degrees.
1 degree = 0.01745 radians.

Angle of Curvature. — In railroad practice the angle of curvature is the angle subtended by a chord 100 feet in length, the curve being the arc of a true circle. The relation between degree of curvature D and radius of curvature R is

$$R = \frac{50}{\sin \frac{D}{2}} \text{ feet.}$$

For D small, the chord is very approximately equal to the arc, consequently under these conditions

$$R = \frac{5730}{D} \text{ feet,}$$

where D is in degrees. The error involved in this approximate formula is less than 2 parts in 1000 for D less than 10°, and to less than 1 per cent for D less than 30°. (*See also Railways, Location and Permanent Way for.*)

Solid Angles. — The solid angle at any point P subtended by any surface S is equal to the portion of the surface of a sphere of unit radius which is cut out by a cone having its apex at the point P and its base coinciding with the perimeter of S. The total solid angle about a point is then equal to 4π. The unit of solid angle as thus defined is called a steradian. A solid angle of 2π steradians is called a hemisphere and a solid angle of $\frac{\pi}{2}$ steradians is called a spherical right angle. See table in *Units and Conversion Factors.*

ARC, ELECTRIC. — (*See also Distribution Systems; Furnaces, Electric; Illumination, Interior and Street; Lamps, Arc; Rectifiers.*) An electric arc is an incandescent vapor bridge consisting of material electrically impelled from a negative to a positive electrode. A spark is also an incandescent vapor bridge, but it differs from an arc, in not depending upon the electrodes for its material medium. The establishment of an arc requires the expenditure of energy for the latent heat of evaporation of the electrode and for the motion of the vapor stream. As no energy can be expended for these purposes until the current flows, an arc cannot start spontaneously. The following expedients are, therefore, adopted to start arcs.

(1) Bringing the conductors into contact with each other and separating them after the current has commenced to flow.

(2) Stressing the dielectric between the conductors until it breaks down electrically and becomes conducting.

(3) Using a subsidiary arc to furnish the initial vapor bridge. The first of these methods is used in carbon-arc lamps and the last in the mercury-arc rectifier.

CARBON ARC. — Until recently the only arc used for illumination was the arc between carbon electrodes, though at the present time there are several materials used, such as magnetite, mercury and the mixtures of various substances with carbon.

Crater. — The vapor column of the carbon arc, impinging on the positive electrode, raises the end of the latter to a very high temperature and volatilizes the carbon. The effect of this is to cause a hollow to be burned in the tip of the positive electrode. This hollow is called the crater.

Temperature. — The maximum temperature of the arc cannot be measured by direct means and the various estimates, which have been made, range from 3200° C. to 6000° C., absl. Using Wien's law connecting temperature and wave length corresponding to maximum radiated energy, Lummer and Pringsheim found that this wave length was 0.7 μ and the corresponding temperature somewhere between 3750° C. and 4200° C., absl., the latter figure being the crater temperature at atmospheric pressure. By raising the pressure to 22 atmospheres, a temperature of 6000° C., absl. may be attained. (*W. Mathiesen, Arcs under Pressure, Elekt. Zeits. 37, pp. 549 and 567, Oct., 1916; 38, p. 573, Dec., 1917.*)

Sources of Luminosity. — The light of the arc is derived either from the vapor column or from a body heated to incandescence by the vapor column.

In the old carbon electrode arc no special effort was made to utilize the luminosity of the vapor column, the incandescent spot or crater on the positive carbon being relied upon for practically the entire light. For this reason the positive carbon was always placed above the negative in order that the crater might better shed its light downward.

The flame arc, on the other hand, owes the greater part of its luminosity to the vapor column and very little or none to the heat of the positive electrode.

Hissing. — When the crater is surrounded by the hot gases constituting the arc, the arc is silent, but if the crater extends over the tip of the carbon and comes into contact with cool air, a peculiar hissing sound is evolved.

Characteristic of Arcs between Carbon Electrodes. — A peculiarity of the solid carbon arc is that, with any particular length of arc, if the current be increased, the difference of potential across the carbons will decrease. This occurs continuously until a certain point, when in the open arc the voltage

Digitized by Google

drops quite suddenly. If the current is still increased the voltage will again become steady at a much lower value. Between the values before and after the drop, the arc is unstable and hisses. The beginning of the hissing period is indicated by the dotted line in Fig. 1, and the hissing continues throughout the lower part of the curve.

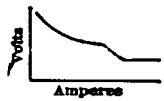

Fig. 1

The hissing point being absent in inclosed arcs, the curve for such arcs is quite continuous.

Steadying Resistance. — In order to maintain a steady current in an electric circuit it is necessary that any decrease in the voltage across the terminals of the circuit shall produce a decrease in the current. Hence, as the arc characteristic shows an increase of current with decreasing voltage there must be placed in circuit with the arc a resistance great enough to compensate for this tendency, if the arc is to be kept in a stable condition. The method of calculating the resistance required to maintain a stable arc for a given current is as follows:

Let e = generator terminal volts = OE,
v = arc terminal volts,
x = resistance in circuit, exclusive of arc and generator resistance,
i = current in amperes,

then, since $e = v + ix$,

the resistance x must be such that

$$x = \frac{e - v}{i}.$$

On the arc characteristic (Fig. 2) find the point P corresponding to the current i and set off $OE = e$ along the vertical axis. Then join EP and continue EP until it cuts the horizontal axis at X. The resistance x is then equal to tan $\angle$ EXO. If EX cuts the curve not only at P, but at S above P, it would appear that the e.m.f. e could support either of two arcs. The point S, although affording a mathematical solution, is not physically possible, as it would involve an increase of voltage, producing a decrease of current, as may be seen by moving EX upward, parallel to its original position. Hence the arc corresponding to P is the only one possible. If EX cuts the curve not only at P, but at some point below P, say T, the same reasoning shows the arc at P to be unstable, while that at T is stable.

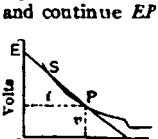

Fig. 2

For any point P, therefore, the arc is stable only if the line EX does not cut the curve below P. Hence, to find the proper value of the resistance x, for a given current i, draw a line tangent to the arc characteristic curve at the point having the abscissa i, then x must be equal to or greater than the tangent of the angle made by this line with the axis of abscissas.

Generator Voltage and Hissing Current. —

Let E = generator voltage,
V = potential difference between carbons just before current is increased to hissing point,
I = maximum amperes which will not produce hissing,
D = drop in volts from silent to hissing,
i = rise of current from silent to hissing,

then $E = V + \frac{I}{i} D$ or $i = \frac{D}{E - V} I$.

Digitized by Google

Thus, if the generator voltage is great compared to the arc voltage, and therefore the steadying resistance great, the rise of current at hissing will be less than when the voltage is small.

Resistance of the Arc. — The relation between the drop of potential across the arc and the current flowing through it depends upon whether the arc is in the steady state corresponding to the current flowing or whether the current has been changed without giving time to the vapor column and electrodes to accommodate themselves to the new strength of current. Let V be the drop of potential across a direct-current arc and A the current flowing. If the current be increased by a small amount dA for so short a time that it produces no effect upon the arc itself, it will be accompanied by a rise in potential difference dV, and the ratio $\frac{dV}{dA}$ will be the resistance of the arc. This may be accomplished experimentally by superimposing upon the direct-current arc a small rapidly-alternating current and measuring the value of the alternating p.d. and current. Unless a very high frequency (about 100,000 cycles) is used, the ratio $\frac{dV}{dA}$ will be negative, due to the fact that the power factor of the arc is not unity for low frequencies and this ratio, therefore, does not represent the resistance (*see Duddell's papers in Bibliography*).

Back Electromotive Force of the Arc. — The product of the direct current of an arc and its resistance, measured as described above, is the ohmic drop in the arc. This is usually less than the actual p.d. by 7 to 15 volts, which represent a back electromotive force. This back electromotive force really consists of two, the larger near the positive electrode, opposing the flow of current, and the smaller near the negative, helping the flow. By varying the direct current carried by the arc, the back e.m.f. is not noticeably affected, but the resistance tends to become infinite for very small currents, and small for large currents. A variation in the length of the arc between solid carbons produces no effect upon the back e.m.f., whereas with cored carbons the back e.m.f. decreases with increase of length. The value of the back e.m.f. depends upon the make of carbons employed. In his experiments which established the existence of a true back e.m.f. in the arc, Duddell used an alternating current of about 1 per cent of the strength of the direct current and having a frequency of 100,000 $\sim$ per second.

ARC AS TELEPHONE RECEIVER. — A direct-current arc may be used as a telephone receiver which can be clearly heard in a quiet room at a distance of 10 or 12 feet. The arrangement of apparatus, which gives the best results, is shown in Fig. 3, which is Duddell's improvement of the H. Simon circuit. In Duddell's experiments AB was a solenoid about 30 cm. long, wound with about 1000 turns of No. 18 D.S.C. wire and having an iron core of about 15 mm. diameter. Six hundred turns of the solenoid were connected to the microphone M and battery B and four hundred to the arc and condenser C.

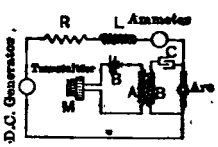

Fig. 3

The arc was between cored carbons of 11 to 13 mm. diameter separated 20 to 30 mm. and took 10 to 12 amperes. The condenser capacity was 2 or 3 microfarads. The resistance R was the usual ballast resistance and the choke coil L served the purpose of confining the telephonic currents to the arc circuit.

ARC AS A TELEPHONE TRANSMITTER. — The arc may be used as a telephone transmitter, but it is unsatisfactory on account of hisses and spits

due to the irregularities of the carbons and to the access of air to the crater. The arrangement of circuits is shown in Fig. 4, the apparatus R, L and C being the same as in the receiver circuit.

MUSICAL ARC. — A direct-current arc of suitable length and current between solid carbons will give a musical note, if it be shunted with a con-

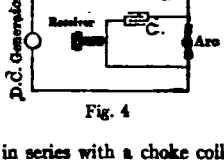

Fig. 4

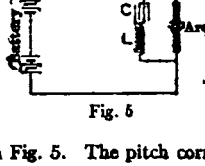

Fig. 5

denser in series with a choke coil, as shown in Fig. 5. The pitch corresponds to the periodic time

$$T = 2\pi\sqrt{LC},$$

where

C = capacity of condenser, farads,
L = inductance of choke coil, henrys.

The choke coil must not have an iron core, or the hysteresis and eddy currents will destroy the effect. A closed circuit, such as a ring of wire placed near the inductance coil, has the same effect. Further details of the musical arc are given below.

THE ARC AS A SOURCE OF HIGH-FREQUENCY CURRENT. — The musical arc owes its pitch to the action of the arc in transforming a part of the direct current into alternating current, the frequency of which can be varied between very wide limits by altering the self-inductance and capacity with which it is shunted. The inclosed arc works just as well as the open arc. In some of Duddell's experiments, the alternating current through the condenser circuit was as large as 5 amperes. Only condensers suitable for high voltages should be used, as, although the arc p.d. may be quite low, the condenser p.d. rises to several hundred volts. Alternating currents of frequencies of from 500 cycles to 500,000 cycles per second are easily obtainable.

Arcs between solid carbons always work well as converters, while those between cored carbons will not work under any conditions. In fact the general conditions under which the arc works as a converter are that $\frac{dV}{dI}$ must be negative and numerically greater than the resistance of the condenser circuit, exclusive of the condenser itself. The expression $\frac{dV}{dI}$ should be taken as referring to small instantaneous changes of the arc voltage and current.

Fig. 6 shows a means of operating several arcs together so as to obtain a greater output than would be possible with a single arc. Direct current is supplied to the arcs from the mains, through the choking coils L_1 and L_2, the ballast resistance R_1 and R_2 and ammeters A_1 and A_2. Alternating current is delivered by the arcs to the circuit containing the capacity C and inductance L. A form of arc used for generating high-frequency currents for use in radiotelephony is the Poulson arc, which is described in this article on *Telephony, Wireless*.

OTHER APPLICATIONS OF THE ELECTRIC ARC. — In addition to its application for welding and electrochemical manufactures (q.v.), the thermal effect of the arc is utilized for burning steel. An application of this was made by the contractors of the Pennsylvania Railroad (East River tunnel), who used a carbon rod one foot long and one inch diameter, bolted to a copper rod, provided with an asbestos shield, one foot in diameter. The operators worked with asbestos masks and aprons and dark-colored eye glasses.

Direct-current was used, the carbon electrode being connected to the positive and the steel to be cut to the negative feeders. The current was varied by means of water rheostats, the voltage at the tool varying between 45 and 60 volts. The current varied from 250 to 400 amperes per tool for burning off rivet heads and light section plates and from 600 to 800 amperes for burning plates 4 inches thick. The best results were obtained with 40 volts, 600 amperes and a ¼-inch to ⅝-inch arc. A fair day's work (8 hours) removed 300 rivet heads, although a record of 350 was reached. In the same time 4 feet 6 inches of 4-inch plate could be burned off. (*H. Jappe, Proc. A.S.C.E. 1909, Vol. 35, No. 9, p. 1230.*)

Portable plants, consisting of a gasoline engine-driven generator of about 25 kw. capacity, mounted on a truck, are now in use for wrecking buildings. Such an outfit is capable of burning off a 15-inch I-beam in 20 minutes, using the full-rated output of the generator. The arc has also been used for cutting scrap iron and steel in rolling mills (*G. Kearney, Gen. El. Rev., 20, p. 876, Nov. 1917*).

Experiments on rock removal for tunnel projects have been carried out by the Southern California Edison Co. of Los Angeles. Both direct-current and alternating-current (three-phase) arcs were tried. With direct-current, 500 amperes at 30 volts, 1 pound of rock per minute was removed at a cost of ¼ cent per pound, and with a three-phase arc, 450 amperes per phase with 40 volts between terminals 1 pound of rock per minute was removed at a cost of ¼ cent per pound (*Engineer, 128, p. 57, July 18, 1919*).

AUTOMOBILES, ELECTRIC. — (*See also Batteries, Storage, Alkaline Type and Lead Type; Batteries, Storage, Applications of; Trucks, Industrial Electric*). There are two types of electric automobiles, namely the battery car and the "gasoline-electric" car. The former type carries a storage battery from which energy is delivered to the driving motor; the latter type, in most instances, carries no battery but electric energy is supplied to the motor by a small generator which is itself driven by a gasoline engine. In other cases storage batteries are used in combination with a motor generator connected to the engine. Thus the machine may be driven by energy from either battery or engine. The battery car only is discussed in this article. A battery car is commonly referred to as "an electric," regardless of whether it belongs to the passenger or the commercial class.

HISTORICAL DEVELOPMENT. — The first battery-driven automobile in this country was built by Fred M. Kimball in Boston in 1888. This machine had 6 cells of lead storage battery and could travel 10 miles on good roads at an average speed of 5 m.p.h. In 1891 there was exhibited at the Mechanics' Fair in Boston an electric surrey built by the Holzer-Cabot Electric Co. Little more was done in the development of electric automobiles until about 1897 when the passenger vehicle was developed in two directions: one for pleasure took the forms of Victoria runabouts, dos-a'-dos and surreys, and the other for business purposes in the form of public taxicabs or vehicles for hire. The latter development expanded during the following four years to the use of fleets of 100 to 400 cabs and broughams in New York, Boston, Philadelphia, Washington, Buffalo and Chicago for public service on a hired basis; these disappeared from use about 1902 or shortly afterwards, largely for financial reasons, but also on account of the fact that large solid or pneumatic tires were not well developed at that date and storage batteries had not progressed beyond the heavy types used for stationary equipment in power stations.

From 1900 to 1903 the commercial type of electric truck began to be employed for merchandise delivery and progressed gradually but steadily until 1910, when the electric light companies recognized in it a desirable "off-peak" power consumer. The Electric Vehicle Association of America with considerable activity materially furthered the use of electric vehicles, both passenger and commercial, until 1914, when there were 37,000 in use; 25,000 passenger cars and 12,000 trucks (*El. World, Jan. 3, 1914*). The average price of the former at that date was $2200 and the latter $2800; this represented $88,000,000 invested by the public in this type of automobile. Following 1914 there was a rapid decline in the rate of production of electric vehicles due largely to general business conditions, but principally to the competitive influence of mass production in the gasoline vehicle industry; although the electric still maintains its superiority in economic operation. In 1920 there were but three manufacturers of each type aggressively conducting production in their respective fields with encouraging reaction, principally in a renewed demand for the commercial type. Another class of the electric vehicle, in the form of indoor industrial material and freight handling trucks, has been in progressive development since 1904; *see Trucks, Industrial Electric.*

APPLICATIONS OF ELECTRIC TRUCKS.— The three types of vehicles which are at present available for urban street haulage are the horse-drawn wagon, the gasoline motor car and the electric battery car. In comparing these three types for use in any given service, the chief factors to be considered are relative speed, distance between stops, length of stops required by the service, expense per vehicle and reliability (i.e., number of days per year upon which

the wagon can be depended for operation). The first three of these factors may be determined by trial or by observation.

In considering the matter of speed it should be remembered that with motor cars the wear and tear on the machine increases approximately as the square of the speed, so that the speed should be such as to give minimum cost of service. The last two of the above factors, namely expense and reliability, can be absolutely determined for any set of operating conditions only by several years of use of each type of vehicle. It is possible, however, to closely estimate the "expected" values of expense from the experience of others in similar kinds of work. See section below on *Costs*.

The electric truck has found its widest commercial application in city services where the hauls are of moderate length, say from two to ten miles, and where the daily service does not exceed 30 miles on the average, with occasional daily mileages of 40 to 50. For very short hauls where the standing time of the wagon is a large proportion of the working time, so that the work per day of each delivery unit is not largely influenced by the speed of the unit, the horse-drawn wagon can perform the work cheaper than any motor vehicle. For the so-called "long hauls" the gasoline truck would be expected to work to better advantage than an electric truck because of higher running speed or greater distance capacity in a day, or both. The rated values of speed and distance on a single battery charge of electric trucks are given in Table V below. The effect of hills or poor pavements would be equivalent to a decrease in the rated values of both speed and mileage. Systems of operating in which discharged batteries are exchanged for charged batteries during the day in order to increase the mileage capacity beyond the rated value have been used with signal success in a few instances, but in general the battery equipment is usually of sufficient capacity to perform the daily service required, or is in some cases supplemented by high-rate boosting charge during the noon hour or other convenient period.

DESIGN. — The necessity of producing cars which would travel at moderate speeds with a low rate of energy consumption has forced the designers of electric automobiles to use equipment which would meet this requirement, even though in some instances less efficient equipment would cost less or might wear longer than that used. Thus tires of low-energy consumption, batteries with large capacity per unit of weight and "anti-friction" bearings in transmission and axles are used almost universally. Consequently an electric automobile is essentially a high-grade machine, for any inefficient equipment directly influences the operating qualities.

Weight and Speed. — In the design of an electric battery car the two primary features are the total weight and the speed under normal conditions. In special cases a car may be built to meet unusual requirements of distance traveled per charge, in which case either the speed or weight must depart from the limitations of common practice. Any decrease in the total weight of the car will result in an increase in either speed or distance capacity or both; or if the weight is brought back to the original value by the use of additional battery capacity, the speed or distance may be still further increased. This has been one of the chief considerations leading to the adoption of lighter batteries, such as the Edison and "thin" paster lead plate, in place of the heavier type lead plate batteries commonly used where their additional weight is not a critical factor. General practice as regards weight and speed for various types of electric automobiles is indicated in Table I.

TABLE I.—SPEEDS AND WEIGHTS OF ELECTRIC AUTOMOBILES

Class of car or rated capacity of truck	Approximate weight in lb., including empty body	Approximate speed in miles per hour	Weight allowance for body, lb.
2-passenger runabout *	2,200	15 to 25	....
2-passenger Victoria *	2,400	15 to 21	....
2-passenger coupe *	2,600	15 to 20	....
4-passenger brougham	3,780	23 to 25	1010
5-passenger coach	3,860	22 to 24	1060
1,000-lb. truck	3,500	12 to 14	500
2,000-lb. truck	4,500	10 to 12	600
4,000-lb. truck	6,000	8 to 10	800
7,000-lb. truck	8,500	6.5 to 8	1100
10,000-lb. truck	9,500	6 to 7	1400
12,000-lb. truck	11,500	6 to 6.5	1600

* These vehicles are not now (1920) manufactured, but many of them are in use.

Similar data for a representative line of electric trucks are given in Table V below.

Load Efficiency. — By load efficiency of a motor truck is meant the ratio of the load on the machine to the gross weight of the machine, including chassis, body and load. Thus, from the above table, a representative value for the rated load efficiency of a 5-ton capacity electric truck is $\frac{10,000}{10,000+9500} = 0.51$. The rated load efficiencies for gasoline trucks of large capacity, 2 tons or more, are practically the same as the values for electric trucks, but small capacity gasoline cars of good design may have a rated load efficiency as high as 30 per cent as compared to about 24 per cent for electric cars with the customary lead battery equipments.

Motors. — Four-pole series motors are now used almost exclusively for electric automobiles. In the majority of cases but a single motor is used on each vehicle. The field coils are usually arranged in two groups which may be connected first in series and then in parallel. All manufacturers do not rate their motors on the same basis, but good practice is indicated by that of the General Electric Co., whose motors will carry their normal rated load continuously with a maximum temperature rise of 65° C. above the surrounding air at 25° C. or will carry 2½ times their rated load for 1 hour with a maximum temperature rise of 75° C. Ratings are based on bench tests, so that when the motor is installed in a car the overload capacity is usually increased due to the improved ventilation. Large overload capacity is necessary to meet severe street and grade conditions, and unusually good commutating characteristics are required.

An automobile motor must also operate satisfactorily over the varying range in the voltage furnished by the battery in the charged and discharged conditions. The motor speeds which are used with single reduction drives range from 750 to 1000 r.p.m.; the speeds which are used with double reduction drives range from 1000 to 2000 r.p.m.

Number of Motors. — All electric passenger cars and most electric trucks are now being equipped with a single motor. It was formerly common

Digitized by Google

practice to use two motors on the larger trucks on account of flexibility in control, but a single motor is now being used on account of space limitations, saving in weight and better electrical efficiency. The peculiar construction of the Couple-gear (*see below*) equipment requires a departure from this practice. Otherwise, either two or four motor equipment is used now only when unusually high tractive effort is required.

Motor Characteristics. — Along with the tendency during recent years to standardize battery equipments at 42 to 44 lead cells and 60 Edison cells, the tendency among motor manufacturers has been to develop a line of motor frames, for each of which two windings could be provided. Thus an 80- or 85-volt motor is usually installed with a 42- to 44-cell lead battery and a 60-volt motor with a 60-cell Edison battery. The windings are so proportioned that a motor has approximately the same speed and torque at both voltage ratings. This development has made it unnecessary to alter either the motor suspension or the mechanical transmission system in changing a car's battery equipment from lead to Edison or vice versa. 24-, 36- and 48-volt motors can also be obtained.

The characteristic curves for a typical Westinghouse motor with the 60-volt and 80-volt windings are given in Figs. 1A and 1B. The relatively small change in efficiency for overload with the field coils in parallel is noteworthy. The "torque ratio" of this motor, i.e., the ratio of torque at 2½ times rated current to torque at rated current, is approximately 5 with both windings.

Table II on page 57 gives a partial list of General Electric automobile motors with their normal ratings.

A.—60 volts, 33 amperes B.—80 volts, 25 amperes

Fig. 1. Characteristic Curves of Typical Automobile Motors

Before recommending motor equipment for automobile service the motor manufacturers usually require that the purchaser submit data upon the weight, speed, battery, wheel dimension, etc., for the car on which the motor is to be used.

Size of Motor Required. — In selecting the size of motor the voltage should be chosen on the basis of 1.9 volts per cell for lead batteries and 1.0 volt per cell for Edison batteries. The average discharge voltages of both types of batteries at their normal rates are higher than these values, but it has been found desirable to install motors on the basis of these values so that at high rates of discharge the terminal voltage may not fall too far below the rated motor voltage.

The current rating of the motor (and also of the battery) should be approximately the value of the current required to drive the car at the rated speed on hard level asphalt. The current input into a vehicle motor when driving a car at constant speed is given by the expression

$$I = \frac{2\,vWr}{E\epsilon},$$

where v = speed of car in miles per hour,
W = total weight of car and load in tons,
r = car resistance in pounds per ton of total car weight,
E = motor terminal voltage,
ϵ = over-all efficiency of motor, controller and transmission.

The value of ϵ at the rated speed is the product of the efficiencies of motor and transmission, usual values falling between 60 and 75 per cent. For value of r see next paragraph.

Car Resistance. — The car resistance depends upon the following conditions: speed, grade, diameter of wheels, load per square inch of tire contact

or per inch of tire width, construction and composition of tire, method of attaching tire to wheel rim, and road surface. The effect of speed is to change r in a manner dependent upon the type of tire, the value of r having a minimum usually at a speed between 6 and 10 m.p.h.; air resistance varies approximately as the square of the speed and need not be considered for speeds of less than 20 m.p.h. The effect of up-grades is to increase r by 20 lb. per ton for each per cent grade. The car resistance with pneumatic tires on hard, level asphalt is given by Churchward (*Soc. of Auto. Eng. Handbook, 1913*) as ranging from 15 lb. per ton for special tires designed for electric runabouts up to 35 lb. per ton for the standard type of tire used on gasoline touring cars; the resistance is greatly affected by the air pressure, increasing rapidly as the air pressure is reduced. Churchward also gives the car resistance with solid tires on hard level asphalt as ranging from 18 to 26 lb. per ton. Other tests have shown a car resistance of 30 lb. per ton for a small capacity electric truck equipped with solid tires (*El. W., May 17, 1913, Vol. 61, p. 1040*).

Effect of Road Surface. — Three sets of values of relative car resistance on various level road surfaces as compared to the value on hard, level asphalt are given in the following table. One set of values is given by Churchward in the *Soc. of Auto. Eng. Handbook* (1913) the set is based on tests conducted at the Massachusetts Institute of Technology in 1913 (*El. W., May 17, 1913, Vol. 61, p. 1040*), and the third set is the result of tests by Kennelly and Schurig, Proc. A.I.E.E., Vol. 35, 1916.

TABLE III.—RELATIVE VALUES OF CAR RESISTANCE

Road surface	Churchward	M.I.T.	Kennelly and Schurig
Asphalt, hard	1.0	1.0	1.0
Wood block	1.15	1.1	1.18
Macadam	1.15 to 3	1.15	1.2
Granite block	1.75	2.0	1.41
Dirt road	1.1 to 2.0	...	1.31
Brick	.....	1.4	1.25
Snow, packed	.....	1.3	....
Snow, fairly hard, without chains	.....	1.7	....
Snow, fairly hard, with chains	.....	1.9	....
Snow, soft, about 3 in. deep	.....	2.1	....
Sand	20	...	....

Transmission Systems. — The transmission systems between motor and wheel which are in common use may be grouped in two classes, known as the "chain" and the "shaft" or gear drives. A single-speed reduction is used in a few makes of cars, but a double reduction is used on a majority of machines. If the first reduction is made by chain and the second by gear, or vice versa, the transmission system is usually designated according to the means employed for the final reduction; e.g., if the final reduction is accomplished by a chain, the system is referred to as a chain drive although the first reduction may be by gears.

Chain Drive. — With chain drive the motor is mounted transversely and a double-speed reduction is used almost without exception. The connection between motor and countershaft is usually by silent chain (Morse or Rey-

nold type, see article on *Chains and Chain Drive*), although spur and herringbo gears are also used; see article on *Gears and Gearing*. The final drive is usua by roller chain, either (*a*) between countershaft and differential in the rear a or (*b*) between countershaft and a sprocket on each of the rear wheels. Cha driven passenger cars are usually equipped with (*a*) and chain-driven commerc cars with (*b*). The chain method of drive possesses the advantages of low i cost and ease of adjustment; its disadvantages are noise, rapid wear due collection of dirt unless properly housed, poor efficiency when not prope adjusted, and unequal wear on the two sides of the car. The chain drive h been losing favor during recent years among both designers and operators a is now (1921) practically abandoned.

Shaft or Gear Drive. — With shaft drive the motor is usually mounte lengthwise of the car, and either a single- or double-speed reduction is used. F single reduction both bevel and worm gears are used as the connection betwee propeller shaft and differential in the rear axle. For double reduction the moto is usually connected to the propeller shaft by spur gear, herringbone gear o silent chain, and the propeller shaft is connected to the differential by a bev gear. The propeller shaft is usually fitted with universal joints. The shaf drive has become standard in passenger cars because it runs quieter than chai drive, and because it can be easily protected from dirt by housing. The shaf drive has the disadvantage of greater weight below the springs than in the cas of the chain drive, which tends to increase the wear on tires.

Worm Drive. — There has recently been a decided tendency among designers of passenger cars and light trucks to use the single-reduction worm gear instead of the double-reduction bevel or chain arrangements, the advantages claimed for the worm being better transmission efficiency and less trouble from adjustment.

Walker Balanced Gear. — In the trucks built by the Walker Vehicle Co. the motor is built into the rear axle, which is made hollow and of a sufficient diameter to contain the motor. The armature shaft is also hollow, so that the drive shafts may extend through from the sockets of the differential to the center of each rear wheel. The wheels are driven by a spur-gear reduction mounted inside the wheels. The wheels have steel-plate sides instead of spokes, so that the gears may run in oil and are thoroughly protected from dirt.

Couple-Gear Wheel. — A device built by the Couple-Gear Freight Wheel Co. has the electric motor mounted inside the wheel. The motor armature carries a pinion on either end which engages with a gear ring on either side of the wheel. The sides of the wheels are dished steel plates. These wheels are being used on both front-wheel-drive and four-wheel drive machines. Being located in the wheels, they do not interfere with the use of the ordinary steering knuckle arrangement.

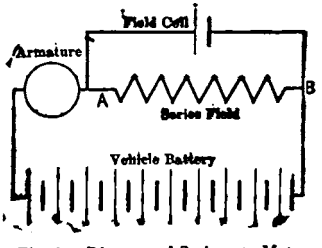

Fig. 2. Diagram of Steinmetz Motor System

Steinmetz System.—A new method of motor excitation consists of connecting a storage battery cell across the field terminals of a series motor employed in vehicle operation. At normal load the drop in voltage between field terminals counterbalances the voltage of battery cell. On starting and heavy grades the current required causes a greater drop in voltage between the field terminals, thus diverting a charging current through

r coil. Similarly if the motor current required in service decreases, the field l will discharge through the field winding. Thus, the field strength varies y within narrow limits and in such a system the coasting of the vehicle down ides and the braking or stopping of the vehicle may be employed to recharge e vehicle storage battery. With this system a motor is used in which both ld and armature rotate; each being connected separately to the two driving eels, no differential being required, and on account of the increased relative ed between field and armature a much lighter motor than the normal type, th stationary field and rotating armature, is required for any given service.

Efficiency of Transmission. — (*See also article on Gears and Gearing.*) aumont gives the following figures on the transmission efficiency of different pes of automobile mechanisms.

Source of loss of power	Efficiency, per cent
One chain, and one and one-half pairs of bearings	89.5
One set of gears, two pairs of bearings	82.0
One set of gears, equivalent of two chains, three pairs of bearings	74.0
Two sets of gears, four pairs of bearings	70.0

The following figures, given by F. Burgess (*Trans. Soc. Auto. Eng., 1912, ol. 7, Part 2, p. 196*), are the results of an efficiency test of a straight type rorm and worm gear for rear-axle drive of electric automobiles. The worm ear was made of phosphor bronze and had 39 teeth; the worm was made of ase-hardened steel and had 4 threads.

R.p.m. of worm	Temperature of worm gear, °F.	Input, trans. dyn., h.p.	Output, brake h.p.	Efficiency, per cent
1383	74	1.64	1.03	61.2
1416	86	3.41	3.17	93.2
1370	90	5.48	5.13	93.7
1389	94	6.72	6.24	93.0
1400	108	9.43	8.5	90.2

Batteries. — There are three types of batteries in general use in electric vehicles, namely, the pasted lead, the "Iron-clad" lead, and the Edison. The performance characteristic (except life) of the first two are identical and are described in the article on *Batteries, Storage, Lead Type;* the characteristics of the Edison battery are described in the article on *Batteries, Storage, Alkaline Type.* The desirable characteristics of a battery for vehicle service are given in the article on *Batteries, Storage, Applications of.*

Number of Cells; Number of Plates. — Practice among electric automobile manufacturers is now practically standardized upon the installation of 42 or 44 cells of lead battery and 60 cells of Edison battery in both passenger and commercial classes of cars, as these numbers permit of charging from a 115-volt circuit with minimum loss in the rheostat. There are, however, in use many old designs of pleasure cars in which from 24 to 38 lead cells are used, and the small capacity delivery wagons in which 48 Edison cells are also employed. A 24-volt to 48-volt battery is used on industrial trucks. For a given watt-hour capacity a battery of a small number of cells is cheaper to buy and

Digitized by Google

maintain than one of a large number of cells, but is more expensive to ch from constant-potential d-c. mains on account of rheostat losses.

As pointed out above the rated current output of a vehicle battery f hours should not be exceeded by the current required to drive the car at m speed on hard, level asphalt (*see section above on Size of Motor*). Thus w the current under these normal conditions is known, the number of plates cell can be determined from a knowledge of the discharge rates of the vari types of plates which are under consideration. For A-type Edison batte the normal (5-hr. rate) is 7.5 amp. per positive plate; conservative desig use this rate in applying batteries rather than the value of 9.5 amp. which co be obtained for 4 hours. The discharge rates per positive plate of 5¾ by 8½ for 4 hours and for the so-called "normal" times of discharge for the types vehicle batteries made by the Electric Storage Battery Co. are given in t accompanying table.

Type of plate	"Normal" discharge		Amperes per positive plate discharged during 6 hr.
	Time, hours	Amperes per positive plate	
Exide	4	7	5.12
Hycap	5	5.5	4.8
Thin	6	4.25	4.13
Iron-clad	4.5	7	5.6

It will be noted that the above rule of installing a battery whose 4-hour discharge rate is approximately equal to the current required for running at rated speed under good street conditions will furnish a minimum practicable battery capacity, and that this capacity may have to be increased materially in order that the car may meet the necessary mileage requirements when operating on grades or poor roads. There is a tendency among electric car manufacturers to recommend battery equipment for given conditions which is much more liberal than they recommended a few years ago.

Construction of Battery Box. — In passenger cars a tight wood-lined compartment is usually supplied for carrying the battery. In commercial cars the battery compartment is also wood lined, and provision is commonly made for ventilation to facilitate charging in warm weather. The details of a typical underslung battery box are shown in Fig. 3. With this construction strips may be laid in the spaces between the floor boards in order to make the compartment entirely inclosed, as is frequently desirable in cold weather. A tight covering should be provided with an underslung battery box to prevent dirt and water falling upon the battery from the floor of the car.

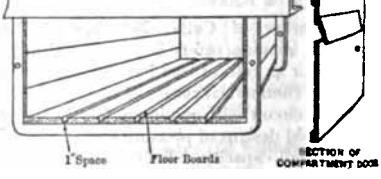

Fig. 3. Typical Underslung Battery Box

Controllers. — Controllers are usually of the drum type with two running positions, known as the "field-series" and the "field-parallel" positions. The motor field coils are arranged in two groups for connection either in series or in parallel.

Digitized by Google

cells of the battery are connected permanently in series. In starting, er 2 or 3 resistance notches are used before the "field-series" notch is :hed. A shunt on the fields is frequently used between the "field-series" the "field-parallel" notches. For normal full-speed running the two ups of field coils are in parallel. An emergency speed is obtained by nting a resistance around the fields when connected in parallel. It was nerly customary to split the battery into two groups which could be rated in series-parallel in order to obtain 4 economical running speeds, but uble was experienced from the unequal discharge of the two halves of the tery. In the magnetic type of control which is used to some extent in senger cars the changes in connection are affected by relays operated by auxiliary electric circuit. Some forms of regenerative control have been ed with only moderate success, although in hilly localities regenerative trol may be desirable on account of protecting the mechanical brakes.

Tires. — Tires for use on electric automobiles are generally more resilient an the standard types of tires commonly used on gasoline automobiles. "High iciency" or special electric tires, both solid and pneumatic, have been devel- ed by most of the tire manufacturers in response to a demand by the oper- ors of electric cars for tires with low consumption of energy. Standard types tires may consume as much as 100 per cent more energy than the special ectric tires. Experience has shown that the smooth starting characteristic f an electric motor produces much less abrasion than the uneven acceleration ith a gasoline motor, so that the rubber compounds in tires for electric cars are sually softer than the compounds in tires for gasoline cars and yet the lives of oth types in point of distances traveled are approximately the same. Electric neumatic tires are usually of the cord type; i.e., the "fabric" consists of arallel strands of cotton impregnated with rubber gum. Some types of solid ectric tires, such as the Motz, have the sides undercut at intervals to allow r the "flow" of the r[illegible]er when under compression.

Carrying Capacities of Tires. — In general a tire of small transverse read will consume less energy than a tire of the same compound with large read when operating on a smooth, hard surface; also, a large wheel diameter ives less energy consumption than a small one as well as improving the riding ualities on uneven surfaces. The Society of Automobile Engineers have recom- ended the use of 32-, 36- and 40-in. tires as standard practice. (*See Trans. oc. Auto. Eng., 1914.*) But in selecting tire equipment it should be remem- ered that there is a limit to the load which any size of tire will stand without ermanent injury by disintegration. The maximum carrying capacities per heel at present (1920) recommended by the B. F. Goodrich Co., are given n Table IV, as are also the recommended inflation pressures for pneumatic ires of the fabric type; the recommended inflation pressures for cord tires re approximately 80 per cent of the values in the table.

Examples of Commercial Car Design. — Table V gives data from the standard specifications of a number of the electric trucks.

PERFORMANCE; ENERGY CONSUMPTION. — The energy con- sumed by an electric automobile will depend very largely upon the care of the driver in coasting up to stops instead of braking directly from full speed; other important factors in determining the energy consumption are efficiencies of battery and driving mechanism, tire equipment, nature of roads and grades, number of stops and miles per day, etc. However, for a car which is operated under similar conditions day after day, the energy consumption per mile should be reasonably uniform, so that any considerable increase in energy consumption may indicate either careless driving or poorly adjusted mechanism, as for in- stance a dragging brake. Table VI gives a series of approximate values for

TABLE IV.—MAXIMUM CARRYING CAPACITY OF TIRES

Size of tire, inches	Maximum load, pounds per wheel				Recommended inflation pressure, lb. per sq. in.
	Solid		Pneumatic *		
	Single	Dual	Rear wheel	Front wheel	
2½	700	1400	....	....	..
3	1000	2000	375	450	45
3½	1300	2600	570	600	55
4	1700	3400	815	1200	65
5	2500	5000	1500	1700	85
6	3500	7000	....	....	..
7	4500	9000	....	....	..

* The allowable load per wheel for a given width of tire increases slightly with the wheel diameter. The sizes quoted in the table are 34 × 4½ in., 35 × 5 in., 36 × 6 in. and 38 × 7 in.

energy consumption per mile which are based upon a large number of reports upon the operation of electric cars in large cities; these reports were collected in connection with the Vehicle Research study conducted during 1912 to 1914 by the Electric Research Laboratory of the Massachusetts Institute of Technology. These figures are representative of experience with modern types of cars under average city conditions; the consumption for a given set of conditions may vary from the figures by as much as 20 per cent, either above or below.

TABLE VI. — ENERGY CONSUMPTION IN WATT-HOURS PER MILE, AT CHARGING BUS BARS

Type of car	Lead battery	Edison battery
2-passenger	300	400
1,000-pounds	550	750
2,000-pounds	650	900
4,000-pounds	830	1150

Garage Load Curves. — Fig. 4 shows a typical daily load curve for a public garage handling 75 electric passenger cars; Fig. 5 shows a similar typical daily curve for the private garage of a large department store (*see paper by E. E. Witherby, Proc. N. E. L. A., 1913*). The "off-peak" character of the electric vehicle load is indicated by these curves. In order to attract such off-peak load most light and power companies are now offering special rates for vehicle charging, frequently with the provision that no charging shall be done during the time of the power company's daily peak load.

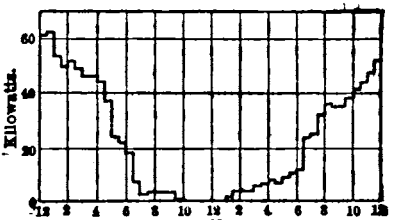

Fig. 4. Daily Load Curves of a Public Garage Handling Passenger Cars

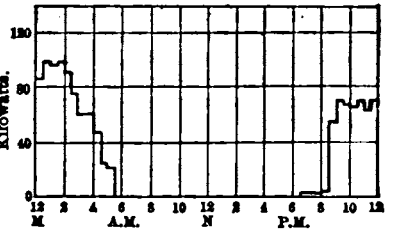

Fig. 5. Daily Load Curves of a Private Garage Handling Trucks

OPERATION.—In the operation of electric automobiles particular attention should be paid to the proper care of the storage batteries. The battery manufacturing companies issue complete instructions for the proper handling of their cells. The manufacturers of the battery, as well as the manufacturers of the car, are usually ready to confer with the operator of a car to the end that he may obtain satisfactory service from his machine. They should be consulted on the first indication of trouble in their respective portions of the equipment, should the cause of the trouble not be understood.

Digitized by Google

The following points upon the care and operation of electric cars should be observed:

1. A battery must always be charged with direct current and in the right direction.

2. Never bring an exposed flame near a battery while charging or immediately afterwards.

3. Do not allow the battery temperature to exceed 110° F.

4. Keep the cells filled to the proper level by adding distilled water only. Never put acid in an Edison battery under any circumstances.

5. Keep the outside of the cells free from foreign substances, both solid and liquid.

6. For boosting a lead battery during a specified short period, the maximum current rate I which may be used without reaching the gassing point is the quotient of the ampere-hours Q previously discharged (read from ampere-hour meter), divided by 1 plus the hours H available for boosting, viz., $I = \frac{Q}{1+H}$.

7. The mechanism of a car should be inspected carefully at least once in two weeks.

8. A car should be entirely overhauled at least once each year, in order that worn parts may be located and replaced.

COSTS. — The initial cost of passenger electrics depends so largely upon the character of body and fittings that it is impossible to quote any but the most general figures; prices range from $2800 to $5000, the most popular cars selling at from $4000 to $5000. It is likewise impossible to quote definite figures on the cost of operating pleasure cars; prices for electricity for private charging vary from about 3 cents per kw-hr. upward; the cost of storage in public garages ranges from $15 to $40 per month, plus a charge for electricity at from 4 cents per kw-hr. upward.

The initial cost of commercial electrics ranges from about 60 cents per pound for large trucks to 75 cents per pound for light cars, based upon usual equipment of solid tires, lead batteries and express or stake bodies. (*For typical weights see Tables I and V.*) Special equipment such as winches or dumping bodies is additional. The operating expense will vary widely for different conditions, so that it is impossible to predetermine the total cost of operating a truck of a given rating without knowing the requirements of the service, the nature of the roads, and the general method of handling and caring for the car. The data in the following table are deduced from estimates by Pender and Thomson given in *Vehicle Research Bulletin No. 3*, issued in 1913 by the Massachusetts Institute of Technology. The figures are based upon reports of the operation of a large number of cars during from 1 to 4 years in city trucking and delivery services.

AUTO-TRANSFORMERS AND COMPENSATORS. — (*See also Starters, Motor; Transformers.*) An auto-transformer or single-circuit transformer, also called a "compensator," consists of a transformer having the usual iron core but only one electrical circuit instead of two. This circuit is tapped at various points as shown in Fig. 1, and the primary and secondary circuits, while independent outside the transformer, unite in the same winding in the transformer. If an alternating voltage is impressed across the points *ab*, a magnetizing current will flow in the winding setting up an alternating flux which will link every turn and induce therein an alternating voltage. The voltage between any two taps, as *ac*, is proportional to the number of turns between the taps; thus any ratio of voltages may be obtained. If the secondary *ac* is loaded a current will flow in the primary and the primary and secondary currents will flow in the two parts of the winding as indicated in the figure.

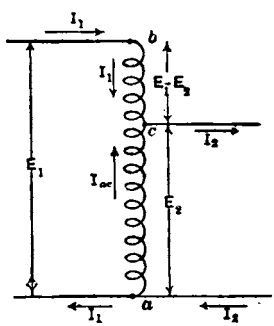

Fig. 1. Auto-transformer

VOLTAGE AND CURRENT RELATIONS. — Let N_1 be the total number of turns between *a* and *b*, N_2 the turns between *a* and *c*, E_1 the voltage across the terminals *a* and *b* and E_2 the voltage across the terminals *a* and *c*. Then, neglecting the resistance and reactance of the winding,

$$E_2 = \frac{N_2}{N_1} E_1.$$

Let I_1 be the current entering the terminal *b*, I_2 the current in the ***external*** circuit connecting *a* and *c*, and I_{ac} the current ***in the transformer winding*** between *a* and *c*. Then, neglecting the resistance and reactance of the winding and the magnetizing current,

$$I_2 = \frac{N_1}{N_2} I_1,$$

$$I_{ac} = I_2 - I_1 = \frac{N_1 - N_2}{N_2} I_1.$$

The current in the turns between *b* and *c* is

$$I_{bc} = I_1.$$

Auto-transformer Versus the Two-circuit Transformer.—For $N_2 = \frac{1}{2} N_1$ the current in the turns between *a* and *c* would be just equal, neglecting the exciting current, to the current in the turns from *b* to *c* (but opposite in direction). Consequently for a 2 to 1 transformation but one winding of an ordinary two-circuit transformer could be used, provided a tap was available at the middle point of this winding, and the rated output of the transformer could be obtained without the current in this winding exceeding its rated value. Since under these conditions there would be no current in the second winding, the heating of the transformer would be less than it would be were the transformer used as an ordinary two-circuit transformer, and therefore a greater output could be obtained without exceeding the nominal temperature rise.

In general, for the same power input into the connected load an auto-transformer requires but $\frac{E_1 - E_2}{E_1}$ of the copper required for a two-circuit transformer,

Digitized by Google

here E_1 is the high-tension and E_2 the low-tension voltage. The higher the atio of transformation the less the saving in copper. There is also a serious bjection to an auto-transformer of high ratio of transformation, in that an cidental ground on the high-tension lead, *b* in Fig. 1, would establish a high oltage between the low-tension leads and the ground, which may cause a angerous shock to a person touching either low-tension lead or may cause ther damage. This may be partially prevented by grounding the common oint of the high- and low-tension circuits, the point *a* in Fig. 1, in which case n accidental ground on the high-tension side would produce a short-circuit, hich would open the circuit breaker in the primary circuit, *provided the resistance between the two grounds is low and the circuit breaker operates properly.* hese two provisions, however, may not always be realized even though reasonble care is taken, and it is therefore not considered good practice to use an uto-transformer of high ratio of transformation, except in special cases where conomy of space is an important factor and danger from shock can be guarded gainst, e.g., on a-c. locomotives.

RATING OF AN AUTO-TRANSFORMER. — In commercial practice he rating of an auto-transformer in volt-amperes is taken equal to the differnce between the high- and low-tension voltages multiplied by the rated urrent in that part of the winding, *bc* in Fig. 1, across which this voltage exists. The capacity of an auto-transformer for a given work bears to the capacity of a two-circuit transformer for the same purpose the ratio $\frac{E_1 - E_2}{E_1}$. For example, to step down the voltage of the supply mains from 500 to 400 volts and supply a load of 100 kv-a. would require an auto-transformer having rating of $\frac{500 - 400}{500} \times 100 = 20$ kv-a. as against a two-circuit transformer aving a rating of 100 kv-a. The weight, dimensions and cost of an auto-ransformer are very nearly the same as for an ordinary two-circuit transformer aving the same voltage and kv-a. rating.

APPLICATIONS. — Auto-transformers are used chiefly where the required hange in voltage is small, e.g., for motor starters (*see Starters, Motor*), and for alancing the voltage between two or more circuits. The smaller the ratio of ransformation the greater is the gain in cost and efficiency resulting from the se of an auto-transformer instead of a two-circuit transformer. Auto-transormers are also used to provide a neutral for the Edison three-wire system; see *Distribution Circuits*. In single-phase railway work single-phase auto-transormers are used on the locomotives for transforming the trolley voltage (from 000 to 6000 volts) to the motor voltage (about 500). This is a rather high atio of transformation for an auto-transformer, but as the saving in weight is ery important and as one terminal is grounded, it has proven satisfactory for his service; see *Locomotives, Electric*.

Auto-transformers are frequently constructed three-phase (and occasionally wo-phase). These are generally used for starting polyphase motors by proiding a lower voltage for the starting period. They are also occasionally sed in high-tension distribution. If the voltage applied to an a-c. motor is educed to one-half, the motor starting current will be one-half and the voltmperes one-quarter. Thus the starting current in the line will be onequarter. A three-phase auto-transformer may be either Y or delta-connected. he Y connection is shown under *Motors, Polyphase Induction, Methods of tarting*. The delta connection cannot be made to give a balanced voltage ss than half that of the higher voltage, as may be readily seen from an inspecon of Fig. 2.

Digitized by Google

DESIGN. — The design of an auto-transformer is quite similar to that of a two-circuit transformer (q.v.) and the leakage reactance is calculated in the same way. For low-leakage reactance the primary and secondary coils must not be entirely separated, but each must be divided into sections and inter-

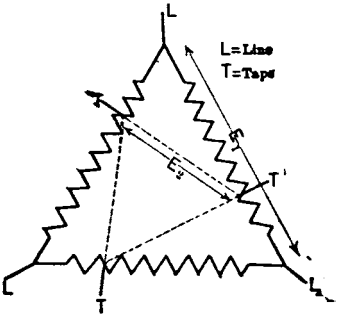

Fig. 2

mixed to as great an extent as possible. Having found the magnetizing current, core-loss, resistance and reactance in the usual manner, the calculations follow the same methods as for power transformers. In general, the efficiency at unity power factor is given by the equation

$$\text{Efficiency} = \frac{E_2 I_2}{E_2 I_2 + (r_1 - r_2) I_1^2 + r_2 (I_2 - I_1)^2 + \text{core-loss}},$$

where r_1 is the total resistance of the winding measured between the high-tension terminals and r_2 the resistance measured between the low-tension terminals. The efficiency is better than that of a two-circuit transformer of the same kv-a. rating.

TESTS, SPECIFICATIONS, ETC. — See *Transformers*.

DIMENSIONS, WEIGHT AND COSTS. — For the same kv-a. rating the dimensions, weight and cost are very nearly the same for auto-transformers as for ordinary two-circuit transformers; see *Transformers*.

ALANCES, CURRENT. — (*See also Ammeters; Electrodynamometers.*) he Kelvin balance consists of a system of two coils mounted one at each end a rigid beam and free to move between two pairs of field coils. The balance ay be used as an ammeter, voltmeter or wattmeter. It may be used for either c. or d-c. measurements, but for d-c. work it has been practically superseded r laboratory standard voltmeters. For a-c. work it is used only as a laborary standard for calibrating other instruments.

A current balance when carefully constructed may be used for the absolute easurement of electric current, since the force of attraction between the coils n be calculated in terms of their dimensions and the current flowing. It has en successfully used to determine in absolute measure the electrochemical nstant or Faraday (*see Electrochemistry, Principles of*).

Principle of Operation. — The principle of the current balance is similar that of the electrodynamometer. The connections for current measurements e shown in Fig. 1. The current passes through all the coils in series and as a sult of the action of the magnetic fields, the ft-hand end of the beam is depressed and the ght-hand end is elevated. The beam on which he middle coils are mounted has an index pointer nd carries a weight that may be slid along a cale on the beam. With no current on and the liding weight at zero on the scale, a counter eight on the swinging system is so adjusted that he index pointer on the system is opposite a fixed mark and the system is alanced.

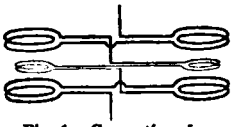

Fig. 1. Connections for Current Balances

Passing current through this system destroys the balance which is restored y sliding the weight along the beam. Since the torque exerted on the moving ystem is proportional to the square of the current, the current flowing will be roportional to the square root of the distance through which the weight has o be moved to balance the beam.

In the case of the wattmeter the current passes through the fixed coils, while he coils on the moving system serve as the potential coils. In this case the ower is directly proportional to the distance through which the weight has to e moved to balance the system.

Range and Cost. — Kelvin balances are built in 5 standard sizes. The seful range and approximate cost of each instrument is given below (**pre-war** rices).

Type	Range, amperes	Approx. cost
Centi-ampere	0.025–1	$150
Deci-ampere	0.25–10	150
Deca-ampere	5–100	150
Hekto-ampere	30–600	150
Kilo-ampere	100–2500	250

BATTERIES, PRIMARY. — (*See also Cells, Standard; Electrochemistry, Principles of.*) A primary battery or cell is a device for the *direct* transformation of chemical energy into electrical energy. It is becoming common practice, though not yet universal, to use the term "cell" for a single unit, and the term "battery" for a group of two or more units or cells.

For convenience of treatment primary batteries may be classified as wet batteries, dry batteries and standard cells. The latter are treated in the article on *Cells, Standard.* The wet battery at one time was largely used in laboratory testing, for telephones, bells and other devices requiring small amounts of energy. In recent years it has been largely supplanted by the dry battery and small storage battery cells (*see Batteries, Storage*). Dry cells, exclusive of the small flash light cells, are now (1921) used, in this country alone, to the extent of some hundred million a year, chiefly for gas-engine ignition and telephone work (see *Gas Engines* and *Telephone Instruments*).

Poles and Electrodes. — The pole or terminal of a battery which is at the *higher* potential is called the *positive* pole or terminal, the other pole being called the negative pole or terminal. The negative pole is the anode or *positive electrode* or plate and the positive pole is the cathode or *negative electrode* or plate. For example, in a copper-acid-zinc battery the copper is the positive pole but the negative electrode or plate.

THEORY OF PRIMARY CELLS. — The modern theory of primary cells is fully discussed in the article on *Electrochemistry, Principles of.* Only one or two points of practical moment will be mentioned here.

Electromotive Force. — A cell consists essentially of two metallic conductors or poles dipping into an electrolyte. Copper or carbon is commonly employed for the positive pole and zinc for the negative pole. The electrolyte may be sulphuric or nitric acid or sal-ammoniac, caustic soda or other salt. For a cell made of given materials the open-circuit e.m.f. is always the same provided the temperature, degree of concentration of the electrolyte and the purity of the materials are the same. The terminal e.m.f. or potential difference (p.d.) on closed circuit is always less than the open-circuit e.m.f. due (1) to the internal resistance of the battery, (2) to the polarization of the battery and (3) to the exhaustion of the battery.

Internal Resistance. — Let E be the initial open-circuit e.m.f. of the cell and V be the p.d. across its terminals, when it is supplying a given current I, then the "apparent" internal resistance of the cell is

$$r = \frac{E - V}{I}.$$

This is not the true resistance of the cell, for its net e.m.f. when a current I is being drawn from it is less than the initial open-circuit e.m.f. due to polarization (*see below*) and partial exhaustion. If, however, after measuring the p.d. on closed circuit the current is interrupted and the open-circuit e.m.f., say E', is measured *immediately* (i.e., before the polarized condition of the cell has had time to change) then the true internal resistance of the cell is

$$r' = \frac{E' - V}{I}.$$

Polarization. Depolarizers. — Polarization is the name applied to the changes produced in the relative concentrations of the electrolyte at the two poles of a cell or to the production at the poles of new chemical substances (such as hydrogen) as a result of the flow of current through it. A depolarizer is any substance which when placed in the electrolyte or on the poles of the cell will partially or wholly prevent these changes. Polarization always tends to reduce the effective e.m.f. of the cell. When a cell which has been polarized is

open-circuited, the relative changes in concentration gradually disappear, due to diffusion, and any new substances formed also tend to diffuse uniformly through the electrolyte, with the result that the open-circuit e.m.f. returns in time to nearly its original value, provided the active materials are not exhausted.

The chief cause of polarization in a cell is the formation of hydrogen gas at the positive pole or to the transfer of the metal from the negative pole to the positive pole. The depolarizer is usually an oxidizing agent which reduces the hydrogen or metal liberated at the positive pole to a form readily soluble in the electrolyte and thereby prevents its accumulation at the positive plate. This is the principle on which depends the depolarizing action of the various metallic oxides, such as manganese peroxide or cupric oxide. The same result may be obtained by surrounding the positive pole by a solution of a salt of itself which has the same acid radical as the electrolyte surrounding the negative pole, but which is less soluble, the two solutions being kept practically separated by a porous cup which renders the diffusion of one into the other very slow.

TYPICAL WET BATTERIES. — Numerous forms of wet batteries have been used; only some of the more common forms can be described here. The materials used and the e.m.f. developed and approximate range of internal resistance are listed in the following table.

TYPICAL WET BATTERIES

	Daniell	Gravity	Bunsen	Chromic acid	Edison-Lalande	Leclanché type
Positive pole	Cu	Cu (b)	C	C	C	C
Negative pole	Zn (a)	Zn (a)	Zn (a)	Zn (a)	Zn (a)	Zn
Electrolyte	H_2SO_4 or $ZnSO_4$	$ZnSO_4$ or $MgSO_4$	H_2SO_4	H_2SO_4 or NaCl	KOH or NaOH	MnO_2
Depolarizer	$CuSO_4$	$CuSO_4$	HNO_3	CrO_3	CuO	NH_4Cl
Separator	Porous pot	None	Porous pot	With or without pot	None	With or without pot
E.m.f., volts	1.07 to 1.14	1	1.9–1.95	2	0.75	1.5
Resistance, ohms	0.3 to 30	0.1 to 6	Low	0.5 to 4	0.02 to 0.1	1 to 5

a. Amalgamated. b. In the Krüger cell copper-plated lead is used.

Daniell Cell (Fig. 1). — A typical form of this cell is shown in Fig. 1. Other forms, differing in certain details, are Muirheads cell, the Siemens & Halske Daniell cell, Minotto's cell (which may also be classed as a gravity cell, *see below*), etc. *J* is a glass or glazed earthenware jar containing a concentrated solution of copper sulphate, *P* is a porous pot containing dilute sulphuric acid (about 10 per cent by volume) or zinc sulphate solution or both, *C* is the positive copper pole and *Z* the negative zinc pole which is usually amalgamated. The chemical reaction which takes place may be represented by the formula

Fig. 1. Porous Pot Daniell Cell

$$Zn + CuSO_4 = Cu + ZnSO_4.$$

Digitized by Google

A current of 1 ampere for 1 hour deposits 1.186 grams of copper and liberates 1.219 grams of zinc. Hence

0.042 oz. copper is deposited per ampere-hour,
0.043 oz. zinc is used up per ampere-hour,
0.164 oz. copper sulphate crystals are used up per ampere-hour,
0.106 oz. zinc sulphate is formed per ampere-hour.

The latter when crystallized out will form 0.189 oz. zinc sulphate crystals. These figures do not include any loss of zinc due to local action, which may amount to 10 per cent or more.

E.M.F. of Daniell Cell. — The e.m.f. of a Daniell cell varies from about 1.07 volts to 1.14 volts, depending on the density of the copper sulphate solution and on the amount of zinc sulphate present in the dilute sulphuric acid. The cell has its highest e.m.f. at the start when the sulphate of copper solution is saturated and no sulphate of zinc has formed. Hence, in order that the e.m.f. shall remain more nearly constant, it is better to start with *both solutions saturated*. The resistance of the cell will be higher and its e.m.f. lower than when dilute sulphuric acid is used, but this lower value of about 1.10 volts will be maintained nearly constant while the cell is sending a current.

Internal Resistance of Daniell Cell. — This depends not only upon the dimensions of the cell but also upon the porosity of the pot or other separating medium. The type of cell shown in Fig. 1, having a pot 7 inches high which is quite porous, has an internal resistance of about 0.3 ohm. The resistance of the Siemens type of Daniell cell is from 10 to 15 ohms, and the resistance of Minotto's modification of the Daniell cell, in which a layer of sawdust or sand is used in place of the porous cup, may be as high as 30 ohms.

The resistance of a Daniell cell, like that of liquids generally, *diminishes* with *increase* of temperature.

Local Action. — Impurities in the zinc form with the zinc small short-circuited voltaic cells, resulting in a wasting away of the zinc without producing a current in the external circuit. This can be largely prevented by amalgamating the zinc, i.e., coating it with mercury, which is readily done by thoroughly cleaning the zinc by dipping it into dilute sulphuric acid and then rubbing mercury over its surface. In the Daniell cell metallic copper also forms in the pores of the porous cup where the zinc touches it; this can be prevented by covering with paraffin those portions of the cup which may come into contact with the zinc.

Care of Daniell Cells. — The type of cell shown in Fig. 1 must be taken to pieces when not in use. If it has to be put to one side for only an hour or two, it will be sufficient to lift the porous pot with the contained zinc rod bodily out of the cell, and to place it in another empty jar, or stand it in a dish while out of use.

Gravity Battery (Fig. 2). — The principle of this cell is the same as that of the Daniell cell, except that no porous pot is used, the copper sulphate and zinc sulphate being maintained separate by gravity. There are various modifications in the form of construction, known as the Meidinger cell, Calland cell, Kelvin tray battery, Krüger cell, etc. The gravity cell is still used in telegraph and telephone work.

The copper electrode is placed at the bottom of the cell, and is then covered with copper sulphate crystals. The zinc electrode is then put in place and the jar either filled with dilute zinc sulphate or with dilute sulphuric acid. With

Care of Gravity Battery. — The resistance of the cell increases rapidly with decrease of temperature; it should therefore be kept at a reasonably high temperature, say 70° F. A gravity cell must, of course, not be moved about, or if moved great care must be taken to avoid the two liquids being mixed together. To prevent the copper sulphate wandering to the zinc plate, it is well to allow the cell to send a weak current through an external circuit of considerable resistance even when the cell is not in ordinary use. The electrolyte should be renewed when the blue sulphate solution turns brown. The line of separation between the copper and zinc sulphates, or the "blue line," should be about halfway between the two electrodes.

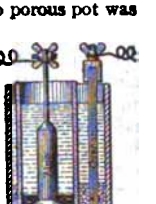

Fig. 2. Gravity Daniell Cell

Bunsen Cell. — In the Bunsen cell a zinc plate is placed in dilute sulphuric acid, as in the Daniell, but the copper plate is replaced by one of carbon and the copper sulphate solution by strong nitric acid, which is generally said to act as the depolarizer. The Grove cell differs from the Bunsen only in the use of platinum in place of carbon. Both cells give a high e.m.f., from 1.9 to 1.95 volts, and have low internal resistances, so they may be used for producing fairly large currents. When working the cells give off dark brown fumes of nitric peroxide, NO_2, and should be placed in the open air or under a chimney.

The chemical reaction which takes place may be represented by the formula $Zn + H_2SO_4 + 2\,HNO_3 = ZnSO_4 + 2\,H_2O + 2\,NO_2$.

Care of Bunsen Battery. — A Bunsen or Grove battery must be taken to pieces at the end of each day's use, since the mixing of the liquids through the walls of the very porous cup used to separate them would render the battery practically useless the next day. The porous pots should be placed in water after use, so that all the zinc sulphate solution may be dissolved out of the pores of the earthenware, for, otherwise, when the pots are dried the zinc sulphate solution will crystallize in the pores and cause the pots to fall to pieces.

Chromic Acid Cell (Fig. 3). — The chromic acid or potassium bichromate cell was devised by Poggendorff. In the original type of cell no porous pot was employed. In the Fuller cell, shown in Fig. 3, a porous pot is used. The depolarizer used is chromium peroxide, popularly called chromic acid, which may be purchased ready prepared, or may be formed by heating potassium or sodium bichromate with sulphuric acid (1 part by weight of the bichromate, 3 parts of acid and 9 parts of water). In the type of cell shown in the figure the wire connected to the zinc rod is well amalgamated or coated with gutta-percha to insulate it. In the porous pot containing the zinc, there is put a quantity of mercury to maintain the amalgamation, and either dilute sulphuric acid or a solution of common salt NaCl. The chromic acid solution is placed in the jar containing the carbon plate.

Fig. 3. Fuller's Mercury Bichromate Cell

The chemical reaction which takes place may be represented by the formula $3\,Zn + 2\,CrO_3 + 6\,H_2SO_4 = Cr_2(SO_4)_3 + 3\,ZnSO_4 + 6\,H_2O$.

This cell has an e.m.f. of about 2 volts, and is suitable for producing a fairly strong current for a short time. When much used the cell becomes saturated with the potassium and chromium sulphates, and a double salt, chrome alum, $K_2Cr_2(SO_4)_4$, crystallizes out and sticks so firmly to the bottom of the cell that it is somewhat difficult to remove.

Edison-Lalande Cell. — In this type of cell the positive pole is a plate of compressed cupric oxide (CuO), the surface of which is reduced to metallic copper. The cupric oxide acts as the depolarizer. The negative pole is amalgamated zinc and the electrolyte a strong solution (1 to 3 by weight) of caustic potash or of caustic soda.

A layer of heavy oil is poured over the solution to prevent evaporation and "creeping." No local action or polarization takes place in this cell; under normal conditions it is an easy matter to set it up to give any required number of ampere-hours, and to so proportion the constituents that they are all exhausted at the same time. This is a matter of considerable importance where closed-circuit working is employed, as in some systems of telegraphy and in alarm circuits. Although the e.m.f. of the Edison-Lalande cell is low, its resistance is also low, and the cell is capable of producing large currents. The cell may be left set up for months without deterioration.

The chemical reaction which takes place may be represented by the following formula

$$Zn + CuO + 2\,KOH = Cu + H_2O + K_2ZnO_2.$$

Leclanché Cells. — In the original form of this type of cell the positive pole was a plate of carbon embedded in a mixture of solid manganese peroxide and broken carbon contained in a porous pot. The electrolyte is sal ammoniac, NH_4Cl, and the negative pole zinc. The manganese peroxide acts as the depolarizer. The only object of the porous pot was to hold the carbon and manganese peroxide. In the later forms of this cell, such as the "agglomerate," Corsak, etc., the porous pot is dispensed with and a mixture of carbon and manganese peroxide are moulded together with a suitable binder, or the mixture of carbon and manganese peroxide is held together by a wrapping of canvas or sacking.

The chemical reaction which takes place may be represented by the formula

$$Zn + 2\,MnO_2 + 2\,NH_4Cl = Mn_2O_3 + H_2O + 2\,NH_3 + ZnCl_2.$$

If, however, too little sal ammoniac be present, zinc oxide or zinc oxychloride is formed instead of zinc chloride, and the solution becomes milky; hence when this happens, more sal ammoniac should be added.

The e.m.f. of a Leclanché cell is about 1.5 volts, but falls rapidly when the cell is used to send a strong current. It will, however, regain its value if the cell be left for some time unused, and it does not sensibly diminish when the cell is put to one side, even for some months. Hence, while the Leclanché cell is much inferior to the Daniell cell for the purpose of sending a steady current for an hour or two, it is much superior to the Daniell cell for producing intermittent currents at any time during the course of a year or more — for example, such currents as are employed for the ringing of electric bells, for house telephones, and for railway signaling.

Care of Leclanché Cells. — When the sal ammoniac becomes exhausted it should be thrown out and a new solution made. Three or 4 ounces of sal ammoniac for a jar of ordinary size is required, the jar to be filled about one-third with water before putting in the electrodes.

DRY CELLS. — The modern dry cell may be looked upon as a modification of the Leclanché cell, the chief difference being that only enough water is added to the electrolyte to moisten an absorbent layer of pulp-board, blotting paper, cheese cloth or starch paste, this lining separating the positive and negative poles. The negative pole, which also serves as a container, is a hollow zinc cylinder; the bottom of this cylinder is also usually made of zinc. About $\frac{1}{8}$

er cent of the dry cells made in this country have these dimensions. The positive pole is a carbon rod, which may be either cylindrical or fluted. The absorbent layer above mentioned is placed next the zinc and is saturated with a solution f sal ammoniac and zinc chloride. The zinc chloride is necessary to reduce he rapid deterioration which would otherwise take place on open circuit. The pace between this lining and the carbon electrode is filled with a mixture of granulated carbon and manganese peroxide, the latter being the depolarizer. The top of the cell is usually sealed with a pitch composition.

Desiccated Cells, sometimes called reserve cells, are usually constructed he same as the ordinary dry cell. The chief difference is that the cell is assembled without water, provision being made for filling the cells with water before they may be required for use. Desiccated cells will not deteriorate so long as they remain dry. It is necessary to fill them with water several hours before use, and 24 hours may be necessary before the cell will give its maximum current on short circuit.

E.M.F. of Dry Cells. — In new cells of practically all types the open-circuit e.m.f. is between 1.5 and 1.6 volts. The decrease in e.m.f. when the cell stands on open circuit is very slight, being only about 0.1 after the cell has stood many months. An open-circuit e.m.f. materially less than 1.5 volts is generally an indication of serious deterioration or of some other defect. The effect of temperature on the open-circuit e.m.f. is slight, amounting to only a few hundredths of a volt for all ordinary temperature ranges. Due to the relatively rapid polarization and increase of internal resistance with use, the average terminal voltage during the useful life of the cell is only about 1 volt.

Internal Resistance. — The internal resistance of a high-grade dry cell when new is usually less than 0.1 ohm, which may increase to 0.5 ohm within 9 or 12 months, even though the cell is not used during this time. The polarization of the cell in actual service causes a much greater decrease in the terminal e.m.f. than does the internal resistance drop, and therefore the internal resistance test is of little practical value.

Short-circuit Current. — Nine out of every ten users of dry cells consider the short-circuit current, i.e., the current produced through an ammeter having a relatively small resistance connected directly between the poles of the battery, as a direct measure of the value of the cell. There are other factors, however, which must be considered, such as the temperature of the cell, the service for which it is to be used, etc. According to D. L. Ordway (*Trans. Am. Electroch. Soc., 1910, Vol. 17, p. 336*) a standard 2.5 by 6-inch dry cell should give when new a short-circuit current (external resistance not over 0.01 ohm) of from 18 to 25 amperes; a cell giving a short-circuit current much above 25 or below 16 amperes should be looked upon with suspicion. A cell giving a short-circuit current much in excess of 25 amperes is liable to polarize rapidly, whereas if the short-circuit current is much under 16 amperes, it is probable that the cell has been made a long time or that cheap materials have been used.

The effect of temperature on the short-circuit current is pronounced. Between 10 and 80° C. the current increases about 1 ampere for each 10° increase in temperature. This effect is even more pronounced at very low temperatures. The short-circuit current returns to its normal value when the cell is restored to normal temperature.

Shelf-life. — The shelf-life of a dry-cell of the ordinary sizes is usually considered as the time in months that the cell may stand on open circuit without its short-circuit current falling below 10 amperes. This current is about half the short-circuit current when the cell is new, and represents a value which is probably lower than the minimum point at which a dealer could dispose of a

cell to the average consumer. The average shelf-life of high-grade cells is from 10 to 12 months, though the very best cells have a shelf-life of from 12 to 15 months. Many makes of cells have a shelf-life of only 8 to 10 months; and cells are on the market having a shelf-life of only 1 or 2 months.

The shelf-life is increased by storing the cells at a low temperature. Ordway gives the following results on standard dry cells kept in storage at the stated temperatures. These cells give initially a short-circuit current of about 20 amperes.

Temperature at which cells were stored, ° C....	0	25	50	75
Short-circuit current at 25° C. after 5 months....	18.1	17.4	0.5	0.4

Ampere-hour and Watt-hour Capacity. — The short-circuit current, however, is not a measure of the ampere-hours obtainable from the cell, as is indicated in the following table, taken from Ordway's paper. The ampere-hours given are those obtained from the various cells when discharged continuously through a resistance of 16 ohms until the closed-circuit voltage fell to 0.5 volt.

Brand of cell.....	A	D	G	J	M	P	V	X
Short-circuit current.....	33.0	24.5	22.5	20.9	20.1	19.2	11.6	6.6
Ampere-hours.....	24.0	33.5	40.0	18.2	11.7	30.3	13.6	4.5

The letters are arbitrary designations.

Although the short-circuit current falls off with the age of a cell, even though the cell is not used, the ampere-hour capacity does not decrease in the same ratio. Ordway gives the following tests on samples from the same lot.

	Freshly made	9 months after manufacture
Short-circuit current.....	22.4	3.6
Ampere-hour capacity (through 2 ohms to 0.25 volt).....	24.9	20.2

Effect of Rate of Discharge on Capacity. — Ordway gives the following results of tests on standard 2.5 by 6-inch cells, when the cells are discharged continuously through 2, 4, 8, 16, 24, 32 and 40 ohms respectively. By "end point in volts" is meant the terminal voltage per cell at the end of the stated number of hours.

HOURS OF CONTINUOUS SERVICE OF 2.5 BY 6-INCH DRY CELLS

End point in volts	Resistances used in ohms						
	2	4	8	16	24	32	40
1.2	4.3	10	39	142	260	414	549
1.0	9.3	35	94	296	548	889	1148
0.8	16.5	51	143	414	751	1078	1550
0.6	28.2	76	225	954	1240	1600	1763
0.4	55	207	648	1197	1711	2280	2040
0.2	160	450	882	1318	1914	2626	3140

Digitized by Google

WATT-HOURS FROM 2.5 BY 6-INCH DRY CELLS DISCHARGED CONTINUOUSLY

End point in volts	Resistances used in ohms						
	2	4	8	16	24	32	40
1.2	3.7	4.3	8.1	15.2	18.8	21.7	23.8
1.0	6.7	13.0	16.5	26.9	33.4	39.8	42.0
0.8	9.7	16.3	21.5	32.8	40.3	44.6	50.6
0.6	12.5	19.4	26.6	48.9	49.5	52.7	53.2
0.4	15.4	27.3	39.1	52.6	54.3	58.2	54.8
0.2	19.8	32.6	41.5	53.3	55.2	59.3	57.1

Capacity on Intermittent Service. — Neither the ampere-hour nor watt-hour capacity of a cell on *continuous* service is a measure of its capacity on intermittent service. What the user wishes to know is the actual number of hours of service that he can obtain from a cell when used to operate a definite piece of apparatus, which as a rule takes current only intermittently, e.g., for telephone or ignition service. From curves given in Ordway's paper for 3 cells connected in series and discharged through the stated resistances the following table has been made up.

HOURS OF INTERMITTENT SERVICE OF 2.5 BY 6-INCH DRY CELLS

(The hours given are the hours the cell is actually supplying current)

End point in volts, 3 cells	Continuous discharge			5 minutes each hour night and day			5 minutes each hour, 8 hours per day, 6 days per week		
	5 ohms	10 ohms	20 ohms	5 ohms	10 ohms	20 ohms	5 ohms	10 ohms	20 ohms
3.6	4	12	30	4	45	80	3	15	45
3.0	9	25	65	29	65	145	12	30	60
2.4	15	40	100	48	90	190	23	45	75
1.8	25	60	150	65	130	225	35	70	100
1.2	42	140	475	80	160	250	52	100	150
0.6	95	...	...	93	200	290	70	115	165

From the above table it is apparent (1) that the terminal voltage falls off more rapidly on continuous discharge than on intermittent discharge, counting hours of *actual discharge* only, but (2) that during the latter stages the terminal voltage falls off more rapidly for the intermittent discharge, this latter effect occurring earlier as the external resistance is increased. The second effect is probably due to the deterioration of the battery while standing on open circuit. It should be kept in mind that the length of time the cells were in service during the intermittent tests were respectively 12 and 40 times the period of actual discharge.

Proper Arrangement of Cells for Best Results. — The data given in the above tables may be used as a basis for the determination of the number and proper arrangement of cells for a given service. For example, if a certain piece of apparatus has a resistance of 8 ohms and cannot be operated at a voltage under 0.8, then 143 hours of service can be obtained from a single battery. If however 4 cells in parallel are used, the drain on each cell will be one-fourth as great as before, which is equivalent to discharging each cell through 32 ohms. Therefore the 4 cells will give 1078 hours of service, or 270 hours per cell. If the 4 cells were connected in series, then drain on each would be 4 times as great as for a single cell, which is equivalent to discharging each cell through 2 ohms, but each cell could discharge to 0.2 volt instead of 0.8. The 4 cells in series would then give 160 hours, or only 40 hours per cell. The parallel arrangement is therefore the best in this case.

For ignition service 6 cells in series are usually required in order to obtain a sufficiently high voltage. On heavy service of this kind two or more such series groups connected in parallel are usually more economical than a single group. For telephone service 3 cells in series are usually required in order to obtain a sufficiently high voltage. For such light service a single group of cells is more advantageous than two or more groups in parallel; any gain which might at first sight be effected is more than offset by the deterioration caused by local action on standing. This may be seen by a consideration of the data on intermittent service given above.

Tests of Dry Batteries. — The proper testing of dry batteries has been the subject of considerable discussion during the last few years. See *Trans. Am. Electrochem. Soc.*, 1909 to date. A preliminary report was submitted by a committee of this society in April, 1912. The following is a brief summary.

In measuring the terminal voltage of a dry battery a voltmeter having a fairly high resistance, 300 ohms or more, should be used. The ammeter and leads for measuring the short-circuit current should have a combined resistance of 0.01 ohm. The internal resistance test is not recommended.

Service Tests. — Dry batteries to be used in telephone work should be tested by discharging 3 cells, connected in series, through 20 ohms resistance for a period of 2 minutes, each hour, during 24 hours per day and 7 days per week, until the closed-circuit voltage of the battery at the end of a period of contact falls to 2.8 volts (0.93 volt per cell). Report the results as the number of days during which the closed-circuit voltage remains above the limiting value of 2.8 volts. This test has been modified and supplanted by the so-called A.T. and T. test, which is as follows: three cells connected in series are discharged through 20 ohms for 10 periods of 4 minutes each in 10 consecutive hours of 6 days per week. On the seventh day every other period is omitted. The end of the test is taken at 2.8 volts for the battery on closed circuit. The results are expressed as the number of days the test lasted.

For ignition service discharge 6 cells connected in series through 16 ohms resistance for 2 periods of 1 hour each per day, seven days per week, the periods being 11 hours apart. Determine at the end of every 12th period of closure the current which the 6 cells are capable of sending through a 0.5 ohm coil in series with an ammeter, the two being in parallel with the 16-ohm coil. The test is considered completed when the current through the 0.5 ohm coil at the end of a period of closure falls below 4 amperes. Report the results as the number of hours of actual discharge to this limiting value of the current.

For flash-light service discharge the battery through a resistance of 4 ohms for every cell in series, for a period of 5 minutes, once each day, until the closed circuit voltage at the end of a discharge period falls to 0.75 volt per cell in series. Report the result as the number of minutes of actual discharge until the voltage reaches this limiting value. At the present time (1921) the end point is gen-

Digitized by Google

nally taken as 0.50 volt per cell instead of 0.75 volt, because the modern lamps re usable to a lower voltage.

Full details for making these tests, together with a description of proper utomatic arrangements for opening and closing the circuit at the designated mes, will be found in the *Trans. Am. Electrochem. Soc.*, 1912, Vol. 21, p. 282. he timing device is an ordinary cheap clock provided with suitable contacts y means of which the hand closes the circuit.

Shelf-life Test. — Keep the cells open-circuited in a dry room at normal mperature. Determine the short-circuit current at the end of every 8 weeks. eport results as the number of months before the short-circuit current falls elow 10 amperes.

SPECIFICATIONS FOR DRY BATTERIES. — See *Circular No. 79, ureau of Standards*, April 25, 1919.

COST OF DRY BATTERIES (Pre-war prices). — Dry batteries of andard size (2.5 by 6 inches) cost at retail from 10 to 25 cents, depending upon e quality of the battery. When bought by the barrel, good dry batteries may e had for 10 cents apiece.

BATTERIES, STORAGE, ALKALINE TYPE. — (*See also Automobiles, Electric; Batteries, Storage, Applications of; Batteries, Storage, Lead Type*) The alkaline type of storage battery consists in its best-known form, i.e., the Edison battery, of an iron-nickel element immersed in dilute caustic-potash solution. The alkaline type of storage battery was first exploited commercially by Edison in 1904. At the present time (1921) it is being used extensively for the propulsion of electric vehicles, the operation of railroad block signals, the electric lighting of trains and in radio work.

THEORY OF ALKALINE STORAGE BATTERY. — Numerous active elements have been used in the alkaline type of storage battery. The elements in the Edison type of alkaline battery consist of nickel hydroxide for the active material of the positive plate, iron for the active material of the negative plate and a solution of potassium hydrate and lithium hydrate for the electrolyte.

The fundamental principle of the Edison storage battery is the oxidation and reduction of metals in an electrolyte which neither combines with nor dissolves either the metals or their oxides. Also, an electrolyte which, notwithstanding its decomposition by the action of the battery, is immediately re-formed in equal quantity, and is, therefore, a practically constant element without change of density or conductivity over long periods of time. Therefore, only a small quantity of such electrolyte is necessary, permitting a very close proximity of the plates. Furthermore, it is unnecessary to take hydrometer readings until about three hundred cycles of charge and discharge have been made; this is simply to determine when it is necessary to empty out the old solution and put in new. The active materials of the electrodes being insoluble in the electrolyte, no chemical deterioration takes place therefrom.

The chemical reactions in charging the Edison storage battery are: (1) the oxidation from a lower to a higher oxide of nickel in the positive plate, and (2) the reduction from ferrous oxide to metallic iron in the negative plate. The oxidation and reduction are performed by the oxygen and hydrogen set free at the respective poles by the electrolytic decomposition of water during the charge. The charging of the positive plate is, therefore, simply a process of increasing the proportion of oxygen to nickel. The proportions of nickel to oxygen in definite oxides of nickel are as follows:

	Atomic Proportions by Weight			
	Ni	O	Ni	O
NiO	1	1	1	.273
Ni_3O_4	1	1.33	1	.364
Ni_2O_3	1	1.5	1	.409
$Ni\,O_2$	1	2	1	.545

The relative amounts of oxygen necessary to oxidize nickelous oxide, or NiO, which is the oxide corresponding to the green nickel hydrate used in making the battery, to the various oxides are given in the three reactions:

$$(1)\quad 6\,NiO + {}_2\,O = {}_2\,Ni_3O_4$$
$$(2)\quad 6\,NiO + {}_3\,O = {}_3\,Ni_2O_3$$
$$(3)\quad 6\,NiO + 6\,O = 6\,NiO_2$$

The NiO_2 is capable of reacting with NiO according to the reaction

$$NiO_2 + NiO = Ni_2O_3.$$

Digitized by Google

would be represented by a ratio of 1 : 1.33 (Ni_3O_4) or lower, depending on the discharge.

The discharge of the cell is simply the reversal of the above reactions, the hydrogen reducing the higher oxides of nickel to lower oxides and the oxygen oxidizing the iron to ferrous oxide.

"Gassing." — In the alkaline type of cell, as in the lead type of cell, a certain amount of the water (H_2O) is broken up on charge by the electrolytic action of the charging current. The rate at which gas is evolved during a charge at the normal rate of current remains approximately constant during the first half of the charge, and increases rapidly during the latter portion of the charge. Of the total amount of gas evolved during a 7-hr. charge, about one-half is evolved during the first 5 hr. of the charge. As the oxygen and hydrogen thus liberated form an explosive mixture, provision should be made with a battery of any considerable size to carry the gases away to prevent their becoming a source of danger.

DESIGN. — The only alkaline type of battery in use at present (1921) in the United States is that made by the Edison Storage Battery Co. This battery is made up of a positive plate having as the active material a high nickel oxide, a negative plate having as the active material powdered iron, and an electrolyte consisting of dilute potassium hydrate solution.

Positive Plate. — The positive or nickel plate consists of perforated steel tubes, nickel plated, filled with alternate layers of nickel hydroxide and pure metallic nickel in thin flakes. The nickel is added to give the necessary conductivity to the active material.

The tube is formed from a perforated ribbon of steel, nickel plated, and has a spiral lapped seam. This tube, after being filled with active material, is reinforced with steel bands, which prevent the tube expanding away from and breaking contact with its contents. The tubes are flanged at both ends and held in contact with a steel supporting frame or grid made of cold-rolled steel, nickel plated.

Negative Plate. — The negative or iron plate consists of a grid of cold-rolled steel, nickel plated, holding a number of rectangular pockets filled with powdered iron oxide. These pockets are made up of very finely perforated steel, nickel plated. After the pockets are filled they are inserted in the grid and subjected to pressure between dies which corrugate the surface of the pockets and force them into contact with the grid.

After the plates have been prepared, as outlined above, the positive or nickel plate is further oxidized electrolytically and the nickel hydroxide converted to a high oxide of nickel, probably NiO_2. The negative or iron plate is reduced electrolytically, the powdered iron oxide being converted into metallic iron. See section above on *Theory* for an explanation of the chemical action.

Separation and Insulation. — After the plates are assembled into a complete element, narrow strips of hard rubber are inserted between the plates to insulate them from each other. The side insulator is provided with grooves and a step or projection at the bottom to insulate the complete element from the steel container. The step acts as a support to the element as well as insulating the plates from the bottom of the container. At the ends of the element, that is, between the outside negative plates and the container, are inserted smooth sheets of hard rubber.

Assembly. — The jar is made from cold-rolled sheet steel, nickel plated. The walls of the jar are corrugated to give the greatest amount of strength with minimum weight.

The cover is of sheet steel, nickel plated, provided with three mountings, two

being pockets for containing stuffing boxes about the terminal posts. The thi mounting is an opening for filling the cell with electrolyte, and for the oc sional (every four or five discharges) addition of distilled water to take place of that which is lost during charge. This opening is provided with hinged cap, on the under side of which is loosely hung a spherical segment hard rubber. The latter, when the cap is closed, seats upon the circ opening beneath and is lifted by escaping gas, permitting its free egress. closes the cell however to the admission of foreign gases or other mate from without. The cap is opened only for filling and is held open or cl by a flat steel spring.

The plates are grouped on steel connector rods with steel spacing washe all being attached to a steel terminal post. The terminal posts are insulat from the cover by means of hard and soft rubber washers and bushings.

The cells are assembled in wood trays, the positive and negative termi of adjacent cells being connected together by copper connecting links. Ea individual cell is insulated from the adjacent cell and from the containing w tray.

RATING AND PERFORMANCE. — It is standard practice to rate a Edison battery in terms of the amperes it will give continuously for 5 hours. T rated capacity in ampere-hours is then 5 times this current rate. The norm rate of charge is the same as the normal rate of discharge and the time normal charge is given as 7 hours. In the trade designations employed, e.g. A–6, the letter designates the size of the plate and the numeral the number positive plates per cell, i.e., in the A–6 cell there are 6 positives; see below und *Dimensions, Weight and Cost.* The values of the rated current and output f each size of cell are given in the following table; the average voltage per c during discharge is 1.2 volts. The G type is rated on a 3½ hour basis with normal charging time of 4¾ hours. The normal current rate is 50 per ce higher than the A type of equivalent ampere-hour capacity.

RATED PERFORMANCE OF EDISON CELLS

Size of cell	Normal rate of charge and discharge, amperes	Rated capacity		Watt-hours per pound of cell for rated capacity	Average watts during discharge at normal rate
		Ampere-hours	Watt-hours		
B–2	7.5	37.5	48	12.2	9
B–4	15	75	90	13.0	18
B–6	22.5	112.5	135	13.7	27
A–4	30	150	180	13.3	36
A–5	37.5	187.5	225	13.4	45
A–6	45	225	270	14.1	54
A–8	60	300	360	13.1	72
A–10	75	375	450	13.2	90
A–12	90	450	540	13.2	108

The capacity of new cells increases for at least twenty cycles of charge an discharge. This betterment may be as much as 30 per cent above rating an comes from an improvement of conditions in the nickel electrode which brought about by regular charging and discharging. It is expedited by ov charging. The capacity then decreases slowly with use until the electrol is renewed, which should be done before the capacity has fallen to the rate

Digitized by Google

value. The capacity again increases for a few charges and subsequently falls.

Voltage Characteristics. — The charge and discharge voltage characteristics of an Edison battery vary with the conditions, among which are temperature, condition of electrolyte, time since last discharge or charge, etc. Typical charge and discharge voltage curves at the normal rate are given in Fig. 1. It will be noted that the voltage rises rapidly at the beginning of charge, decreases somewhat during the second hour, and then rises gradually during the remainder of the charge. This hump in the voltage curve is characteristic of the Edison battery, and may lead to confusion as to battery's condition of charge. The value and duration of this hump may vary considerably even on successive charges of the same battery. The final charging voltage, with current on, is approximately 1.8 volts per cell, but ranges from 1.7 to 1.95 volts per cell. The rise in voltage near the end of charge is not sufficient to serve as a very satisfactory criterion of complete charge, but the Edison Storage Battery Co. recommends that if the extent of the previous discharge is unknown, the charge at the normal rate should be continued until the voltmeter reading has remained constant for 30 minutes at about 1.8 volts per cell.

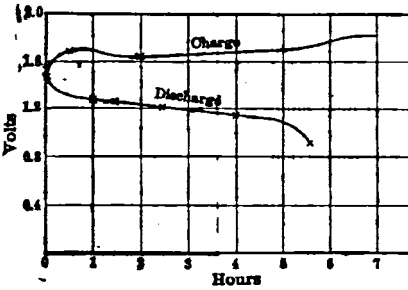

Fig. 1. Voltage Curves at Normal Rate

Effect of Temperature on Charging Voltage. — The normal average temperature of a battery on charge is between 90 and 100° F. The values of average and maximum charging voltage are higher for low temperatures of the electrolyte than for high temperatures. The range is indicated by the results of a series of tests given in the accompanying table.

Temperature, deg. Fahr.	Average voltage	Maximum voltage
35	1.88	1.94
55	1.81	1.92
75	1.76	1.88
95	1.70	1.84
115	1.67	1.77

Discharge Voltage. — On discharge the voltage performance of an Edison battery is more uniform than on charge, although during the early portion of the discharge the voltage is liable to vary considerably from the values indicated in Fig. 1. This depends chiefly on the length of time the cell has stood on open-circuit since the completion of the charge. The average discharge voltage is 1.2 volts per cell when discharged to 1.0 volt per cell (with current on) at the normal (5-hour) rate.

As with lead cells the open-circuit voltage is valueless as an indication of the state of charge. The open-circuit voltage in general will be about 20 per cent higher than the corresponding terminal voltage at normal rate of discharge.

Specific-gravity Characteristics. — The normal specific gravity of the electrolyte is about 1.200, and decreases slowly as the cell is used. (*See section below on Tests of Electrolyte.*) The specific gravity does not change materially on charge or discharge. A slight concentration has been noted during discharge, but the variation is too small to have commercial significance. The specific gravity decreases 0.002 with each 10° F. increase in temperature.

Variation of Capacity with Rate of Discharge. — The ampere-hour capacity of an Edison battery is practically independent of the rate of discharge, provided the discharge is carrried to a sufficiently low voltage. In this connection it may be pointed out that no harm is done an Edison battery by discharging it to zero voltage. The total ampere-hour outputs of a battery, when discharged to zero voltage at various current rates from one-third normal to four times normal, after a normal charge in each case, vary by only 2 per cent. As the low voltage part of a discharge cannot be considered useful, it is customary to consider the discharge completed for any rate of discharge when the voltage has reached a value differing from 0.9 volt per cell by an amount equal to the difference between the resistance drop in the cell corresponding to this rate and that corresponding to the resistance drop at the normal rate. Thus for a cell with an internal resistance (*for values see paragraph below on Internal Resistance*) of 0.003 ohm and a normal rate of 30 amperes, the terminating voltage for a discharge at 60 amperes would be 0.9 − 0.003 (60 − 30) = 0.81 volt. Fig. 2 shows a series of voltage curves for discharges at various rates following normal charges. The discharge has been discontinued in each case in accordance with the above rule. The variations of average voltage, ampere-hour output and time of discharge, with discharge rate are shown in Fig. 3, where values of these factors for the normal (5-hour) rate are each taken as 100 per cent.

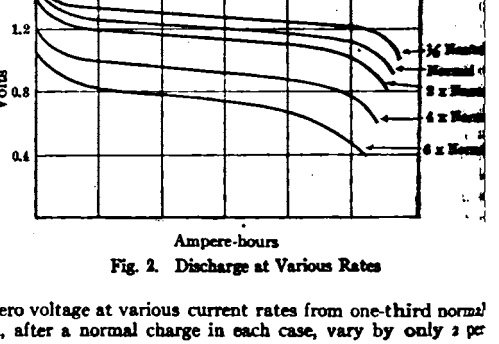

Fig. 2. Discharge at Various Rates

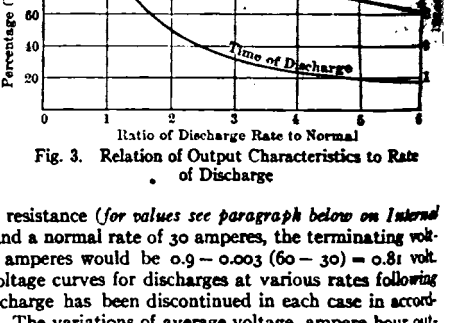

Fig. 3. Relation of Output Characteristics to Rate of Discharge

Variation of Capacity with Rate of Charge. — The energy contained in a newly charged Edison cell depends upon both the rate and length of charge. Fig. 4 gives the variation in the time of discharge at normal rate for various charge rates and periods for a particular battery. In this particular test when the cell was discharged at the normal 5-hour rate to 0.9 volt, after a 7-hour

charge at this same rate it gave this current for 5.9 instead of 5 hours. The curve for the normal rate of charge shows that the capacity for a 10-hour charge is 13.5 per cent and for a 14-hour charge 22.0 per cent greater than for a normal (7-hour) charge. The results of a series of charges of various lengths and subsequent discharges, both at the normal rate, are given in the accompanying table.

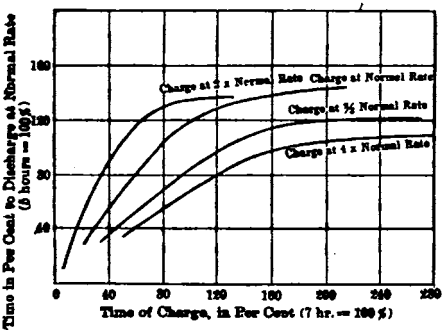

Fig. 4. Capacity at Normal Rate Discharge after Charging at Various Rates and Periods

Length of charge, hours	5.5	7.0	10.0
Length of discharge, hours	5.0	5.8	6.4
Average discharge voltage	1.19	1.202	1.203
Ampere-hour efficiency, per cent	91	83	64
Watt-hour efficiency, per cent	66	59	45

Variation of Efficiency with Length of Charge. — As shown by Fig. 4 the capacity of a cell depends upon the rate as well as upon the length of charge. For charge and discharge at the normal rate, the watt hour efficiency is approximately 72 per cent for a short charge (i.e., one hour or less), it drops to about 58 per cent for a normal or 7-hour charge, and has smaller values for larger charges, being approximately 30 per cent for a 15-hour charge. The normal rate of charge has been chosen by the manufacturers such that for an output of approximately the rated number of ampere-hours at the normal rate the efficiency is higher for the normal rate of charge than for a rate which is considerably higher or lower than the normal.

Variation of Capacity with Temperature. — With the Edison battery, as with all alkaline batteries, there is a critical electrolyte temperature for each rate of discharge below which the capacity falls to a low value The higher the rate of discharge the higher is this critical temperature. If the electrolyte throughout the cell has been chilled below the critical point for a given rate of discharge, the full capacity can be obtained as soon as the cell is warmed above the critical range. A series of tests, reported by W. E. Holland (*Central Station, Nov., 1911*), showed that the temperature should be kept above 55° F. if a large current is to be required. In the operation of Edison batteries in electric automobiles in cold weather it is recommended that the batteries be given a warming charge shortly before the car is taken from the garage. See also next paragraph.

Rate of Cooling of Electrolyte. — The rate of cooling of the electrolyte depends upon the initial temperature of the battery, the circulation of air in

contact with the battery, the temperature of this air, and the rate at which current flows from the battery. Another series of tests reported by Holland (*Central Station, Nov., 1911*) showed that in an open box a battery which had been charged in a room temperature of approximately 65° F. could stand idle in still air at 8° F. for a period of about 4 hours before the electrolyte dropped to 55° F. When placed in a closed box it took about 13 hours for the battery to cool from an initial temperature of 90° F. (which a battery would have at the end of a normal charge) to the critical temperature for high discharge rates. These tests pointed out the efficacy of a closed battery box for keeping cells warm. (*See also Automobiles, Electric.*)

Internal Resistance. — The effective internal resistance of a cell determines the immediate change in voltage at the cell terminals with a sudden change in the discharge rate. For method of measuring see section on *Testing*, below. The value in ohms of the mean effective internal resistance for an A-type cell discharging at normal rate is approximately equal to 0.012 ohm divided by the number of positive plates as given by the designation of the cell size, and for a B-type cell is approximately equal to 0.024 ohm divided by the number of positive plates. For two or more cells in series the total effective internal resistance is the product of this value by the number of cells in series. The internal resistance of Edison cells is such as to cause an immediate drop in terminal voltage of between 7 and 8 per cent with a sudden increase in current equal to the normal rate. The virtual internal resistance increases slightly during the progress of a discharge.

Retention of Charge. — The rate of loss of charge of a battery during idleness varies with the temperature at which it stands. The loss is slight in the cold and becomes greater as the temperature increases. The variation for cells charged under normal conditions and discharged after resting for various periods in one case at normal temperature of 75° F., and in another case at 35° F. is shown in Fig. 5. Accordingly a cell which has not been used for 10 days following a normal charge may be expected to retain at least 85 per cent of its initial capacity. It will be noted that the *rate* of loss of capacity after the second day is practically the same at both temperatures.

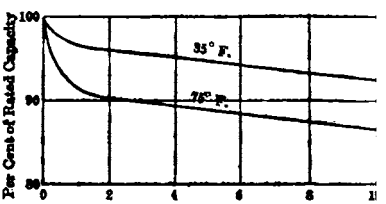

Fig. 5. Retention of Charge when Standing Idle

TESTING. — There are described below only those tests which are of interest in the commercial operation of the batteries. The methods of conducting several of the tests are the same as for the lead type of battery and are described more fully in the article on *Batteries, Storage, Lead Type.*

Tests of Electrolyte. — The normal specific gravity of the electrolyte at 80° F. is 1.200 as measured by hydrometer but may range from 1.160 to 1.230. Specific gravity is not necessarily a true indication of the suitability of the electrolyte, since harmful impurities may get into the electrolyte when watering or in other ways. The manufacturers recommend that the electrolyte be removed when the specific gravity has fallen to 1.160; this will usually be required after from 8 to 10 months of daily service. It is advisable to discharge the battery before renewing the electrolyte, and to give it a 12-hour charge, at the normal rate after renewing.

Digitized by Google

Test for Internal Resistance. — The internal resistance of a battery may be ermined by momentarily opening the switch during discharge and noting rise in voltage. This rise represents the *IR* drop in the battery due to its rnal resistance and cell connections. Hence the value of the internal re-ance at the given point of discharge will be the quotient of the volts rise ided by the current rate. This value divided by the number of cells in series l give the internal resistance per cell. Since on interrupting the current the tage may rise for some time, due to change in the e.m.f., a better voltage ding may be obtained by momentarily reducing the current flow instead of ening the circuit. In this case the resistance is found by dividing the differ-ce in voltage at the two rates by the change in current.

Capacity; Efficiency. — In testing for the capacity of an Edison battery at y given rate, the discharged battery should first be charged for 7 hours at e normal (5-hour) discharge rate. The battery is then discharged at the sired constant-current rate until the terminal voltage has reached the value determined by the rule given in the paragraph above on *Variation of Capacity ith Rate of Discharge*. The capacity in ampere-hours is the product of time of scharge in hours by the rate of discharge in amperes. The watt-hour efficiency the battery is the ratio of the energy given out on the discharge to the energy t in on the charge. The term "volt efficiency" is used to express the relation the average voltage of discharge to the average voltage of charge. For harge and discharge at the normal rate the value of the volt efficiency will be lose to 72 per cent for any length of charge not extremely short or long. Thus 2 per cent is the limit of possible efficiency at the normal rate. The watt-hour fficiency on any normal rate test may be calculated accurately enough for all ractical purposes by taking 72 per cent of the ampere-hour efficiency, i.e., by aking 72 per cent of the ratio of ampere-hours output to ampere-hours input.

Test Electrodes. — The best substance for a third electrode in analyzing oltage curves of alkaline batteries is a partially reduced oxide which will ndergo reduction in the electrolyte without polarization, and which is insoluble n the electrolyte. Either cupric oxide or the high nickel oxide of a charged dison positive fills these conditions for alkaline cells. For a discharge at ormal rate the readings of the cell electrodes to a test electrode of cupric oxide re: iron, approximately 0.44 volt, nickel, 0.9 to 0.5 volt; for a test electrode f nickel oxide the readings are: iron, approximately 1.28 volts, nickel — 0.1 to - 0.4 volt.

INSTALLATION. — The A- and B-types of cells are usually assembled by he manufacturer in wooden trays holding from 2 to 12 cells each, according to equirements. There is an air space between cells for ventilation and in-ulation. The standard form of tray is made "bottomless," in order to prevent hort-circuits between cells from the collection of dirt and moisture. If A-type ells are to be used where they will be pulled horizontally for filling, etc., trays vith bottoms are used on account of the greater strength. Data on typical ssemblies in bottomless trays are given in the following table:

Size of cell	B–2	A–4	A–6	A–12
Width of standard tray, in.	6 1/8	6 1/8	6 1/8	9
Over-all height (filler cap closed), in.	9 5/8	14 5/16	14 5/8	15 1/2
Length of trays, in.:				
2-cell tray	5	7 3/4	10	13 1/2
5-cell tray	10 3/4	17 1/8	22 3/4	32 1/4
8-cell tray	16 1/2	27 1/8	36 1/4	....
12-cell tray	24 3/8	40 3/8	....	.....

Digitized by Google

For the extra high container which is sometimes furnished (designated by E) the over-all height for B-type is 2 in. greater and for A-type 3 in. greater than the figures given in the above table.

The over-all height with filler cap open is about 1½ in. greater than the height with filler cap closed.

If a battery is to be used for stationary service a clearance of 6 in. above cells should be allowed so as to permit the proper filling of the cells in place. In vehicles from which the battery is removed for filling the clearance need be only ¾ in.

OPERATION. — An Edison battery should never be operated in any manner except in accordance with the instructions received from the Edison Storage Battery Co. Disobeying these instructions may result in forfeiture of the guarantee with regard to the life of the cell. As the detailed instructions differ somewhat for various services, only general directions which apply to all services are noted below.

Charging. — The batteries are now usually shipped in a charged condition. The initial charge should continue for 12 hours at the normal rate. A similar overcharge should be given after 30 days of service, one after 60 days of service, and another after each renewal of electrolyte. The normal charging rates are given above in the section on *Rating and Performance;* the time of a normal charge is 7 hours. The boosting rate may be as high as desired provided the temperature does not exceed 115° F. in any of the cells. The best results are obtained when the temperature is kept between 75 and 95° F. Under average operating conditions the charge in ampere-hours necessary to replace a discharge is from 15 to 25 per cent greater than the discharge. The Edison Storage Battery Co. recommends that if an ampere-hour meter is used, it should be set to operate 20 per cent slow on charge.

Precautions as to Gases. — The battery should be well ventilated while charging, and no open flame or arcing contact should be allowed near the cells while charging or immediately afterward, as the evolved gases may be exploded.

Standing Idle. — An Edison battery may be allowed to stand idle in any state of discharge provided the level of the electrolyte is kept above the plates. After long idleness an overcharge may be required to bring the battery up to rated capacity.

Watering Cells. — The level of the electrolyte must be kept above the plates by adding distilled water from time to time. The frequency of adding water will depend upon the amount and rate of charging. The manufacturers of the battery supply an indicating filler which is of assistance in preventing slopping and over-filling.

Cleaning. — The trays and containers must be kept dry, and dirt or other foreign material must not be allowed to collect between or under cells. Dirt and dampness may cause leakage which may result in corrosion of the containers. The outside of the cans may be cleaned with a steam or air blast. If a container becomes leaky it should be returned to the manufacturer for repair.

DIMENSIONS, WEIGHT AND COST. — The Edison battery is made in two standard types, the plates of the A-type being approximately 4¾ by 9¼ in. and those of the B-type 4¾ by 4⅝ in. Plates of other dimensions can be obtained for special purposes. The sizes of cells are commonly designated by the type letter and a number which indicates the number of positive plates, as for instance, an A-6 cell has 6 positive and 7 negative plates. The several sizes of cells together with data on the dimensions and weight of each are given in the following table:

Digitized by Google

DIMENSIONS AND WEIGHTS OF EDISON CELLS

Size of cell	Over-all dimensions of cell, in inches			Weight in pounds	
	Length	Width	Height	Complete cell	Average per cell with trays and connectors
B-2	1.5	5.1	8.8	4.6	5.5
B-4	2.6	5.1	8.8	7.4	8.7
B-6	3.8	5.1	8.8	11.0	12.0
A-4	2.7	5.1	13.4	13.3	14.5
A-5	3.2	5.1	13.4	16.8	18.5
A-6	3.8	5.1	13.4	19.0	21.0
A-8	5.0	5.3	14.0	27.0	30.0
A-10	6.2	5.5	14.0	34.0	37.5
A-12	7.4	5.5	14.6	41.0	45.0

For services, such as the lighting of railroad cars, which require that the tteries work for long periods without the addition of water, the A-type plates e assembled in containers (designated by H) about 3 in. higher in each case han those indicated in the table, in order to obtain additional space above he plates for the electrolyte. The weight per cell is then about 15 per cent reater than the above.

Before the war the cost of Edison cells assembled in trays was approximately .91 per pound, including weight of trays and connectors. This is equivalent a cost of approximately $410 per kilowatt at the normal (5-hour) rate of dis-harge or $105 per kilowatt at the one-hour rate of discharge. The manu-acturers guarantee that these cells will show at least their rated capacity after ing used a specified time, the usual guarantee period for A-type cells being least 4 years and for B-type cells, at least 5 years.

BATTERIES, STORAGE, APPLICATIONS OF. — (*See also B teries, Storage, Alkaline Type; Batteries, Storage, Lead Type.*) The follow list shows some of the more important applications of storage batteries; th are briefly treated in the following pages.

Central Stations
- Emergency reserve — "Stand-by service."
- Load or voltage regulation.
- Taking peaks.
- Day load on small systems.
- Exciter reserve.
- Remote-control switch operation.

Isolated Plants
- Mine hoists, steel mills and other heavy motor regu tion; see Index.
- Carrying entire load during certain hours of light load
- Load and voltage regulation in office buildings or hot where electric elevators are in service.
- Giving 24-hour service in residences.
- Operation of drawbridges.

Other uses are:

- Regulation of long feeders; see *Trolley Systems, Ov head.*
- Propulsion of pleasure cars, trucks, street cars, s marine boats, launches, industrial trucks and tracti mine, and industrial locomotives, etc.
- Gas-engine ignition.
- Railway passenger-car lighting; see *Lighting of trains Electricity.*
- Railway signaling, see *Signaling, Railway.*
- Telephone and telegraph (q.v.).
- Portable and small stationary lamps.
- Fire and burglar alarm (q.v.).

Extent of Application in the United States. — The first applicati in America of storage batteries to central-station service was in 1886. In 19 there were in service in the United States, for central-station "stand-by" w 193 storage batteries of the lead-lead acid type, having a combined capacity approximately 177,000 kw-hr. at the one-hour rate of discharge. Most of th are of the Faure or Pasted type, some are of the Planté type, or a combinati of Planté and Faure types.

There were in service in the United States in 1920 approximately 700,0 cells of the lead-lead acid type, operating telephones, lighting railway cars a operating signals.

At the end of 1920 there were in operation lead batteries for other uses appro mately as follows:

For automobile, starting lighting and ignition 15,000,000 cells aggregati approximately 3,000,000 kw-hr.

For farm lighting plants 3,000,000 cells aggregating 1,000,000 kw-hr.

For electric passenger cars, street trucks, mine and industrial locomoti industrial trucks and tractors, 1,166,000 cells aggregating 444,000 kw-hr.

TAND-BY BATTERIES IN CENTRAL LIGHTING STATIONS. — nerly the storage battery in a central lighting station served a dual purpose: as a source of current in an emergency, and second, to take short peaks ad, thus cutting down the generating capacity in service and increasing economy of plant operation. In certain cases the batteries are used in this ner to-day, but owing to the desire always to have the full battery reserve ase of emergency, the peak battery feature is being abandoned and the d-by feature only is being retained.

his method is considered by some authorities to be even more conducive to nomy of station operation than that in which the battery was also used on peak, inasmuch as the presence of a fully charged battery behind the generat- apparatus permits station operation at a much higher load factor than were battery fully or partly discharged. Furthermore, as one of the important ors in the life of the battery is the amount of work it does, this life is greatly eased if the battery be used only for emergency service.

Connections for Battery and Its Auxiliaries, Stand-by Service. — . 1 shows a general standard scheme for the operation of a battery on a ire lighting system, either for peak work or stand-by emergency work. As be noted in this scheme, the neutral of the battery is connected to the tral of the system.

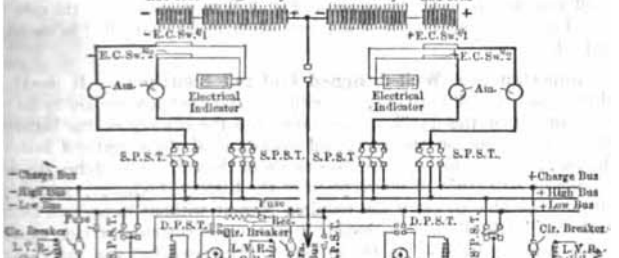

Fig. 1. Connections for Stand-by Service

Charging. — For stand-by emergency work it is standard practice to take battery off the bus for charge and in most cases the battery is floated on y one bus. In this service the battery is kept fully charged and floating on bus-bars continuously, except during charge. Except in case of an emer- cy discharge having been required from the battery, it will only be necessary ive the battery an occasional overcharge about once a week or once in two ks in order to keep the active material in proper condition. Since this over- rge is given at the normal rate for only a few hours, once every week or every weeks, a time for this overcharge can be selected when it will be safe to take battery off the bus. It will also be noted that on charge, sufficient voltage btained for charging the complete battery by adding to the bus voltage the tage of a simple charging booster. It is necessary with the 3-wire system to e two generators, one on each side of the system, in order to be able to charge two halves of the battery at different rates in case the battery has become balanced on discharge. The diagram shows a simple shunt motor driving se two booster generators.

Digitized by Google

End-Cells and Switches for Stand-by Service. — The connec between the two sides of the battery and the outside bus-bars of the sy are made through "end-cell switches," by means of which the number of on the system can be varied at will within certain limits. This sch shows two end-cell switches in parallel on each side of the system, this n ber of switches being installed in this case in order to provide sufficient capa for the discharge.

The number of end-cell switches necessary on each side of the system dep upon the current to be carried, upon the number of bus-bar voltages to be m tained from the battery simultaneously, and upon whether or not it is de to keep the battery on the bus during charge. It is frequently required to the battery on more than one bus. In such cases there must be one end switch on each side of the system for each bus. If it is not desired to keep battery on the bus during charge, and if the battery is to float on only one one end-cell switch on each side of the system will be sufficient, provided one end-cell switch has sufficient current-carrying capacity.

If, however, it is deemed advisable to keep the battery on the bus at all ti it will usually be necessary to have at least two end-cell switches on each of the system and the number of end cells required will be greater than number of end cells required where the battery can be taken off the bus charge. This point is referred to again in the next section.

It will be noted from the diagram in Fig. 1 that on discharge the cells connected in series and that the voltage on discharge is controlled by mean the end cells.

Importance of Well-designed End-cell Switches. — It should noted that the end-cell switches used with this standard scheme are by far most important of the auxiliary apparatus and the efficacy of the batter absolutely dependent on the successful operation of these end-cell switc The factors necessary for successful operation of the end-cell switches are, f there must be no chance of interruption of the battery discharge; second, switch must be able to carry the required current without dangerous hea or sparking. End-cell switches having a continuous current-carrying capa of 10,000 amperes are now on the market. These switches can carry 40 amperes for six minutes and the contact brushes can be moved from point point without injurious sparking or heating.

Number and Capacity of Cells for Stand-by Service. — The num and the capacity of the cells depends upon the lowest bus voltage maintai under normal operating conditions, the minimum allowable voltage at the of discharge in case of emergency, and the load required to be carried du emergency.

If the battery can be taken off the bus for charge, the number of cell the main battery will be equal to the lowest bus voltage (between outside bars) divided by 2.1. The number of cells in the entire battery will be e to the lowest allowable voltage in emergency divided by the final voltage cell at the rate of discharge required by the emergency. The difference betw the number of cells in the main battery and the total number of cells will course, be the number of end cells. When the total number of cells in battery is determined it will become necessary to put half the numbe cells, including half the end cells, on each side of the system.

If it is deemed necessary to keep the battery on the bus at all times du charge and discharge, the total number of cells will be determined as indic above, but the number of cells in the main battery will be equal to the voltage divided by 2.7, since this is the average cell voltage at the end of cha In this case, at least two end-cell switches on each side of the system will

ired. On charge one end-cell switch on each side of the system is connected
ie main bus and is set at such a position that the total voltage of the cells
ircuit during charge equals the bus voltage. The other end-cell switch is
o as to include the cells being charged. That is, at the start of charge, the
nit from the charging booster to one end-cell switch will include all of the
, and the circuit from the lighting bus to the other end-cell switch will only
ade sufficient cells to give the lighting-bus voltage. As the charge proceeds,
end-cell switch in the charging circuit will be shifted to cut out end cells as
r charge is completed, and the end-cell switch connecting the battery with
lighting bus will be shifted to cut out cells as the voltage of the battery comes
so that the voltage of the cells in circuit on the lighting bus can be held at
lighting-bus voltage.

t is seen that with this operation the end-cells included between the two end-
switches will have to carry the charging current plus or minus any current
nsferred between the battery and the lighting bus. It is thus apparent that
a this method of operation, unless especial care is taken to float the battery
he true lighting-bus voltage, the end cells will be worked unequally. It is
seen that, if it is desired to keep the battery on the bus at all times, the
ount of end-cell copper is considerably increased and the cost of the battery
allation is proportionately increased, for the number of end-cells required
reater than the number of end cells required when the battery can be taken
the bus for charge. On account of this increase in cost and the possibilities
unequal work on the end cells, it is desirable to install the simpler scheme
wn in *Fig.* 1.

Determination of Size of Stand-by Battery. — As an example of the
thod used in determining the number and capacity of cells required for this
e of work, suppose it were desired to install a battery to take care of an
rgency of 20,000 amperes for 20 minutes at a normal bus voltage of 230
ts with a minimum allowable voltage during emergency of 225 volts. The
minute rate of discharge is 8 times the normal rate, as shown in Figs. 3
6 in the article on *Batteries, Storage, Lead Type*, and it will be noted from
6 that the final voltage per cell at the end of this rate is 1.5 volts. The
l number of cells will be 225 divided by 1.5, or 150 cells. If it is desired
se standard practice, taking the battery off the bus for charge, the number
ells in the main battery will be equal to the normal bus voltage, 230, divided
2.1, or 110 cells.

t will, therefore, be necessary, in this case, to install a battery having 150
, including 40 end cells, each cell having a capacity of 20,000 amperes for
minutes. This battery will be installed with 75 cells, including 20 end cells,
each side of the neutral. In standard stand-by practice the 20 end cells on
h side of the neutral will be connected to the end-cell switches, with two
s per switchpoint for a few of the cells and with 3 or 4 cells per switch-
nt for the remainder of the end cells. A certain number of two-cell con-
tions will be required in order to take care of the variation in the bus voltage,
t may be necessary to cut in and out cells while the battery is floating.
: rest of the equipment necessary should be in accordance with the diagram
wn in Fig. 1.

LARGE REGULATING BATTERIES FOR RAILWAY WORK,
C. — Often the load (particularly a railway load) on the power house is
ject to frequent and violent fluctuations, causing severe strains on the gen-
ing apparatus in service and in many cases requiring the operation of a
ater number of units than would be necessary to furnish a steady average
l. This not only results in a lower load factor and consequent loss of econ-
y, but it reduces the surplus capacity of the generating station by the extra

amount of apparatus required in operation. Another loss in economy is to the rapid changes in the cut-off point of reciprocating engines, due to violent fluctuations of load. Fig. 2 shows a simplified wiring diagram of scheme generally used.

Carbon Regulator. — The carbon regulator shown in Fig. 2 consists piles of carbon disks arranged in two groups on opposite sides of the fulcr of a lever, the lever being subjected at one end to the tension of a spring at the other end to the pull of a coil connected in series with the main bus-bar. Variations in the force applied to opposite ends of this lever will increase the pressure on one group of carbon disks and decrease the pressure on the other, thus varying their relative resistances. These piles are connected in series across the battery terminals, and the field winding of the booster exciter is connected between the middle poi the battery and a point in the circuit between the two groups of carbon di Variation in the resistances of these two piles, produced by variation of pressure of the lever, will cause current to flow in one direction or the ot through the field of the exciter, thus controlling the operation of the boo and compelling the battery to charge and discharge with small variation current in the series coil.

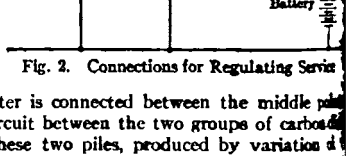

Fig. 2. Connections for Regulating Servic

In this manner the load on the generator can be maintained constant wi a few per cent on either side of the average value for which the apparatus been adjusted. The load on the generator is determined by the tension of spring, which may be adjusted to balance any average current in the series If the average load on the line should exceed for a considerable period of t the generator load for which the spring is adjusted, the battery will be subje to a sustained discharge which may in time exhaust its available capacity. on the other hand, the average load on the line falls off for a considerable pe of time, the battery will be subjected to a sustained charge which may prod excessive and unnecessary overcharge. To follow these variations in aver load, it is necessary to adjust the spring from time to time.

Automatic "Average" Adjustor. — In order to eliminate the neces for such frequent adjustment by hand in cases where the average load is c tinually changing and where the generator is capable of handling these compa tively slow changes, the automatic average adjustor has been designed. T piece of apparatus consists of a small motor connected by a reducing gear to drum which controls the tension of the carbon regulator spring. The armat of this motor is connected across the main bus-bars through a fixed resista which maintains a practically constant current through the armature. T field of the motor is connected across the terminals of the booster.

Whenever the booster voltage is in the direction to discharge the batte the motor field is energized and the motor revolves in the direction to incre the tension of the spring, thus gradually increasing the load on the gener and relieving the battery of its discharge until the booster voltage comes b to zero. If, on the other hand, the booster voltage is in the direction to cha the battery, the motor of the average adjustor will operate in the oppo direction, gradually relieving the tension on the spring and reducing the aver load on the generator until the booster voltage is again brought back to

he battery is again restored to its floating condition. This transfer of load en the battery and generator is brought about slowly so that the battery l free to relieve the generator of all quick fluctuations of load. The battery, ver, is relieved from a considerable amount of sustained peak charge and arge.

Load-limiting Device. — To prevent the average adjustor from throw- ad on the generator beyond its capacity, a load-limiting device has been ed. This consists of an electrolytic valve in series with the field e motor. Ordinarily this valve is short circuited by a switch. When the which regulates the tension of the spring has traveled to a certain point sponding to the maximum permissible load on the generator, a projection nted on the shaft of this drum engages with the switch and opens it, where- the valve prevents current from passing through the motor field in a tion to cause a further increase in the spring tension. The valve will, ever, permit the current to flow in the opposite direction so that as soon as load has decreased sufficiently to cause the battery to charge, the motor will rate so as to relieve the tension on the spring and at the same time permit the ch to close, thus restoring the original adjustment.

utomatic Current Stop. — While the capacity of a storage battery to stand an excessive momentary overload without injury is practically un- ited, the booster must be protected by an automatic circuit breaker. When- e the setting of this circuit breaker is exceeded on heavy overload and the aker opens, the entire maximum load is thrown on the generator. This ally results in opening the generator circuit breaker also and interrupting supply of current to the line. To avoid this and permit the battery to nish the maximum current which the booster can handle without danger of rloading the latter or opening the circuit, there has been designed an auto- tic current stop. This stop is arranged to automatically prevent the battery n discharging above a certain predetermined value, for which this stop has n adjusted. All load demand above this predetermined value is thrown upon generator. The generator is thus subjected only to the excess of load above maximum capacity of the battery booster, instead of having the entire load he line suddenly thrown on it when the battery circuit breaker opens. The ustment of this automatic current stop can be changed within certain limits meet the requirements.

Batteries for Controlling Alternating-current Loads. — For controlling tuations of an alternating-current load a solenoid which is responsive to the rgy component of the alternating current is substituted for the series coil wn in Fig. 2. The general operation of this scheme is the same as described ve, except that it is, of course, necessary to discharge the battery on to the rnating-current bus through suitable alternating-current-direct-current trans- ming apparatus. There are in service at present several battery installations ich regulate fluctuating alternating-current loads. Most of these installa- ns are based on the carbon regulator principle, as outlined above.

Number of Cells and Capacity of Cells and Booster. — The number and acity of cells required for regulating work depends upon the bus voltage and on the nature of the fluctuating load. It is also frequently desirable to ize a regulating battery for emergency and peak work, and the extent of the ergency and peak requirements will also be a factor in fixing the capacity of battery. The number of cells installed will be equal to the bus voltage ided by 2.1, since this is the floating voltage per cell. A reference to Fig. 2 ws that during the regulation of load fluctuations all of the battery discharge ws through the armature of the booster generator. It is thus seen that it ecessary for the booster to generate sufficient voltage to make up for the drop

in battery voltage on discharge. This drop in battery voltage depends upon capacity of the battery, and the amount and duration of the discharge. fore the booster can be properly designed it will be necessary to have comp data on these points.

Emergency Work. — For emergency work, where the battery is carr the entire load without the assistance of any generating apparatus, it ma may not be necessary to keep the booster in circuit, depending upon whe or not it is desired to maintain a constant bus voltage. If it is not desire maintain a constant bus voltage, a saving can be effected by cutting the boo out of circuit and allowing the battery to discharge directly on to the syste

Peak Work.— For peak work, where the battery must work in par with the generators, it will either be necessary to keep the booster in ci in order to maintain the same voltage as the generator or else to give the ge ators a drooping characteristic so that the battery can discharge in par with the generators without the aid of the booster.

Current Capacity. — If it is desired to float the battery on the sys at all times in order to regulate load fluctuations, it will be possible to float battery about 75 per cent fully charged. If this battery must have a defi capacity always available for peak or emergency work, it is seen that the bat must be of sufficient capacity, when 75 per cent fully charged, to deliver the l called for by the emergency or peak conditions.

Determination of Size of Regulating Battery. — In all cases whe battery is to be considered for any one of the above conditions or any combi tion of them, it is recommended that the complete data summarized belo sent to the battery manufacturer with a request for a complete report cove the battery and accessories recommended to suit the conditions. The d necessary are as follows:

Number, type and capacity of boilers, if the plant is a steam plant.
Schedule of boiler operation, if the plant is a steam plant.
Number, type and rating of generators.
Schedule of generator operation.
Bus voltage maintained.
If the generators are of the alternating-current type, give frequency, num of phases, and the number and rating of any static transformers used
If the station in question is a substation, describe the complete substa equipment along these same lines.
Give complete 24-hour load curve showing half-hour readings of the t load on the station bus bars. A graphic recording meter chart wil sufficient, if such an instrument is available.
If possible, obtain five-second readings on the total indicating ammete wattmeter, over a period of one-half hour during the time of maxim fluctuations.
If the battery is required to assist the generators on the peak, give the amo of load in kilowatts required from the battery and the length of time load is required. It would be well to have an exact load curve show the shape of this peak, if it is possible to obtain such a record.
If the battery is to be used for emergency, give the amount of the load the time over which this emergency extends. In all cases state the ex nature of the load required, that is, whether it is a motor load, a ligh load, etc.

BATTERIES FOR REMOTE-CONTROL SWITCH OPERATION

It is standard practice in central stations of any magnitude to install a sto battery of sufficient capacity to give ample insurance against interruptio

switch-control circuit. It is the usual practice to utilize this battery, not for the operation of the remote-control switches, but for the operation of signal lamps and a sufficient number of emergency lamps throughout the on. In some stations the remote-control switches are operated from the ter bus bars, but it is better practice to operate these switches together with r signal lamps and the emergency lamps from a separate source of power.

ontrol Battery Connections. — Fig. 3 shows a scheme which is more or standard with the larger central-station companies. This figure shows a or-generator set consisting of an in- ion motor driving a direct-current rator whose voltage can be varied 1 110 volts up to 168 volts, the r voltage being required to com- dy charge the 62 cells in series. nder normal operation the battery ated on the 130-volt bus with the or-generator set, the battery switches g thrown into positions 1 and 2. It be noted that with this arrange- t all 62 of the cells are floating the bus. When it becomes necessary to charge the battery, the battery tches are thrown into positions 1 and 4, and the generator voltage is raised iently to start the charge of the entire 62 cells. With this arrangement voltage at the load bus bars will be the voltage of 55 cells. At the finish of rge the battery switches are thrown into positions 3 and 4. It will be noted in these positions the group of 7 end cells is out of circuit, as they have re- ed their complete charge, and the motor-generator set will be furnishing er to charge the 55 cells and to carry the load.

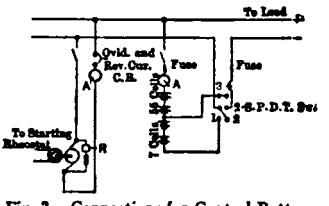

Fig. 3. Connections for Control Battery

ize of Battery. — With this arrangement the voltage at the bus bars may y from 145 volts to the minimum voltage of the battery on discharge. The nber of cells for this scheme can be varied to suit the voltage conditions. e capacity of the battery is fixed by the maximum current demand, the total pere-hour current demand over the period of estimated possible shutdown, l the minimum allowable voltage on the load bus bars. With these condi- s known, it will be possible with the aid of trade catalogues showing the ge and discharge curves of the battery and the battery capacity at various s, to select a battery to suit the conditions.

Control Battery on Exciter Bus. — If the oil-switch load is furnished from exciter bus it will be necessary to float the emergency battery on the exciter s, or to supply automatic means for throwing the battery on the exciter bus en the voltage of the exciter bus drops below a certain predetermined value. this method is used, unless the battery is of sufficient capacity to carry the ire exciter load, it will be necessary to place a reverse-current circuit breaker ween the battery and the exciter load, so that when the exciter bus "goes d" the battery will be automatically cut off from the exciter bus and left the remote-control switch bus.

EXCITER BATTERIES. — It is standard practice with the larger central- tion companies to install a battery of sufficient capacity to carry the total ximum exciter load for from one hour to two hours continuously. The nber of cells will depend upon the voltage of the exciter bus, which is usually) but is sometimes as high as 250 volts.

If it is desired to maintain constant the voltage on discharge, it will be neces- y to utilize end cells by means of an end-cell switch. In this case the number cells in the main battery will be equal to the bus voltage divided by 2.1, and

the total number of cells in the battery will be equal to the bus voltage divi by the voltage per cell at the end of discharge for the discharge rate used. T difference between the number of cells in the main battery and the number cells in the whole battery will be the number of end cells. These end c can be connected to the points on the end-cell switch singly or in pairs, d pending upon the voltage regulation desired. If it is not desired to maint a constant voltage on an exciter bus, the end cells will not be required. T total number of cells will be kept on the bus bars and as the voltage of th battery falls the field excitation of the generators can be maintained constant changing the generator field rheostats.

The ampere capacity of the cells will be determined by the amount and dur tion of the load to be carried. Knowing the ampere capacity, the length time and the minimum allowable voltage during the period, the number of ce and the type of battery can be determined by the use of the charge and di charge curve and battery rating given in trade catalogues.

LINE BATTERIES FOR RAILWAY WORK. — (*See also Trolley Sy tems.*) The functions of a storage battery floating on an electric railway li at a distance from the power house are as follows:

1. To improve the line voltage and displace a certain amount of feed wire.
2. To relieve the power house of fluctuations of load.
3. To keep the cars moving when the power supply is temporarily interrupted.
4. To supply power for the operation of a few cars or lights at night when t power house is shut down.

Location. — Before any calculations can be made, the location of the batte must be decided. Where there are no other determining factors, the batte would ordinarily be located about three-quarters of the distance from the pow house to the end of the line, or, if the line is fed from both ends, midway betwe the feeding points. In some cases the location of the maximum momentar load, due, for example, to a severe grade or to the passing of two cars at a sidi will influence the location of the battery. In other cases the location of a su able piece of property owned by the company, or the location of a car ba where attendance would be available, may be the determining factor.

Line Battery without Boosted Feeder. — In this class of line-batte installation the number of cells is determined by the average line voltage the proposed battery site on the basis of approximately 2.1 volts per cell. Th if the average voltage at the battery site, as determined by voltage readi taken at frequent intervals, such as five or ten seconds, over a considerab length of time, should be found to be 500 volts, the number of cells suitable f this average voltage would be 238. If it is found that, owing to changes in loa conditions at different hours of the day or on different days of the week, th average voltage varies considerably for prolonged periods of time, it may b necessary to provide means for changing the number of cells connected to th line. This may be accomplished by separating a group of cells at one end o the battery, and arranging suitable switches so that these cells may be connect either in series with the main battery when the average voltage is high or i parallel with an equal number of cells of the main battery when the averag voltage is low It is found preferable to connect these end cells in parallel wi a portion of the main battery, and thus keep them active rather than disconne them from the system entirely.

Calculation of Size of Battery Required. — See article on *Trolley Syste Overhead*, and *Bulletin No. 134* of The Electric Storage Battery Co.; also Ch 44 of Lyndon's *Storage Battery Engineering.*

Digitized by Google

BATTERIES FOR SMALL CENTRAL STATIONS AND ISOLATED PLANTS. — The objects of a battery installation in small electric lighting and power plants may be any one or all of the following:

1. Twenty-four-hour service with but a few hours daily operation of engine.
2. Reduction in size of engine and dynamo otherwise required.
3. Improved voltage regulation.
4. A source of current during breakdown of machinery, or while repairs are being made.

Twenty-four-hour Service. — In this service the battery supplies the current during the hours when the engine is not running. As the capacity of a battery of normal size in many instances in this class of work, especially in residential service, is not generally exhausted in daily operation, it may usually be charged by running the engine and dynamo only two or three hours each day at the most convenient time. In summer, when the lighting hours are shorter, it may be sufficient to charge only once in two or three days.

Reduction in Size of Generator. — If the plant is so designed that the combined capacities of the dynamo and the battery are equal to the maximum load requirements, a smaller engine and dynamo may be installed than would be required if the dynamo alone had to carry the total maximum load. The battery will then be discharged in parallel with the dynamo, to assist it by taking a part of the total load on special occasions, as when the maximum number of lights is in use.

Improved Regulation. — Objectionable fluctuations of voltage and consequent flickering of lights, due, for example, to the operation of an electric elevator or other motor work, may be eliminated by floating the battery across the lighting bus.

Emergency. — In case of temporary derangement of the engine or dynamo, which may occur when the lighting service is most important, or in case repairs to the machinery are required, a battery will serve to tide over the break and avoid any interruption in the current supply.

Small Regulating Battery with Counter Cells. — Fig. 4 shows an ideal arrangement for small battery lighting plants where the capacity of the battery does not greatly exceed 300 ampere-hours at the normal rate. This figure shows 62 cells in the main battery with 8 counter cells, the whole being designed to operate on a 110-volt bus-bar. It will be noted that the battery is charged with two halves in parallel. During charge each half is placed across the bus-bars in series with a fixed resistance. At the beginning of charge the counter cells are all in circuit and assist the fixed resistances in reducing the bus voltage to the proper charging voltage. The counter cells are cut out of circuit as the battery voltage rises. On discharge, all of the cells in the main battery and the full number of counter cells are connected in series. As the voltage falls on discharge the counter cells are cut out of circuit, thus maintaining a steady voltage at the bus-bars. The number of cells and counter

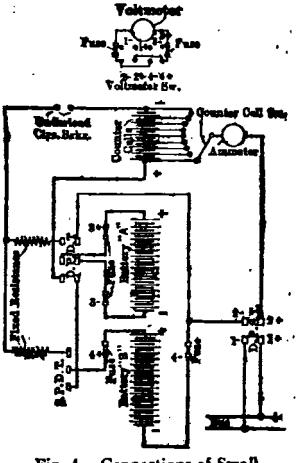

Fig. 4. Connections of Small Regulating Battery

cells shown in the figure are selected to maintain a steady voltage of 110 volts at the normal rate of discharge. The counter cells are composed of unformed battery plates or grids, and since they have very little active material they have practically no capacity. Each counter cell will, however, furnish an opposing voltage of approximately 2.3 volts; this counter voltage is practically constant over the range in current demand for an ordinary small station.

Small Regulating Battery with Charging Booster. — For larger-sized plants this method of operation is not economical owing to the loss in the charging rheostats and the loss in the counter cells. For a straight lighting plant where a battery of more than 400 ampere-hours capacity is required, it is usual to use the scheme shown in Fig. 5. It will be noted in this scheme that the cells in series are connected to the bus for discharge, the voltage being controlled by cutting in and out the end cells at one end of the series. On charge the required voltage to complete the charge is obtained by adding to the bus-bar voltage the voltage of a small booster generator.

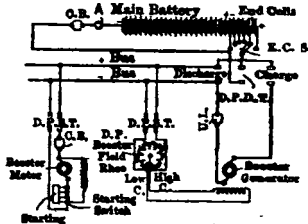

Fig. 5. Connections of Small Battery with Booster

Size of Battery. — For ordinary small plants which operate at a bus voltage of 110 the standard equipment consists of 64 cells, including 12 end cells. The capacity and type of the cells are fixed by the ampere-hour requirements and the minimum-voltage requirements on discharge. For any bus voltage other than 110 volts the complete number of cells, including the end cells, can be determined by dividing the minimum allowable bus voltage by the minimum voltage per cell at the end of discharge at the rate which will be used. The number of cells in the main battery will be equal to the bus voltage divided by 2.1. The difference between the number of cells in the main battery and the total number of cells will give the number of end cells. An end-cell switch having one point more than the number of end-cells required will be necessary.

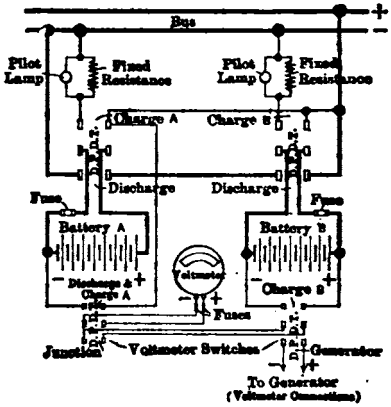

Fig. 6. Connections of Small Battery without Booster Cells

Small Battery without Voltage Regulation. — If voltage regulation on discharge is not required, the scheme shown in Fig. 6 can be used. It will be noted that this scheme is practically the same as shown in Fig. 4 except that the counter cells have been omitted and only 56 cells are used.

Small Battery on 3-Wire System. — In small central stations or isolated plants which utilize the 3-wire 110 to 220-volt system, the battery is arranged in two halves, one on each side of the neutral. A group of end cells on each side of the system and two booster generators direct con-

nected to one motor are used. This scheme of operation is shown in general in Fig. 1 which is described in detail above in the section on *Stand-by Batteries*.

Small Battery for Low-voltage Lighting — So-called Farm Lighting Plants. — Since the advent of the tungsten lamp 32-volt plants are growing very popular.

Numerous manufacturing concerns have gone extensively into this business and there are several concerns to-day marketing these plants by the thousands. One concern in America during 1920 marketed considerably more than 50,000 complete farm lighting plants.

All of these plants consist of a gas engine driving a 32–42-volt generator, a switchboard and a storage battery. The capacity of the low-voltage farm lighting plant varies from ½ kw. to 5 kw. Usually where the capacity required exceeds 5 kw., especially when the distance of transmission exceeds a few hundred feet, it is better to go to 110 volts, as the low-voltage plant is designed primarily for small loads and short distances of transmission.

There are various schemes of operation which are now successfully used, but they all include a storage battery. These schemes vary all the way from the one extreme, where only sufficient storage battery is installed to automatically start up the engine-generator unit when the load is switched on, to the other extreme where a storage battery of quite large capacity is used and all the load is usually taken from the storage battery, the engine generator set being run only at intervals (about once a week) to charge the battery.

Because of the multiplicity of schemes it will not be attempted here to describe any of them in detail and it is suggested that those interested obtain literature from numerous manufacturing concerns putting out these plants.

As an evidence of the growth in the use of storage batteries for this application there were in service at the end of 1920 in low-voltage farm lighting plants approximately three million storage battery cells aggregating a capacity of one million kilowatt-hours.

SMALL REGULATING BATTERIES FOR ELEVATORS, ETC. — Fig. 7 shows a scheme of load regulation which has been adopted as standard for situations where it is desirable to operate a lighting load and a fluctuating motor load from the same generator. This scheme is known as the "constant-current" scheme.

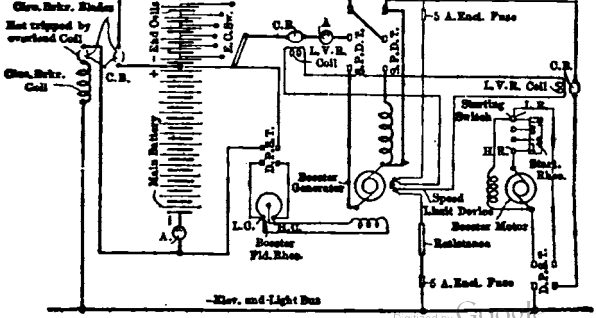

Fig. 7. Connections for "Constant-current" Regulation

Digitized by Google

Elevator Load Regulation. — This scheme finds its greatest use in office buildings, hotels, etc., where electric elevators are in service. The load on such a plant is a very fluctuating one on account of the heavy current required for starting the elevators. This starting current is generally about twice the elevator running current. Moreover, as the elevators are not in service continuously, the average current per elevator is usually much less than the running current per elevator. There is generally, therefore, a considerable difference between the average load on the station and the maximum momentary load. This difference varies with the number and type of elevators, the character of elevator service and the magnitude of the lighting load. If the fluctuations above and below the true average are a comparatively large percentage of the true average load, they are liable to cause fluctuations in the generator voltage with consequent flickering of lights. In addition to this objection, the generating capacity necessary without a battery must be increased and it is necessary to operate the whole plant at a poor load factor.

Constant-current Scheme. — Reference to Fig. 7 shows that the battery and the elevator circuit are in multiple, and that the booster is in series between the lighting bus and the elevator bus. The booster in the constant-current scheme, as the name would imply, is wound in such a manner that the current going through it is rendered constant. Therefore, the parallel system of battery and elevator circuit can only draw a constant current from the generator, and it follows that all of the fluctuations due to the elevator load must be taken by the battery. When the elevator current is greater or less than the average, the difference is given or absorbed by the battery. It is important to note that the battery voltage applied to the elevator motors is that of the battery alone and is therefore variable. Ordinarily this is not a disadvantage as the heavy load is caused by the starting of motors, in which case high voltage is not an object.

It will be noted that the scheme given in Fig. 7 shows end cells. These are used for regulating the voltage on the lights when the generator is shut down and the booster is out of circuit, the battery carrying the entire lighting and elevator load.

Other Uses of Small Regulating Batteries. — Electric-elevator service has been taken as an example, as this is the class of work usually encountered. This scheme may be used, however, for other fluctuating loads, such as are due to electric cranes, shop tramways, mine hoists, etc., and in general for any fluctuating load where the maximum load is greatly in excess of the average load and constant potential on the motor bus is not required.

For fluctuating loads where constant potential on the power bus is required, the scheme described above under *Large Regulating Batteries* and shown in **Fig. 2** should be used.

Number and Capacity of Cells. — The number of cells in the main battery is usually determined by dividing the bus voltage by 2.1. The number of end cells necessary will be determined by the minimum allowable voltage and the final cell voltage at the end of discharge when the battery is carrying the entire load. The capacity of the battery will be determined by the amount of the fluctuations to be taken care of by the battery and the amount of load to be taken out of the battery when the generating apparatus is shut down.

Booster. — It will be noted in Fig. 7 that the diagram shows a differentially-wound booster. The desired regulation is obtained by means of the series field which carries the constant current between the lighting bus and the elevator bus, and which is designed to produce a booster voltage in the direction to oppose this current. The relation between the series field and the shunt field is adjusted for any given average load.

Digitized by Google

A straight shunt booster with the field controlled by the carbon regulator as shown in Fig. 2 can be utilized with this constant-current scheme, if the solenoid is connected between the lighting bus and the elevator bus and if the carbon regulator actuated by this solenoid is utilized to control the field of the exciter as shown in Fig. 2. In all other respects this carbon regulator constant-current scheme operates according to the same general principle as the scheme for the differentially-wound booster.

It will be noted also that with the scheme shown in Fig. 2 the booster is in series with the battery and carries only the battery current, whereas in the constant-current scheme shown in Fig. 7 the booster carries the average current of the fluctuating load. The relative magnitude of the fluctuations as compared with the average will determine which booster will be least expensive and may, therefore, be a factor in deciding between the two schemes.

Two- and Three-wire Systems. — The scheme shown in Fig. 7 is for a two-wire system. This same general scheme is utilized for a three-wire system where the motor load is connected across the outside wires and the lights are balanced on each side of the neutral. Where the three-wire system is used, the general principles of the scheme are exactly the same as shown in Fig. 7, except that it will be necessary to have one booster generator and one set of end cells on each side of the system.

ELECTRIC-VEHICLE BATTERIES. — The growth in the use of storage batteries for electric vehicle propulsion has been enormous during the past few years. This is especially true in case of street trucks, industrial trucks and tractors and mining and industrial locomotives. The voltage and capacity of the battery necessary to operate any given vehicle is usually specified by the manufacturer of the vehicle, as the design of the vehicle determines the number of watt hours per car mile under certain definite conditions. Unless the vehicle user is a battery expert and a vehicle expert, it is not advisable that he specify either the number or capacity of cells to be used.

Desirable Characteristics of Vehicle Batteries. — The following are the chief characteristics of a good vehicle battery.

1. Low internal resistance, because of high current demand required for acceleration or for ascending grades.

2. Small capacity temperature coefficient, in order that the capacity of the battery shall not be unduly affected by chilling of the cells.

3. Voltage characteristic as nearly flat as possible under average conditions of discharge.

4. Construction of sufficient ruggedness to prevent breakage of parts in ordinary service.

5. Assembly such as to minimize possible labor and attention for flushing, cleaning, removing short-circuits, etc.

6. Ability to stand some abuse, as the average vehicle operator is not a battery expert.

The use of batteries for vehicle work is treated in greater detail in the article on *Automobiles, Electric.*

DRAWBRIDGE BATTERIES. — It is becoming standard practice to install storage batteries in connection with electrically-operated drawbridges, chiefly as an insurance against the interruption of power from the generating station. The voltage of drawbridge motors is usually 220 or 500. The number of cells and the capacity of the cells to meet the requirements will depend upon the maximum and minimum allowable voltages, and the total energy required from the battery before recharging.

Size of Drawbridge Battery. — Assume a 2000-ton bascule lift bridge with a 185-foot span. This bridge is to be operated with 220-volt motors. The time

required to open or close is 1¼ minutes, or a total of 3 minutes for a complete opening and closing. Assume the following conditions: The battery will be required to open and close the bridge 40 times on one charge, the maximum allowable voltage during bridge operation will be 250 and the minimum allowable voltage 200; the average current demand over a complete cycle will be 100 amperes with a maximum momentary current demand of 320 amperes lasting a few seconds.

It is seen that the total energy in ampere hours required for the 40 complete openings and closings of the bridge would be equal to $\frac{3 \times 100 \times 40}{60} = 200$ ampere hours during a total period of $3 \times 40 = 120$ minutes or 2 hours. The battery, therefore, must have a capacity not less than 200 ampere hours at the 2-hour rate of discharge. Bearing in mind the voltage limits specified above, an inspection of Figs. 3 and 6 in the article on *Batteries, Storage, Lead Type*, will show that the battery capacity will be fixed by the voltage limits in this case and not by the ampere-hour requirements. In any case that may arise, if there is any doubt as to which requirement will fix the capacity of the battery, select a battery having the ampere-hour capacity required and then examine Fig. 6 to see if a battery having this ampere-hour capacity will meet the voltage requirements.

For a maximum allowable voltage of 250 and a floating voltage of 2.1 volts per cell, there would be required 120 cells. Referring to Fig. 6 and using the upper curves, for plates 10¾ inches square, we will assume that the battery must not discharge at a higher rate than 4 times the normal rate. At 4 times the normal rate the voltage drops almost immediately to 1.9 volts per cell. With 120 cells the voltage would drop to 228 volts. It is noted that the normal rate of this battery will be 80 amperes, and the average discharge of 100 amperes will be 1¼ times the normal rate. By interpolating a curve between the normal curve and four times the normal curve, it is seen that with an average discharge at this rate for 2 hours, the voltage per cell at the end of the two hours, with 100 amperes flowing, will be approximately 1.9 volts, or the voltage of the 120-cell battery will be 228 volts. If, now, the current were increased to 320 amperes (4 times the normal rate), and this current flow continued for an appreciable period of time, the voltage would drop further, by about 20 volts, leaving a voltage of 208 at the battery terminals. It is, therefore, evident that the voltage requirements will be met by a 120-cell battery having a capacity of 80 amperes at the normal rate.

A battery having a normal rate of 80 amperes could be discharged at 1¼ times the normal rate for something over 4 hours. It is, therefore, seen that the battery which we selected has more than ample ampere-hour capacity to meet the requirements, its capacity being fixed by the momentary current demand.

It usually will be found that the capacity of cells required for drawbridge operation is fixed by the maximum discharge rate and not by the ampere-hour capacity at the average rate.

Size of Charging Generator.— If a separate power plant is installed for the operation of the drawbridge, it will be well to install an engine-generator set having an available voltage range of from 220 to 325 volts. There may be required 2.7 volts per cell for charge, which with 120 cells would call for 324 volts. If the battery installed is of sufficient capacity to carry the bridge a complete day or more on one discharge, it is good practice to install a generator of only sufficient capacity to charge the battery at the normal rate and to

Digitized by Google

emergencies, the generator must have sufficient capacity to carry the maximum current required by the bridge motors.

IGNITION BATTERIES FOR PORTABLE AND STATIONARY GAS ENGINES. — Probably the largest single application of storage batteries to-day is for the starting, lighting and ignition of gasoline automobiles. There are now in service in this use storage batteries of the lead-acid type numbering approximately 15,000,000 cells with an aggregate capacity of approximately 3,000,000 kw-hr. Batteries of from three to twelve cells (6 to 24 volts) are used for this purpose, but the common standard to-day is a 6-volt (3-cell) battery with a capacity of from 80 ampere hours to 150 ampere hours. For this purpose the essential requirement is a battery of as low internal resistance as can be designed compatible with a reasonable life.

For further details in regard to automobile starting and lighting batteries the reader is referred to the various manufacturers of automobiles and starting and lighting equipment and also to the bulletins and catalogs of the various storage battery manufacturers. See also *Ignition, Electric* and *Starting and Lighting Systems for Automobiles.*

For stationary engines of large capacity it is customary to use a voltage ranging from 90 to 110 volts. Glass-jar batteries of sufficient ampere-hour capacity to meet the requirements are installed in a cabinet in the main engine room. The number of cells in the main battery necessary to float on the system will be equal to the bus voltage divided by 2.1. The capacity of the battery will depend upon the number of ampere-hours required on one charge and the minimum allowable voltage during a discharge. These requirements being known, the correct number and type of cells can be determined from the characteristics of the batteries (*see Batteries, Storage, Lead Type and Alkaline Type*), in connection with trade catalogues.

Occasionally, there is installed in addition to the cells in the main battery a group of end cells which can be cut in on discharge by means of a single switch and thus hold up the voltage of the battery. The number of cells in this end-cell group usually varies from 3 to 8, depending upon the voltage requirements.

Usually a large ignition battery is charged by placing the two halves in parallel, each half being connected to the bus through a fixed resistance somewhat after the fashion explained above and indicated in Fig. 6.

BATTERIES FOR STEADY-VOLTAGE REQUIREMENTS. — It is frequently required to obtain a source of direct current with a steady voltage, as, for instance, in electroplating, instrument calibration, telephone work, laboratory work, etc. In such cases there should be chosen a battery that has more capacity at the normal rate than the ampere hours actually required before recharging, in order that the battery may be worked on the flat portion of the discharge curve.

For instance, to furnish 10 amperes continuously for 8 hours at about 20 volts, with a variation of 1 per cent between the beginning and the end of the discharge, the time of discharge must be limited to about 50 per cent of the total time. A cell having a capacity of 10 amperes for 16 hours should, therefore, be chosen.

TYPES OF LEAD CELLS. — A secondary or storage cell is any voltaic couple which can be regenerated, after exhaustion, by passing a current through it in a direction opposite to the direction of current flow when the couple delivers energy to the external circuit. Three types of storage batteries are now in use in this country, the Planté type, the Faure type, and the alkaline or Edison type. The special features of the alkaline type are treated in a separate article, viz., *Batteries, Storage, Alkaline Type.*

Planté Type. — The principle of the storage battery was discovered in 1801 by Gautherot, a Frenchman. However, practically nothing further was done until 1860 when Gaston Planté constructed a storage cell consisting of two lead strips immersed in dilute sulphuric acid. Planté found that, by giving this cell a long charge by passing the current through in one direction, and then giving the cell a long charge in the opposite direction, and repeating this cycle many times, the capacity of the cell was considerably increased. Little improvement was made in the Planté cell until a number of years after Planté's discovery.

At present the Planté type of storage battery is made by preparing a pure lead plate with a large superficial area exposed and then oxidizing the surface electrolytically so that it is covered with lead peroxide. A plate formed this is a positive plate. To form a negative plate the peroxide, after electrolytic formation, is reduced to metallic sponge lead by reversal of current. In this manner a thin layer of active material which is porous and which adheres firmly to the supporting lead plate is produced.

Use of Planté Type. — The Planté type is used chiefly where weight and space are of no great importance.

Faure or Pasted Plate. — In 1880 Camille A. Faure, in France, and Charles F. Brush, in America, simultaneously developed the "pasted" type of storage battery. In this type of storage battery the active material, on both the positive and negative plates, instead of being formed electrolytically, as was done by Planté, was applied, in the form of a paste, to a stiff lead-antimony alloy supporting grid. This type of plate is now commonly called the Faure type of plate, and it was the discovery of this type that gave the storage battery its first commercial impetus.

Use of the Faure or Pasted Plate Type. — The Faure type is used chiefly where it is desired to obtain the greatest possible capacity with a minimum of weight and space occupied. This type is used chiefly for vehicle propulsion and for central-station "stand-by service."

THEORY. — The electrochemical theories of the storage battery are quite complicated and the various authorities on these subjects do not agree on all details. In this outline no attempt will be made to cover the various theories in detail; only the simplest fundamental chemical actions will be described.

Positive and Negative Plates. — The terms positive and negative are employed throughout this article in accordance with engineering usage; that is, the positive plate is the one from which the current flows on discharge and the negative plate is the one into which current flows on discharge. In a lead battery the positive plate, on which the lead peroxide is formed, has a comparatively hard surface of a reddish-brown or chocolate color, while the negative plate, which carries the sponge lead, has a much softer surface of a grayish color.

Chemical Reactions. — The active elements of the lead-lead acid type battery consist of lead peroxide (PbO_2) on the positive plate, sponge lead (Pb) on the negative plate and dilute sulphuric acid (H_2SO_4) for the electrolyte. Whatever the secondary reactions may be, it is agreed that the final result of discharge is the formation of lead sulphate ($PbSO_4$) on both the positive and negative plates, the SO_4 radical of the sulphuric acid combining with the lead of both plates to form this compound, resulting in the formation of some water (H_2O), with a consequent decrease in the specific gravity of the electrolyte. On charge the electric current splits up the lead sulphate ($PbSO_4$), returning the SO_4 radical to the electrolyte, oxidizes the positive plate to its original condition of lead peroxide (PbO_2) and reduces the negative plate to its original condition of sponge lead (Pb). This action may be represented as follows:

$$\underset{+\text{Plate}}{PbO_2} + 2H_2SO_4 + \underset{-\text{Plate}}{Pb} = \underset{+\text{Plate}}{PbSO_4} + 2H_2O + \underset{-\text{Plate}}{PbSO_4}$$

If this equation read from left to right is the equation of discharge; if read from right to left, it is the equation of charge. In practice, on charge, towards the end of charge some of the water (H_2O) is split up by the current into its component parts, hydrogen (H) and oxygen (O), the hydrogen being liberated at the negative plate and the oxygen at the positive plate. This occurs whenever the intensity of charging current is greater than can be utilized in decomposing the lead sulphate remaining in the plates.

DESIGN. — The capacity of a storage-battery plate depends not only upon the amount of active material but also upon the active surface exposed to the electrolyte. Plates should therefore be designed to expose a maximum amount of surface consistent with the strength of the supporting grid or lead base. In order that the active material of the plates can be acted upon by the electrolyte, it should be as porous as is consistent with its proper support by, and proper contact with, the grid or supporting lead base.

Sponge lead and lead peroxide possess little mechanical strength. Lead peroxide is a poor conductor. Since mechanical conditions require a certain amount of rigidity in the plates and since the current generated by the active materials must be carried away, a battery plate must necessarily consist of two parts, viz., the grid or supporting base and the active material which in the lead battery is finely-divided porous sponge lead or porous lead peroxide.

Lead Plates. — There are certain ideal requirements to be met by a lead storage-battery plate, among which may be mentioned:

1. The grid and active material should be so proportioned as to obtain, as near as possible, uniform current distribution over the entire surface.
2. The active material should be applied to, or formed on, the grid in such a manner that good electrical contact exists when the plate is new and this contact should be maintained during the life of the plate.
3. In pasted plates and pellet plates the grid should be of material that is not injuriously affected by the electrolyte.

Digitized by Google

4. The material of the grid should be such as to insure a minimum of loc action between itself and the active material.

5. The surface of the active material exposed to the action of the electroly should be as great as is compatible with proper mechanical strength and suitable provision for the natural expansion of the active material in use.

6. The plates should be so made and assembled as to allow the maximum pos sible diffusion of the electrolyte through and around the plates and through th containing vessel.

7. The grid or lead base should be of ample cross section to carry the curre generated under working conditions without undue loss.

8. The lugs which collect the current from the grids should be of ample cro section, and when designed for heavy currents they should be so arranged as t distribute the current uniformly through the grid.

9. The negative, sponge-lead plate should be constructed so that the spong lead retains its porous character and does not grow hard and dense in servic and thus lose its capacity.

10. The lead and the electrolyte should be pure; otherwise secondary reaction will be set up, with a consequent decrease in efficiency.

Of the many lead plates on the market to-day, the most commonly used are the "pasted," Planté and composite or "pellet" plates. Cuts showing the construction of the various types of plates may be found in manufacturers' catalogues; the essential features of design are briefly discussed below.

Pasted Plates. — The pasted plate is usually made by applying to a hard lead-antimony grid a paste made of some oxide of lead, usually litharge (PbO) or red lead (Pb_3O_4), and some liquid and other substances. In the so-called "Iron-clad" battery made by the Electric Storage Battery Co., the active material is held in perforated hard rubber tubes. Various substances are used to mix with the lead oxide, the idea being to increase the hardness, porosity, toughness and conductivity. Some of the substances used by different manufacturers include anthrocine, glycerine, graphite, potassium silicate, asbestos, ammonium-sulphate, etc.

"Forming" of Pasted Plates. — After the grid is filled with the paste the plate is dried. After being completely dried a number of plates are assembled in a forming bath of dilute sulphuric acid with dummy lead plates for the opposite electrode and the forming charge is given by passing the proper current through the voltaic couple thus formed. Positive plates are formed by connecting the plates to be formed as the anode; the current oxidizes the lead oxide further to lead peroxide (PbO_2). Negative plates are formed by passing the current in the opposite direction, reducing the lead oxide to sponge lead. After the forming charge the plates are dried and are ready for the market.

Planté Plates. — Of the various types of Planté plates, among those most commonly in use may be mentioned the central-web type; the cast-lead having no central web; and the composite or "pellet" type. The main idea in any of these methods of manufacture is to produce a large surface on which to form the active material.

Central-web Type. — In the central-web type there is a solid sheet or "web" of pure lead on which the ribs are formed. This web prevents the circulation of the electrolyte through the plate. The ribs are formed from the original lead plate, either by rolling, spinning or cutting. In the rolling and spinning processes the plate is formed from a lead blank by means of a number of steel disks placed side by side and separated by small spacers on a shaft. The lead blank is passed between two sets of disks by forward and backward movements. The disks gradually work deeper into the plate and squeeze it

Digitized by Google

lead into the spaces between the adjacent steel disks. In the cut type of plate the ribs are formed from the lead sheet by a tool, which at each stroke turns up one complete rib. The cutting edge works at an angle so that the finished ribs stand out from the surface. The ribs may incline upward from the central web and thus form pockets to hold the active material and prevent its falling away.

The disadvantage of the *web* type is the web itself. There is invariably a tendency towards unequal work on the two sides of the positive plate, this tendency being caused by difference in the plate spacing, unequal capacity of the negative plate on either side, inequality in the shape of the ribs, etc. Where the active material and the active surface of a plate are disposed in planes perpendicular to the face of the plate and extend *through* the plate, excessive action on one side simply works the plate a little further through from that side, the effect on the active material, however, being uniform throughout. With a plate provided with a central web, preventing such action, any inequality of work will charge or discharge one side more than the other, producing a tendency to buckle.

Cast-lead Type. — The type of plate which has no central web is made by casting pure soft lead in a mold, casting having the advantage of allowing for distributing metal in the plate without limitations in manufacturing process. The plate as it comes from the mold consists of a great number of short vertical ribs running entirely through the plate and bound together by transverse ribs to give strength to the plate. In this manner a large surface may be obtained and in a plate having no central web the electrolyte can circulate through the plate, and the active material will be uniformly worked throughout even though the amount of work on the two sides of the plate be unequal. The best-known form of this plate is the "Tudor" positive.

Composite or "Pellet" Type. — The composite or pellet-type plate is made by rolling up into pellets pure soft-lead corrugated ribbons. These pellets or buttons are then forced by pressure into circular openings in a grid composed of a hard-lead-antimony alloy. The openings in the grid are beveled towards the center so that when the pellets are formed the swelling action causes them to rivet tightly into place. The corrugations on the lead ribbon allow the electrolyte to circulate through the plate and thus expose the full surface of the closed lead spiral to the action of the electrolyte. It will be noted that in this type of plate additional mechanical strength is obtained from the supporting grid. The best-known form of this plate is the "Manchester" positive.

"Forming" of Planté Plates. — In all Planté positives, after the ribs or corrugations have been formed on the lead blank or the pellets have been placed in the hard grid, the plates are assembled in a sulphuric-acid bath containing some corrosive chemical, called a "forming agent," together with dummy lead plates. The forming agents used by various manufacturers are usually kept as trade secrets; the nature and method of using such agents determines largely the quality of the battery. To form the positive plates the dummies are connected as the cathodes, and a current is passed through the couple thus formed. The electrolytic action of this current causes lead peroxide (PbO_2) to be formed from the lead of the ribs. The strength and duration of the current produce the desired thickness of lead peroxide on the ribs or pellets.

Negative Planté plates are made from positive plates by electrolytically reducing the lead peroxide to sponge lead. In most types of Planté negatives, however, it is necessary to form them with an initial capacity considerably in excess of the capacity of the positive plate. This is due to the fact that in actual service the sponge lead shrinks and loses its spongy nature, thereby reducing its capacity, since insufficient surface is exposed to the action of the electrolyte.

Digitized by Google

"Permanizing" Process. — One of the large manufacturers of storage batteries has recently developed a process for making the Planté negative plate permanent. This method consists of injecting into the sponge lead a material which prevents the shrinking of the sponge lead and thus enables it to maintain its spongy character and its initial capacity. This permanizing process can be applied to the pasted negative plate as well as to the Planté negative plate. The most widely used form of the permanized negative plate is one in which the sponge lead, formed by reducing lead oxide electrolytically, is retained in boxes made by casting a soft-lead perforated sheet on a hard lead-antimony grid. This negative is known as the "Box negative."

Applications of the Various Types of Plates. — In stationary work requiring frequent discharges, where expert attention is available at all times and where the conditions of operation are properly suited to its use, the Planté lead Planté type of plate with through-and-through circulation is the plate that should be used. Where the battery is to receive little attention and where the conditions of service are variable and uncertain, the composite or "pellet" type of plate is the safest plate to use, on account of its rugged structure and its ability to stand great abuse. As stated above, for stand-by service and for vehicle service and other service where high capacity with a minimum weight and space is desired, the pasted type of plate is more desirable.

Electrolyte. — The electrolyte used with the lead type of battery is always a dilute solution of sulphuric acid. The specific gravity of the electrolyte, when the battery is fully charged, varies from about 1.210 for stationary batteries to 1.300 for automobile ignition batteries. These values have been adopted as standard by all the leading manufacturers.

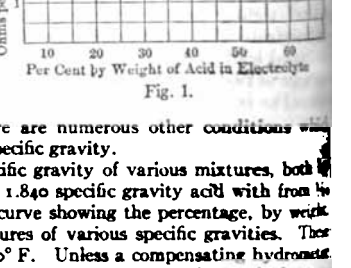

Fig. 1.

The proper specific gravity to use varies with the conditions. Fig. 1, showing the variation with specific gravity of the resistance of one cubic centimeter of electrolyte, shows that the resistance of dilute sulphuric acid is least at a specific gravity of from 1.224 to 1.240, this resistance increasing if the specific gravity be either increased or decreased. There are numerous other conditions which influence the selection of the proper specific gravity.

The curves in Fig. 2 show the specific gravity of various mixtures, both by weight and by volume, of one part of 1.840 specific gravity acid with from ½ to 7 parts of water. There is also a curve showing the percentage, by weight, of 1.840 specific gravity acid in mixtures of various specific gravities. These curves are approximately correct at 60° F. Unless a compensating hydrometer is used in determining the specific gravity, allowance must be made for temperature variation, on the basis of an increase of one point (i.e., one one-thousandth) in gravity for each 3 degrees Fahrenheit *decrease* in temperature, and vice versa; for instance, electrolyte that has a specific gravity of 1.210 at 70° F. will have a specific gravity of 1.213 at 61° F., and 1.207 at 79° F.

Impurities in Electrolyte. — The electrolyte should be free from organic substances, iron, chlorine, copper, arsenic, mercury, nitrates, acetates and the slightest possible trace of platinum. The various battery manufacturers issue exact specifications to the acid manufacturers, specifying the maximum amount of these injurious ingredients which the acid may contain. Electrolyte that is not approved by the company furnishing the battery should never be used.

Digitized by Google

Preparation of Electrolyte. — In preparing the electrolyte, sulphuric acid, approved by the battery manufacturer, should be diluted with sufficient pure distilled water to bring the mixture to the required specific gravity. The acid should be poured into the water; *never pour the water into the acid.* If the water is poured into the acid, the heat formed by the mixture is sufficient to cause sputtering and damage may ensue.

The sulphuric-acid manufacturing companies furnish electrolyte for battery work in such large quantities that they carry a stock of various standard mixtures. It will usually be found cheaper and more convenient to purchase the electrolyte ready-mixed than to purchase the concentrated sulphuric acid and prepare the mixture on the ground. The latter course, however, is sometimes adopted where the amount of acid used is considerable and where the item of freight saving is appreciable.

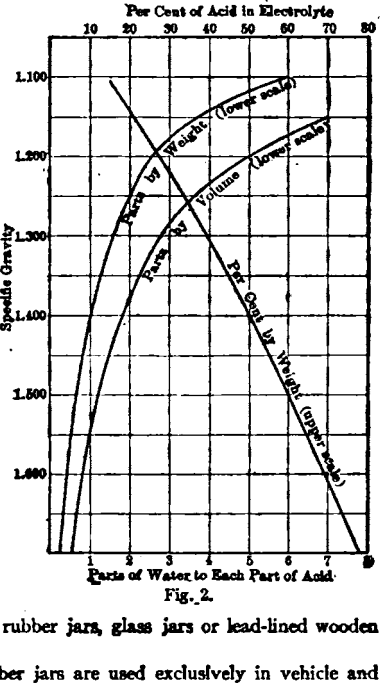

Fig. 2.

Containers for Lead Batteries. — The containing receptacles for holding the battery plates and electrolyte are usually rubber jars, glass jars or lead-lined wooden tanks.

Rubber Jars. — Hard-rubber jars are used exclusively in vehicle and portable batteries. In these batteries the plates are supported on ribs at the bottom of the jars. To reduce cleaning to a minimum, these ribs should be of sufficient height to leave ample space in the bottom of the jar for the reception of the active material which falls away from the plate. If the sediment in the bottom of the jars is allowed to reach the plates and short-circuit them, serious damage will result. The jars themselves should be made of the very best hard rubber which is not affected by sulphuric acid.

Glass Jars are ideal containers for small batteries when they are properly installed. The glass jar has the advantage that the plates and electrolyte can always be seen. The use of the glass jars is limited to the smaller sizes on account of their liability to break, due to strains left in the glass after annealing, temporary strains set up by unequal temperatures between the inside and outside of the jars, and to strains due to weight of the plates and electrolyte. Glass-jar manufacturers have, up to the present time, been unable to produce a thoroughly reliable jar larger than 21 by 13 by 18 inches.

Lead-lined Tanks. — In the larger sizes of batteries lead-lined tanks are standard. Tanks are generally made from specially selected yellow pine, dovetailed together without the use of nails or other metallic fastenings. The upper edges should be slightly beveled inward so that the moisture will drain into the tank. The bottoms under the linings should be drained and venti-

Digitized by Google

lated; these bottoms are usually constructed of slats across the tanks, separated by a small spacing to provide drainage. To further facilitate drainage under the lining, the upper surface of these slats should be grooved crosswise. Before the tanks are lined they should be coated inside and outside with two coats of acid-resisting paint, and a third coat should be added outside during installation. The tanks should be lined with lead of 3 to 4 pounds per square foot, depending on their size. The lining should extend over the upper edge of the tank and a short distance down the sides. The outer edge of the lining should be provided with drip points projecting clear of the tank, so that any drip from the lining will clear the wood of the tank and the tank supports. Especial attention should be paid to the seaming of the linings. All seams should be burned with the hydrogen flame with pure lead, without the use of any flux. The lower corners of the lining should be reënforced by puddling with lead. The upper corner should be reënforced by burning on an additional thickness of sheet lead. Each tank should be so built that it is self-supporting without the use of any braces or reënforcements. If this is done, any tank in the battery can be removed and replaced without affecting the remaining tanks in any way. A poorly constructed wood tank is bound to cause trouble. Special attention should be paid to this detail in preparing specifications.

Covers. — While covers are not absolutely necessary for stationary batteries, it is considered good practice to cover all cells. Covers should preferably be made of glass of sufficient weight to prevent excessive breakage in handling. Covers will more than pay for themselves in reducing evaporation and keeping out dirt. They are absolutely necessary in situations, such as steel mills, where the air is liable to contain particles of foreign matter injurious to the battery.

Support of Plates in Container. — As stated above, in the portable and vehicle types of batteries, the plates are supported on ribs at the bottom of the jar.

In stationary types, using glass jars or lead-lined tanks, it is preferable to support the elements from the top. In glass jars, plates are supported on the top edges of the jars by means of lugs cast or burned on to the plates. In lead-lined tanks it is, of course, necessary to insulate the plates from the lead lining. The plates are, therefore, supported in the tanks by vertical sheets of glass resting on the bottoms of the tanks. The bottom of the tank lining, under the glass sheets, should be heavily reënforced. These glass sheets should be ground top and bottom and the lower corners should be cut off at an angle of about 45°, to avoid injury to the lead lining during installation by sharp corners.

Separation and Separators. — Since the positive and negative groups, forming the complete element in a cell, are assembled with positive and negative plates alternating, it is necessary that some means be provided to prevent contact between adjacent positive and negative plates. Such contact would mean a short-circuit and might result in injury to the element. Various forms of separators have been used for keeping the plates apart. The most common practice to-day, and the one considered the best for stationary work, is to use wooden diaphragms. Each wooden diaphragm should consist of a thin sheet of porous wood mounted in slotted dowels which will allow free passage of the electrolyte between the plates. The wood should be specially treated to insure the absence of elements which in conjunction with the electrolyte might form acids injurious to the plates.

In vehicle batteries rubber separators are generally used in addition to the wood separator. That is, a rubber separator is placed on each side of each positive plate and one wood separator between each positive plate and the adjacent negative plate. In the so-called "iron-clad" battery, made by the

Digitized by Google

Electric Storage Battery Co., the active material of the positive plate is contained in rubber tubes, and therefore additional rubber separators are not necessary. Ignition batteries use wood separators only. Portable batteries use rubber only. Car-lighting batteries use wood only or rubber only. Yacht-lighting batteries use rubber only.

Sediment Space. — In all types of batteries, no matter what container is used, there should be a certain amount of free space between the bottoms of plates and the bottoms of jars. This space is designed to receive the sediment or active material which falls away from the plates. The amount of sediment space required will depend upon the service, and no fixed rule can be given to cover this point. If not prohibitive from space or expense limitations it would be well to have this sediment space great enough to take all of the active material which will be shed from the plates during their useful life.

Assembly of Parts. — All portable, automobile, car-lighting and other batteries that will be subject to jar or vibration should be assembled in the containing vessel in such a manner that the plates cannot move. They should be packed in as tightly as is possible with due consideration to the amount of electrolyte necessary and the avoidance of injury to the plates when being put into or taken out of the jars. Hard-rubber covers should be used and these covers should be so sealed as to avoid any splashing of the electrolyte. The crates containing the jars should be constructed, as far as possible, without the use of metallic fasteners and they should be thoroughly painted with acid-resisting paint. In portable batteries that will receive rough handling, if several jars are assembled in a single crate, they should be imbedded thoroughly in an acid-proof elastic compound.

Cells assembled in crates should be connected by burning together the adjacent positive and negative terminals. Cell connections should never be soldered. The main terminals of the series in one crate should be brought out and fastened in such a manner that these terminals will not be attacked by the acid.

The methods of assembling and connecting stationary types of cells are described below in the section on *Installation*.

METHODS OF TESTING. — The tests described below are intended to cover only those tests that are of interest in the commercial operation of batteries.

Test of Specific Gravity. — The specific gravity of the electrolyte is the most accurate guide as to the state of charge of a lead-type storage battery. Specific instructions furnished by the manufacturer of the battery are given, showing the range in specific gravity over a given amount of charge and discharge and the operator should be guided by the instructions of the manufacturer. The test of the specific gravity is made by means of a hydrometer having a suitable scale for the type of cell to be tested. In stationary types of batteries the hydrometer has a scale reading of 1150 to 1250 and is left floating in one cell. In all portable types of batteries, and ordinarily in vehicle- and car-lighting batteries, it is usually necessary to draw some of the electrolyte from the cell in order to test its specific gravity with the hydrometer, which should have a scale reading of 1150 to 1300. Hydrometer syringes, with hydrometer contained in a glass barrel, can be obtained on the market for this purpose. There is also on the market a regular acid-testing set consisting of a syringe for withdrawing the acid and a test tube into which the acid is poured from the syringe, in order that the hydrometer may be floated for reading.

Test for Impurities in Electrolyte. — The proper testing of electrolyte for impurities requires not only some knowledge of chemistry, but also experience in such work, in order to correctly interpret results; it is therefore inadvisable

for the ordinary user to attempt it. Furthermore, it is usually entirely unnecessary that he should, since the leading battery manufacturers make analyses for their customers free of charge. The harmful impurities most likely to be present are iron, hydrochloric acid, oxides of nitrogen, sulphurous acid, arsenic, organic matter and platinum. In order to insure freedom from the latter, it is advisable to specify acid which has not been concentrated in platinum.

Test of Internal Resistance. — The most accurate method of determining the internal resistance of a cell is to subject it to a discharge current of a certain amount, and after the voltage has become sufficiently constant to permit accurate reading with the discharge current flowing, the current is instantly interrupted and the rise of voltage noted. This rise of voltage divided by the current will give the internal resistance. If this test is made on a battery of more than one cell in series the result shows the internal resistance of the entire battery, including the cell connections.

Test of Capacity. — The capacity of a storage cell depends on various conditions, such as the temperature, the rate of discharge, the strength of the electrolyte, the character of service to which it has previously been subjected, and the attention it has received. The "normal capacity" of a storage cell is usually expressed in ampere hours at the 8-hour rate at 70° F., down to a certain definite voltage per cell. For instance, when it is said that a cell has a capacity of 100 ampere hours, it is *usually* meant that this cell can be discharged at a rate of 12½ amperes continuously for 8 hours at 70° F., down to the limiting voltage specified by the battery manufacturer. In lead cells this limiting voltage is usually taken at 1.75 volts per cell. The "watt-hour" capacity of a battery is equal to the ampere-hour capacity multiplied by the average voltage during discharge.

The "available" ampere-hour and watt-hour capacity of a battery varies with the rate of discharge, the available capacity decreasing with increase of rate. The higher the rate of discharge the lower the limiting voltage at end of discharge. Therefore, to test the capacity at any given rate of discharge, the limiting voltage at that rate as specified by the manufacturer should be known.

Bearing in mind the above facts, to test the capacity of a storage battery at any given rate, the battery should be first charged at the normal rate, as specified by the manufacturer, until the voltage and gravity in all of the cells will rise no further and until all cells gas freely at both the positive and negative plates. The capacity of the battery, as a whole, will be limited by the capacity of the lowest cell and all cells should be as nearly as possible in a condition of full charge before the discharge is started to test the capacity of the battery. Individual cell readings should be taken of the voltage and gravity while the charging current is flowing.

When it is certain that the battery is fully charged, discharge the battery at a constant current at the desired rate, down to the limiting voltage at this rate. The ampere-hour capacity will be equal to the constant current in amperes, multiplied by the time of the discharge in hours; and the watt-hour capacity of the battery will be the ampere-hour capacity multiplied by the average voltage during discharge.

In order to be sure that the battery is in good condition it is well to take several complete discharges before making the final charge, preceding the final test discharge.

On each charge and discharge observations should be taken of the voltage, the current, the temperature and the specific gravity. The temperature of the room should be held as nearly constant as possible throughout the test. In order to facilitate the plotting of curves, the readings should be taken at intervals of time which are even factors of an hour.

Digitized by Google

dmium Test. — When a strip of cadmium is placed across the top of the s in a cell, and properly insulated from them, there will be a difference in ıtial, as measured by a voltmeter, between the cadmium and the positive s and between the cadmium and the negative plates; the sum or difference ending on the relative directions of the two potential differences) between two readings being equal to the internal voltage of the cell.

ch a test, when properly interpreted, is a valuable guide to the capacity condition of the positive and negative plates separately. The results are, ver, very apt to be misleading to one who has not had a wide experience orage-battery work. See *Tech. Paper* No. 146, Bureau of Standards.

ıst of Efficiency. — The ampere-hour efficiency of a battery is the ratio ıe output on discharge in ampere-hours to the input on charge in ampere-s; the watt-hour efficiency of a battery is the ratio of the output on dis-ge in watt-hours to the input on charge in watt-hours.

ıe efficiency of a battery depends upon numerous conditions, chief among h are the charge and discharge rates and the temperature.

has been noted above that the *available* capacity of a battery depends upon lischarge rate. For instance, if a battery is discharged at the one-hour rate ıe allowable final voltage limit, the energy taken out at this rate is approxi-ly only fifty per cent of the energy that could be taken out at the normal . However, if, at the end of one hour's discharge at the one-hour rate, the of discharge be reduced to the normal rate, much of the available *normal* acity of the battery can be obtained.

t is thus seen that any statement of the true efficiency of a battery should ude the charge and discharge rates. It is also seen that in order to make a efficiency test an average of several charges and discharges should be taken, the battery should be given several discharges and charges before the actual is begun. Failure to observe these conditions may result in figures that misleading. The writer has seen test figures showing an efficiency of more ı one hundred per cent; he has also seen figures showing efficiencies far below actual efficiency.

o determine the efficiency of the battery, get all the cells in satisfactory dition by preliminary charge and discharge, as outlined above under the acity test, and then take a preliminary discharge down to the final voltage ified by the manufacturer for this rate of discharge. The first test charge uld then be made at the normal rate until the cells are fully charged. The test discharge should then be taken at the specified rate down to the same l voltage used in the preliminary discharge. The watt-hour efficiency of battery will then be the ratio of the total watt-hours discharged to the l watt-hours charged. If greater accuracy is desired, this cycle should be eated several times (say, from four to six times) and the watt-hour efficiency l then be the ratio of the total watt-hours of all the discharges to the total t-hours of all the charges.

RATING AND PERFORMANCE. — The capacity of a storage-battery te of a given size varies somewhat with the conditions, chief among which the specific gravity of electrolyte, the temperature of electrolyte, the ount of electrolyte, the original formation of the plate, the design of the d, the age of the plate, the length of time between charge and discharge l the final voltage limit specified.

Rating of Stationary Batteries. — The rate of discharge of a storage battery he number of amperes that it will supply continuously for 8 hours, for 3 hours for 1 hour. The 8-hour rate is the so-called "normal" rating, the 3-hour rate approximately twice the normal rating and the 1-hour rate is approximately times the normal rating. The *capacity* of a storage battery is usually

Digitized by Google

stated in ampere hours. Since the capacity varies with the rate of discharg it is necessary to specify the rate of discharge in stating the capacity ampere-hours. If the rate is not specified, the normal rate is assumed.

Certain plates especially designed for high rates of discharge are rated terms of the amperes they will supply for 6 hours, this rating being designat as "normal." The corresponding 1-hour rate is 4 times this 6-hour rate.

While the above is standard for ordinary batteries, plates for certain class of service are designed to give the normal rate for from 7 to 7½ hours.

The capacity of a storage battery is sometimes expressed in kilowatts, b this is ambiguous unless the rate of discharge is specified.

Rating of Vehicle and Ignition Batteries. — It is standard practice rate a vehicle battery in terms of the amperes it will give continuously for 4½ or 5 hours, specifying the battery to have a capacity of so many amper hours at one of these rates. In most portable types of ignition batteries t batteries are rated at so many ampere-hours at the "service rate," i.e., the ra of discharge (amperes) corresponding to the service for which they are designe

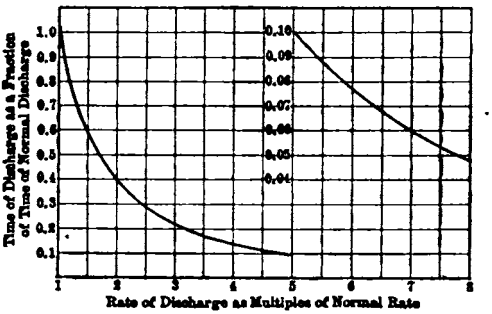

Fig. 3.

Variation of Rate of Discharge with Time of Discharge. — Fig. 3 show an average capacity curve for a Planté plate, the time for a complete di charge at any rate being shown as a fractional part of the normal time and t rate of discharge for any given time being shown as a multiple of the normal rat

From these curves it will be noted that a cell which will give its normal ra for 8 hours will give 4 times that rate for about 1⅛ hours; and a cell whic will give 4 times the normal rate for 1 hour will give the normal rate for onl 7 hours. These are approximately correct relations for the average Plant cell. Trade catalogues usually specify the normal rate for 8 hours and times the normal rate for 1 hour. This is due to the fact that a cell which regularly worked at the normal rate will tend to hold its 8-hour capacit while a cell which is regularly worked at 4 times the normal rate will tend t lose some of its 8-hour capacity and finally give only 1 hour at 4 times th normal rate.

Variation of Capacity with Rate of Discharge. — It will be note from the capacity curves that the available capacity in ampere-hours decreas with increase of rate of discharge. This is largely due to the time required f fresh electrolyte to penetrate into the pores of the active material of the plat At the higher rates of discharge the diffusion of electrolyte is not sufficient

Digitized by Google

he battery, the battery be allowed to rest or the rate of discharge be de-ed, additional capacity can be obtained from the battery.

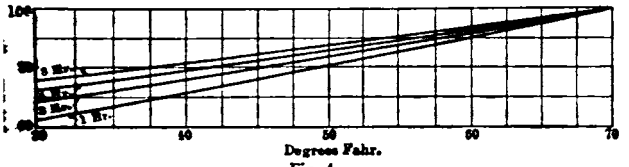

Fig. 4.

Variation of Capacity with Temperature. — Fig. 4 shows the varia-n of capacity with temperature at various rates of discharge. This change apacity is temporary and the capacity will be restored to its original value en the temperature is restored to its original value.

Voltage and Specific-gravity Characteristics. — The charge and discharge tage characteristics of a battery vary with the conditions. Fig. 5 shows sical average voltage and spe-c-gravity charging characteris-s of a Planté type of cell de-gned for stationary service. It ill be noted that the specific grav-r increases gradually until all of e lead sulphate in the plates has en reduced, the (SO_4) radical ing returned to the electrolyte form sulphuric acid, which ac-unts for the steady increase in cific gravity and for the fact at the specific gravity will rise further after the battery is mpletely charged.

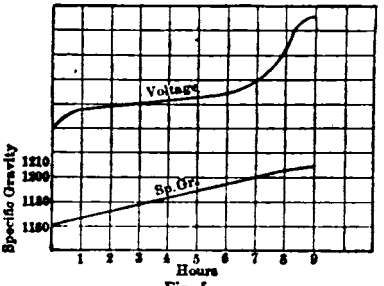

Fig. 5.

Final Charging Voltage (Fig. 5). — The scale of volts on the upper rve has been purposely omitted, t this curve shows the general ape of charging curve for any pe of lead battery. The final arging voltage of any lead type battery varies over a consider-le range, according to the type cell, age of plates, temperature electrolyte, strength of electro-te, etc. The final charging vol-ge may vary anywhere from 4 to 2.8 volts per cell. It will e noted that the voltage rises pidly at the beginning and at e end of charge.

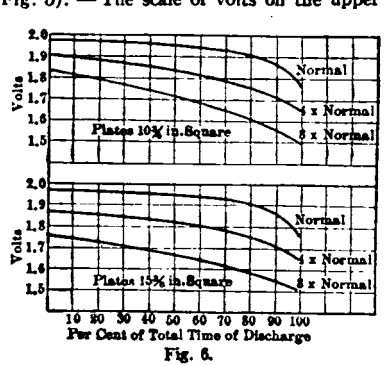

Fig. 6.

Discharge Voltage. — Fig. shows discharge curves at the rmal, four times the normal and eight times the normal rates, respectively, for wo different sizes of Planté plates The upper set of curves are for plates 10¾ nches square and the lower set of curves are for plates 15¾ inches square.

Digitized by Google

These curves, used in conjunction with the capacity curves shown in Fig. 3, will enable anyone to determine the approximate performance of any lead battery when the capacity at any given rate is known.

The voltage readings at the very beginning of the discharge are liable to vary more or less from those shown on the curves depending upon the length of time the cell has been allowed to stand on open circuit after the completion of the charge.

Open-circuit Voltage. — The open-circuit voltage of a lead cell is of no value as an indication of its state of charge. A healthy cell will regain its full voltage on open circuit, even though fully discharged, if sufficient time is allowed for depolarization.

Internal Resistance. — The true internal resistance of a cell may be determined by the method explained above in the paragraph on *Test of Internal Resistance*. This internal resistance determines the *immediate* change of voltage at the cell terminals with any sudden change of discharge rate. In the ordinary commercial types of lead cells at 70° F. the internal resistance is such as to cause an immediate drop in terminal voltage of between 5 per cent and 7 per cent, with a sudden increase of current equal to four times the normal rate of discharge, the drop being proportional to the change in current. If this change in current is not strictly momentary, the change in terminal voltage will be greater, due to the effect of polarization. The internal resistance of a cell increases with reduction of temperature; at 0 °F. the internal resistance is twice as great as at 70° F.

DIMENSIONS AND WEIGHTS. — In determining the dimensions and weights of a storage battery to meet the requirements, it is suggested that the proper type of battery be determined in accordance with the curves and examples given above and a battery be selected from trade catalogues to meet the specifications. When the battery has been thus chosen, the dimensions and weights of individual cells can be obtained from the trade catalogues. In order to determine the total installed dimensions and weights, it will be necessary to make a layout according to standard practice. The distances between adjacent cells and the dimensions of aisles are given below in the section on *Installation*.

SPECIFICATIONS, CONTRACTS AND PROPOSALS. — (*See also article on Specifications.*) In preparing specifications for a storage-battery plant and accessories, special care should be taken to avoid drawing up specifications in such a manner as needlessly to embarrass the manufacturers who are requested to bid.

Preliminary Specifications. — It is recommended that preliminary specifications of a very general nature be prepared. These specifications should contain complete detailed data of the conditions to be met, so that the manufacturers who are requested to bid can readily determine the number and capacity of cells, the proper scheme of operation, the correct design of booster, switchboard and other accessories recommended by them to meet the requirements in hand. That is, the preliminary specifications should state plainly just what the battery is intended to accomplish. These preliminary specifications should be sent to the manufacturer with a request for a complete proposal.

Manufacturer's Proposal. — This proposal should give detail specifications covering the apparatus recommended by the manufacturer. In order to obtain the best results, it is recommended that after these proposals are received, the prospective purchaser confer with the bidders that are to be considered, and that complete final specifications be prepared, covering all details of the necessary equipment. These final specifications can then be sent to the manufacturers for their final bids.

Digitized by Google

nal Specifications. — As a guide in preparing the final specifications the ts enumerated below should be thoroughly covered:

aber of cells;
aber of plates in elements initially installed;
of plates;
acity of the elements initially installed;
rging rate of the elements initially installed;
: of the containing vessels expressed in the number of plates which the vessel can contain;
arators and supports;
ctrolyte;
ulation;
embling and lead burning;
bars, both plain and reënforced;
d-cell switches;
copper work and cables;
itchboard in detail;
Detailed specifications for booster and exciter apparatus according to the A.I.E.E. Standardization Rules.
Foundation for booster and switchboard;
Testing instruments;
Battery room;
Erection;
Skilled and unskilled labor;
First charge;
Operation;
Test;
Freight, cartage;
Delivery;
General scheme of operation;
Temporary work;
Cutting of walls, etc.;
Access, storage and hoisting;
Acceptance.

If specifications are drawn, covering all of these points clearly and if the ecifications are attached to, and form part of, the contract, no trouble should se in the future from misunderstandings.

Contract. — The contract should cover the price, time of payments, guarantee, tection from patent litigation and insurance of the material during conuction.

INSTALLATION AND ERECTION. — *Never install any battery without lowing explicitly the detailed instructions furnished by the manufacturer who de the battery.*

If the battery is of considerable capacity, detail drawings showing the method installation should be obtained from the battery manufacturer. The leading nufacturers issue printed instructions and detail drawings describing the thod of installation. Much time and money can be saved by obtaining these ta from the battery manufacturers.

Spacing of Glass Jars. — The spacing between cells along rows varies from ½ inches with the smaller types of multiple plate-glass cell batteries to 3½ ches for the largest size multiple plate-glass cell batteries. This space is the ace from jar to jar. It is standard practice to place the jars on wood or glass nd trays filled with sand; the distance between the sand trays along the rows ries from ½ inch to 2⅛ inches, depending upon the size of the glass jars. As e outside dimensions of the sand trays are not usually given in trade catames, it would be well in figuring the length of the rows to use the spacing tween glass jars as given above, for the outside dimensions of the glass jars e usually stated.

With glass-jar batteries the aisle space between the rows should never be s than 24 inches, and aisles of 36 inches are recommended. In the case of uble rows or where a row is installed near a wall or partition, the distance tween rows, or the distance between a row and the wall, should not be less an 6 inches.

All batteries should be installed in one tier, if space is available, though glass-r batteries (and occasionally lead-lined wood-tank batteries) can be installed

in two or three tiers, if more space is not available. In installing batteries i more than one tier, sufficient headroom should be allowed in each tier to perm the removal of the elements from the jars without displacing the jars. Th minimum headroom for a single-tier glass-jar battery varies from 4½ feet t 5 feet; for two tiers from 5 feet to 7½ feet and for three tiers from 7 feet to 1 feet, depending upon the size of the battery. In all cases the ceiling of th battery room should be of sufficient height to allow for the passage of a ma without stooping.

Spacing of Lead-lined Tanks. — Lead-lined tank batteries should alway be installed in one tier, if space is available. More than one tier should not b installed without consulting with the battery manufacturer. With lead-lin tanks the distance between tanks along rows is from 2 to 2¼ inches. Th aisle space between rows should never be less than 30 inches and should alway be sufficient to allow the tank to be pulled out into the aisle for repairs. Whe space will not allow the tank to be pulled out its full length the aisle shou have at least sufficient width to allow the tank to be stood on end in the aisl In double rows or in rows next to the wall, at least 18 inches should be allow between rows or between the tanks and the walls so that a man can get in t examination. The battery room should have sufficient headroom for a ma to walk upright. With large-sized batteries where the amount of gases libe ated on overcharge is considerable, sufficient headroom should be allowed f proper ventilation.

Dimensions of Containers. — For any given type of plate, either in gl jars or lead-lined wood tanks, there is one dimension for all jars or tanks whi is practically constant, independent of the number of plates in the cell. This the dimension parallel to the horizontal edge of the plates. This dimensi is usually specified in trade catalogues as the "width." The other dimensi is the dimension across the row and is usually specified in trade catalogues the "length."

Dimensions of Battery Room. — Keeping in mind these definitions o can determine from trade catalogues the approximate inside dimensions of battery room necessary to house the battery in question. Note, however, th any manufacturer will gladly furnish a sketch showing an ideal layout for given battery and such a layout should always be obtained from the manufa turer, if there is sufficient time. If there is available space in a buildi already built, the battery manufacturer will gladly prepare a sketch showi the layout of any given battery in the available space.

Insulation of Cells. — Cells in stationary batteries, whether in glass j or in wood tanks, must be insulated from the ground and from each other.

Glass jars are usually mounted in glass or wooden sand trays which rest glass insulators. The glass insulators, in turn, rest on wooden racks or stringer these racks or stringers being mounted on vitrified brick set on the batte room floor.

For lead-lined wood-tank cells the standard practice at present is to mou each tank on a sufficient number of oil insulators. These insulators consi of a glass insulator provided with a circular trough partly filled with oil. th oil surrounding a central section which supports the tank. Over the insulat is placed a lead-alloy cap, designed to exclude spray or other foreign matt from the oil. This cap rests on the central section of the glass insulator, the being no connection between the tank and the glass except at this section. Th oil around this central section of glass is for the purpose of preventing a fil of acid from collecting thereon; if, by any chance, acid or water should g into the trough, it would sink to the bottom, the oil would float on top, a perfect insulation would be maintained.

Digitized by Google

The glass insulator rests upon a heavy earthenware truncated cone, having ee feet. Between this cone and the glass is a Y-shaped lead washer. Thus ee-point support is obtained between the floor and the earthenware, and ween the earthenware and the glass. This form of support is not necessary ween the glass and the tank, because the wood and lead cap take up any face inequalities.

Connections between Cells. — In glass-jar batteries of small size, elements adjacent cells are usually bolted together. In the larger-sized glass-jar tteries and in all lead-lined wood-tank batteries the positive plates in one cell burned to the negative plates in the adjacent cell through the medium of ead bus bar. The bus bars at the ends of rows, and wherever current taps made, are reënforced by a bar of copper embedded in the lead.

Battery-room Design. — Though no battery should be installed without ecific instructions from the manufacturer, the following points should receive cial attention.

Floor. — The floor of the battery room should be made acidproof and uld be graded to drain. A wood floor should never be used, as it is bound become acid soaked and eventually be destroyed. For small batteries a ent floor can be used, but, unless it is kept thoroughly washed, acid will t holes in it. A glazed tile floor is preferable.

Ventilation. — All battery rooms should be well ventilated. With small tteries natural ventilation is usually sufficient; with large-capacity batteries, here the gassing during overcharge is considerable, artificial ventilation should provided. Exhaust ventilation is preferable to compression ventilation.

Temperature. — The temperature of the battery room should be kept near 70° F. as possible.

Exposed Metal. — The amount of exposed iron or metal work in the ttery room should be reduced to a minimum on account of the action of acid mes upon it. Any iron or metal work that must be in the battery room should protected with an acid-resisting paint.

OPERATION. — *Never operate any battery in any manner except in accordce with the instructions of the battery manufacturer furnishing the battery.*

With all large battery plants there should be supplied by the manufacturer e proper testing instruments and detail instructions for the operation of the ttery under the conditions obtaining. The blank forms furnished by the nufacturer should be filled in at regular intervals and mailed to the manucturer for analysis and recommendations.

No general instructions for the proper operation of a battery are given in is article, since the different manufacturers differ in their opinions on certain ints of operation.

Printed instructions for operating any type of battery can be obtained free charge from the manufacturer.

Attention from Operator. — The successful operation of a battery plant es not require much time from the operator, but attention given the battery hould be systematic and absolutely in accordance with the instructions furished by the manufacturer. If the manufacturer's instructions are followed xplicitly and systematically, it will be found that the battery can be kept in ood condition with a small amount of labor and time. If the operator neglects follow the regular instructions and does not appeal to the manufacturer until t gets into trouble, the usual result will be considerable loss in time and money.

Addition of Water. — Pure distilled water, or natural water that has been nalyzed and approved by the battery manufacturer, should be added to the lls from time to time to replace evaporation. If there is not available a source

of pure, natural water, and if distilled water cannot be purchased cheaply, a distilling outfit will usually be found necessary with large sizes of batteries. Standard water stills, for this purpose, can be purchased on the market.

Addition of Acid. — *Acid should never be added to a battery except upon the recommendation of the battery manufacturer.* The manufacturer should specify the specific gravity and the proper amount of acid.

REPAIRS. — Very few repairs, other than battery plates, should be required. For replacing the plates in the larger sizes of batteries, a lead-burning outfit and the necessary lead-burning material will usually be required. No one but a skilled lead burner should attempt to burn in plates.

Smaller sizes of batteries, with bolted connections between adjacent cells, can be purchased from the manufacturer with each element assembled.

Leaky Tanks. — A leaky tank should be repaired immediately. No one but an expert sheet-lead burner should be allowed to repair a leaky lead-lined tank. To repair the leaky lead-lined tank it will be necessary to cut loose from the bus bars all of the plates in the leaky tank and remove the tank into the air. If it is necessary to keep the rest of the battery in commission while the repairs are being made, the cell or cells cut out should be jumped by a jumper of sufficient current-carrying capacity.

FIRST COST. — It is impossible to give exact figures for the total cost of installation of a complete battery plant of any size. An analysis of the first costs of a great many plants now in operation shows that the first cost per kilowatt for the entire battery installation, exclusive of building, varies from $80.20 per kilowatt to $250.00 per kilowatt. The kilowatt rating as used here and elsewhere in this article is an arbitrary rating determined by multiplying the one-hour discharge rate in amperes (four times the normal rate) by double the number of cells.

ANNUAL COST. — The total annual cost includes operation, maintenance, depreciation and interest.

Operating Cost. — The operating cost will consist largely of labor. Any material except necessary water should be included under maintenance.

Maintenance and Depreciation. — The cost of maintenance of a battery varies with the conditions. Other things being equal, the life of a battery is dependent upon the work done. The maintenance cost of a battery varies from 4 per cent to 10 per cent per annum. When the battery is used only for strictly emergency service the maintenance cost may be less than 4 per cent.

These figures cover not only maintenance, but also what is commonly included under the term depreciation. The plate being the essential component of the battery, plate renewals, which are made from time to time, involve such improvements that have been made in design and construction and serve to bring the battery up to date. An increase of voltage or capacity to meet changed conditions may be effected by the addition of cells or by increasing the number of plates in each cell, without sacrifice of the original investment. In the opinion of the writer there is, therefore, little, if any, true depreciation in a battery installation which is properly maintained.

BEARINGS. — *(See also Friction; Lubricants and Lubrication; Shafting.)* The common types of shaft bearings may be classified as follows:

Plain Cylindrical Bearings. — The usual form of bearing is a metal cylinder of cast iron, brass, bronze or gun-metal, mounted in a pedestal, bracket or frame, which serves as a support for the shaft. The portion of the shaft within the bearing is called the journal. Plain bearings are usually lined with some soft metal, such as babbitt metal or other white metal. In a self-aligning bearing the seating of the bearing in the pedestal is made a portion of a sphere, so that the bush may automatically align itself with the shaft. Cylindrical bearings are sometimes provided with an oil bath within the pedestal just below the bearing proper; rings or chains running loosely over the journal through slots in the bearing and dipping into this bath supply a steady stream of oil to the rubbing surfaces.

T. D. Lynch (Amer. Soc. Test. Mat., June, 1913) gives the following data in regard to plain Babbitt bearings: (1) The constituent metals of the alloy (*see Alloys*) must be of superior grade. (2) A temperature of 500° C. or less has been found sufficient for satisfactory alloying (3) A pouring temperature of 460° C. has been found to give excellent results. (4) The shell should be heated to 100–150° C. before the bearing metal is poured in. (5) Babbitted bearings must not be jarred during the solidification of the metal. (6) A Brinell hardness of 23.5 for lead-base and 30 for tin-base babbitts have been found to give excellent results.

Roller Bearings. — In this type of bearing the journal is supported on rollers which are in turn supported by smaller shafts in smaller bearings. The rollers support the journal of the main shaft.

Step Bearing. — A step bearing is essentially a large pivot bearing used at the end of vertical shafts carrying a heavy load. The end of the shaft is provided with a steel plate or "step," which rests on a second plate or bearing. The bearing proper may be either of the ball or roller type, or may be a plane surface with one or more grooves into which oil can be forced under pressure. The stationary plate is sometimes supported on short helical springs and is held against rotation by dowel pins (*H. G. Reist, A.S.M.E. Journ. 40, p. 393, May, 1918*).

Thrust Bearings. — Thrust bearings are used on horizontal shafts when the shaft is subjected to a horizontal thrust. They are similar to step bearings for vertical shafts, except that a collar fitting around the shaft is used instead of a plate at the end of the shaft. Steamship shaft bearings have numerous collars on the shaft, with thrust blocks between them. Roller or ball bearings may be used instead of collars.

Ball Bearings. — A ball bearing consists essentially of a track of curved cross-section which is filled with a set of balls. For a discussion of the use of ball bearings in electric machinery see H. N. Turnbull (*Elec. Rev. and West Ltn. 70, p. 1054, 1917*).

Pivot Bearings. — Various types of pivot bearings are used. The pivot may be either a flat surface, a pointed cone, a truncated cone, a hemisphere or a surface of special form, such as Shiele's "tractrix."

ALLOWABLE LOADS AND SPEEDS. — If the pressure on a bearing is too great the oil film between journal and bearing surface will be destroyed and the bearing will overheat and "seize." Various formulas have been developed for the allowable pressure in terms of the speed and type of bearing.

Safe Loads, Line Shaft and Mill Bearings. — F. W. Taylor (*Trans. A.S.M.E., 1905*), as the result of an investigation of line shaft and mill bearings

that were running near the limit of durability and heating, yet not dangerously heating, gives the formula

$$p = \frac{400}{v},$$

where p = pressure in pounds per square inch of projected area (i.e., product of diameter of the journal by its length) and v = peripheral velocity of journal in feet per second.

The formula is applicable to bearings in ordinary shop or mill use on shafting which is intended to run with the care and attention which such bearings usually receive, and gives the maximum or most severe duty to which it is safe to subject ordinary *chain* or *oiled* ball- and socket-bearings which are *babbitted*. It is not safe for ordinary shafting to use *cast-iron boxes*, with either sight feed, wick feed or grease-cup oiling, under as severe conditions as $p \times v = 200$.

Safe Loads, Miscellaneous Bearings. — Alford in *Bearings and their Lubrication*, gives the following allowable bearing pressures in pounds per square inch of projected area.

Kind of bearing and condition of operation	Allowable bearing pressure in lb. per sq. in. of projected area	
United States Naval Practice		
Main engine bearings	275– 400	For weight alone.
Main engine crank pin bearings	400– 500	For weight alone.
Steam turbine bearings	85	For weight alone.
Thrust bearings for torpedo boats	50	For weight alone.
Merchant Marine Practice		
Main engine bearings	400– 500	
Main engine crank pin bearings	400– 500	
High-speed Stationary Engine Practice		
Main bearings	60– 120	For dead load.
Main bearings	150– 250	For steam load.
Crank pin bearings, overhung crank	900–1500	
Crank pin bearings, center crank	400– 600	
Cross-head pin bearings	1000–1800	
Slow Speed Stationary Engine Practice		
Main bearings	80– 140	For dead load.
Main bearings	200– 400	For steam load.
Crank pin bearings	800–1300	
Cross-head pin bearings	1000–1500	
Gas Engine Practice		
Main bearings	500– 700	
Crank pin bearings	1500–1800	
Cross-bead pin bearings	1500–2000	
Electrical Machinery Practice		
Generator and motor bearings	30– 80	
Main engine bearings, driving generators	40– 80	
Horizontal steam turbine bearings	60– 400	
Vertical steam turbine steps	200–1000	

Digitized by Google

Kind of bearing and condition of operation	Allowable bearing pressure in lb. per sq. in. of projected area
MISCELLANEOUS PRACTICE	
Bearings for slow speed and intermittent load as in punch presses, shears and the like	3000–4000
Main bearings of slow speed pumping engines	600
Heavy line-shaft bearings, bronze or babbitt lined	100– 150
Light line-shaft bearings, cast-iron	15– 25
Heavy slow-speed step bearings	2000
Drill-press thrust collars	325
Angular-thrust bearing for boring mill tables	75

Safe Loads, Roller Bearings. — The following table gives the safe load in pounds for Mossberg roller bearings (*Trans. A.S.M.E., 1905*). D = diameter of journal, in inches; d = diameter of roll, in inches; N = number of rolls; P = safe load on journals, in pounds. The rolls are enclosed in a bronze supporting cage.

D	d	N	P	D	d	N	P	D	d	N	P
2	¼	20	3,500	6	1 1/16	24	50,000	15	1⅝	28	255,000
2½	5/16	22	7,000	7	1 5/16	22	70,000	18	1⅝	32	325,000
3	⅜	22	13,000	8	⅞	22	90,000	20	1½	34	400,000
4	7/16	24	24,000	9	1	24	115,000	24	1½	38	576,000
5	5/16	24	37,000	12	1¼	26	175,000	..	....	..	.....

Surface speed of journal from 0 to 50 feet per minute. Length of journal 1½ diameters. The rolls are made of tool steel not too high in carbon, and of spring temper. The journal or shaft should be made not above a medium spring temper. The box should be made of high-carbon steel and tempered as hard as possible.

Marks in his "Mechanical Engineers' Handbook" gives the following formulas for load capacities of roller bearings.

"For rollers such as are used on bridge turn tables and in similar places where the speeds of rotation are slow, the safe load in pounds is $P = cnld$, in which n = number of rollers in the bearing, l and d the length and diameter of each roller, in., $c = 360$ for hard cast-iron rollers running on hard cast-iron tracks, and $c = 850$ for hard steel rollers on hard steel tracks. Where $l > 5d$, smaller values of c should be used. In case conical rollers are used, d is the mean diameter.

"The Standard Roller Bearing Company determines load capacities of roller bearings by the formula $P = 130{,}000d^2\,nl/3s$, in which P = load on bearing, lb.; d = diam. of roller, in.; n = number of rollers; l = length of each roller, in.; and s = circumferential speed of each roller, ft. per min. In bearings with conical rollers d is the diameter of the roller at its mid-length. The safe load per inch of length of a solid roller is taken at 2000 lb., with the assumption that one-third the number of rollers take the whole load on the journal.

Digitized by Google

"Another formula for the safe load on a roller bearing is $P = kld^2/(ND + 2000d)$ in which N = r.p.m. of the shaft; D = diam. of the sleeve or roller path, in.; and k = 1,200,000 to 2,000,000 for first class workmanship, hardened steel rollers with $l = d$, running on hardened ground surfaces; k = 400,000 for ordinary workmanship and soft steel rollers running on a soft steel shaft."

Safe Loads, Ball Bearings. — The following formula is given by Mr. Henry Hess, 1910. See also paper by Mr. Hess in *Trans. A.S.M.E., 1907*.

Let

W = total safe load on bearing in pounds,
n = number of balls,
d = diameter of balls in *eighths of an inch*.

Then for *radial* (cylindrical) bearings

$$W = Knd^2,$$

where K ranges from 0.9 to 9 depending upon the condition and type of bearing and the hardness of the balls, but for ordinary speeds is practically independent of the speed. (*See Kent's Mechanical Engineers' Pocket-Book.*)

For *thrust* bearings

$$W = \frac{K_1 nd^2}{\sqrt[3]{N}},$$

where N is the number of revolutions per minute, which may range from 3000 down to 1 revolution per minute, as for crane hooks and similar elements. For high quality ball K_1 ranges from 25 to 40 for a race having a cross section of radius 1.66 × (radius of balls). For unhardened steel, occasionally used for very large races, $K_1 = 0.5$.

In both types of bearings the balls must be carefully selected to make sure that all that are used in the same bearing do not vary among one another by more than 0.0001 inch. A ball that is more than that larger than its fellows will sustain more than its proportion of the load, and may therefore be overloaded and will in turn overload the races.

FRICTION OF BEARINGS. — The coefficient of friction of a well-lubricated plain cylindrical bearing is practically independent of the projected area of the journal, the pressure per unit area remaining constant, and in the case of plain bearings is also practically independent of the nature of the rubbing surfaces, provided these are smooth.

Friction of Plain Bearings. — The coefficient of friction of plain bearings however, does depend to a very great extent upon the following factors:

1. The method of lubrication.
2. The nature of the lubricant.
3. The temperature of the lubricant.
4. The peripheral velocity of the journal.
5. The pressure of the journal on the bearing surface.

1. The more perfectly the bearing is bathed in oil the less will be the coefficient of friction. The friction coefficient of a scantily lubricated bearing may be from 6 to 10 times the coefficient when an oil bath is used.

2. As a rule the lower the viscosity of an oil the less will be the coefficient of friction. There are other factors, however, which must be taken into account in selecting the proper lubricant for any service (*see article on Lubricants and Lubrication*).

3, 4 and 5. The variation of the friction coefficient with temperature, speed and pressure is shown by the curves in Fig. 1. The pressures are nominal

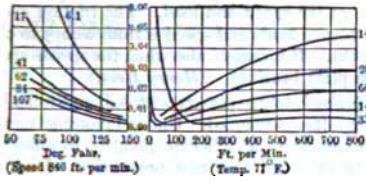

Fig. 1. Numbers at end of curves are pressures in lb. per sq. in.

pressures, i.e., pounds per square inch of projected area of journal. These curves are taken from a paper by Stribeck (*Zeit. Ver. Deutsch. Ing., 1902, Vol. 46*, p. 1341), and are test results on a Sellers bearing with oil rings; journal 13 inches long, 2.75 inches in diameter, lubricated with "gas motor oil." These curves are typical of ordinary bearings.

POWER LOST IN BEARINGS. — Let

f = coefficient of friction,
W = weight on journal or pivot in pounds,
r = radius in inches,
d = diameter in inches,
S = space in feet through which sliding takes place per minute,
r_1 = inner radius in inches,
r_2 = outer radius in inches,
n = number of revolutions per minute,
α = the half-angle of the cone, i.e., the angle of the slope with the axis.

Type of bearing	Friction torque in in.-lb.	Power loss ft.-lb. per min.
Flat surfaces		fWS
Shafts and journals	$\frac{1}{2}\ fWd$	$0.2618\,fW\,dn$
Flat pivots	$\frac{2}{3}\,fWr$	$0.349\,fWrn$
Collar-bearing	$\frac{2}{3}fW\frac{r_2^3 - r_1^3}{r_2^2 - r_1^2}$	$0.349\,fWn\frac{r_2^3 - r_1^3}{r_2^2 - r_1^2}$
Conical pivot	$\frac{2}{3}\,fWr \operatorname{cosec}\alpha$	$0.349\,fWrn \operatorname{cosec}\alpha$
Conical journal	$\frac{2}{3}\,fWr \sec\alpha$	$0.349\,fWrn \sec\alpha$
Truncated-cone pivot	$\frac{2}{3}fW\frac{r_2^3 - r_1^3}{r_2 \sin\alpha}$	$0.349\,fWn\frac{r_2^3 - r_1^3}{r_2 \sin\alpha}$
Hemispherical pivot	fWr	$0.5236\,fWrn$
Tractrix, or Schiele's "anti-friction" pivot	fWr	$0.5236\,fWrn$

It should be noted that for peripheral speeds of 100 feet and over the coefficient of friction is approximately proportional to the square root of the peripheral velocity of the journal. These particular curves also indicate that the coefficient of friction is approximately inversely proportional to the square root of the pressure. Other experimenters, however, have found that this variation is inversely as the first power of the pressure.

Friction of Roller and Ball Bearings. — The friction coefficient of a well-made annular ball bearing is 0.001 and 0.002 of the total load on the journal

Digitized by Google

and is independent of the speed and load. The friction coefficient of a good roller bearing under normal loads and speed is from 0.0035 to 0.014; it rises very much if the load is light. It increases also when the speeds are very low, though not so much as with plain bearings. (*Henry Hess.*)

Lubrication is absolutely necessary with ball-and-roller bearings, although the contrary claim is often advanced. Under favorable conditions an almost imperceptible film is sufficient; a sufficient quantity to immerse half the lowest ball should always be provided as a rust preventive. Rust and grit must be kept out of ball-and-roller bearings. Acid or rancid lubricants are as destructive as rust. (*Henry Hess.*)

Comparison of Plain, Roller and Ball Bearings. — Thomas, Maurer and Kelso (*A.S.M.E. Journ. 36, p. 89, March, 1914*), give the following relative power consumption, based on tests of 20 bearings of each type:

Bearings	100 ft. per min.		300 ft. per min.	
	77° F.	100° F.	77° F.	100 F°.
Ball	1.0	1.0	1.0	1.0
Roller	2.2	2.5	2.7	3.0
Plain Babbitt	3.0	3.6	4.5	4.0

BELTS AND BELTING. — (*See also Ropes and Rope Drive.*) Belts are usually made of tanned leather, though rubber belts are frequently employed, as well as various woven fabrics. Rubber belts are made of two or more layers of canvas connected together with a rubber composition, and then heated until the rubber vulcanizes. The "ply" of a rubber belt is the number of layers of canvas. Leather belts are referred to as single, light-double, medium-double, standard-double and 3-ply. Wire belts with paper driving surface have recently been developed in Germany (*Zeits. Vereines Deutsch. Ing. 63, p. 1057, Oct. 1919*).

Thickness of Belts. — The following figures are from a paper by Samuel Webber (*Am. Mach., May 11, 1909*). The thickness of leather belts, however, is variable, depending on the hide and process of manufacture.

BELT THICKNESS, INCHES

Leather		Rubber	
		30-oz. duck, new rubber vulcanized	
Single thickness	1/8	3-ply	0.18
Light-double	1/4	4-ply	0.24
Medium-double	5/16	5-ply	0.30
Standard-double	1/3	6-ply	0.35
3-ply	9/16	7-ply	0.40
		8-ply	0.45

Weight. — The average weight of leather per cubic inch is 1/30 pound (*Barth*). The average weight of rubber belting made of 30-ounce duck is about 0.045 pound per cubic inch.

Strength. — The strength of the solid leather in belts is from 2000 to 5000 pounds per square inch; at the lacings, even if well put together, only from 1000 to 1500. If riveted, the joint should have half the strength of the solid belt. Rubber belts have approximately the same tensile strength as leather belts. The working tension on the driving side is generally taken at not over one-third of the strength of the lacing, or from one-eighth to one-sixteenth of the strength of the solid belt.

Belt Tension. — Let

T_1 = actual, or "total," tension in pounds per square inch on driving side of belt,

T_2 = actual tension in pounds per square inch on slack side of belt,

T_0 = "initial" tension in belt, i.e., the tension in each side when the belt is at rest,

$T = T_1 - T_2$ = effective tension in pounds per square inch, i.e., T corresponds to the force actually driving the driven pulley,

T_c = the tension produced in the belt due to centrifugal action as it goes around the pulleys,

m = weight of belt per cubic inch in pounds,

f = coefficient of friction between belt and pulley,

Digitized by Google

n = ratio of arc of contact between belt and pulley to an arc of 180°, i.e., if the arc of contact is 180°, $n = 1$,

$C = 1 - \epsilon^{-nf\pi}$. The value of $\epsilon^{-nf\pi}$ may be found directly from the table in the article on *Exponential Functions*, putting $nf\pi = x$,

V = velocity of belt in feet per minute.

Then

$$T_c = \frac{mV^2}{9660}, \tag{1}$$

$$T = C(T_1 - T_c), \tag{2}$$

$$T_2 = T_1 - C(T_1 - T_c), \tag{3}$$

$$T_0 = \left(\frac{\sqrt{T_1} + \sqrt{T_2}}{2}\right)^2 \text{ approximately.*} \tag{4}$$

Barth recommends that for belts running at various speeds the initial tension T_0 should not be the same in all belts, but that the belts should be tightened initially to such a tension that under load the sum

$$A = T_1 + \tfrac{1}{2} T_2 \tag{5}$$

is a constant. Barth also states, basing his conclusion in part on the studies of the economics of belting made by F. W. Taylor (*Trans. A.S.M.E., Vol. 15, p. 204*), that the best values of A for greatest economy are the following:

	Machine belts	Counter-shaft belts
Maximum value of A, belt first put on	320	240
Minimum value of A, belt to be retightened	240	160

These values of A are for full-load conditions. The corresponding values of the various tensions are given below.

Belt Friction and Belt Slip. — The value of the factor C depends upon the coefficient of belt friction, which is subject to considerable variation, depending upon the condition of the belt and pulleys. Barth gives the following formula for f for leather belts on cast-iron pulleys

$$f = 0.54 - \frac{140}{500 + V}.$$

Barth also gives a formula for the belt slip which may be written

$$s = \frac{V_1 - V_2}{V} = \frac{320}{V}\left(\frac{1 + 0.0055\,V}{85 + 0.03\,V}\right),$$

where V_1 and V_2 are the peripheral velocities of the driving and driven pulley respectively.

* See paper by C. G. Barth, *Trans. A.S.M.E.*, 1909, Vol. 31, p. 29. In this paper Barth also gives a more exact formula, and takes into consideration the difference in the relation between T_1, T_2 and T_0 for vertical and horizontal belts.

Power Loss Due to Belt Slip is proportional to the slip, i.e., if the slip is 0.03 the power lost is 3 per cent of the power transmitted by the belt. Under normal conditions the power loss due to belt slip is from 2 to 4 per cent. The power loss in mill shafting due to the friction of the shaft bearings ranges from 10 to 60 per cent, depending upon the type of bearing, belt tension, etc., See article on *Bearings*.

Power Transmitted by Belt. — Let

V = velocity of belt in feet per minute,
w = width of belt, in inches,
t = thickness of belt, in inches,
m = weight, in pounds, of 1 cubic inch of belt,
T_1 = actual tension in driving side of belt in pounds per square inch of belt cross-section,
s = slip of belt as a fraction of belt speed.

Then the horse-power transmitted by the belt is

$$P = \frac{wtCVT_1}{33{,}000}\left(1 - \frac{mV^2}{9660\,T_1}\right),$$

where C, defined above, depends on the belt friction and arc of contact between belt and pulley.

As a rough approximation C may be taken equal to 0.6, and the second term in the bracket zero, at least for low speeds, and the formula then becomes

$$P = \frac{wtVT_1}{55{,}000},$$

or the horse-power transmitted per square inch of belt cross-section is

$$p = \frac{VT_1}{55{,}000}.$$

The power lost in the transmission from one pulley to the other, excluding the loss due to shaft friction, is sP, the driving pulley absorbing approximately $(P + 0.5\,sP)$ horse-power and the driven pulley receiving $(P - 0.5\,sP)$ horse-power.

The following tables are derived from curves in the paper by Barth above referred to.

HORSE-POWER TRANSMITTED BY BELTS DRIVING MACHINES
(For $A = T_1 + 0.5\,T_2 = 240$)

Velocity, ft. per min.	500	1000	2000	3000	4000	5000	6000
Initial tension, T_0	124	120	121	128	136	144	152
Centrifugal tension T_c	o+	3	13	31	56	86	124
Difference, $T_0 - T_c$.....	123	117	108	97	80	58	28
Tension on tight side, T_1...	210	212	211	207	198	187	173
Tension on slack side, T_2...	60	54	57	68	84	107	134
Effective pull, $T_1 - T_2$	150	158	154	139	114	80	39
Sum of tensions $T_1 + T_2$	270	266	269	274	282	294	307

Digitized by Google

HORSE-POWER TRANSMITTED BY BELTS DRIVING COUNTER-SHAFTS

(For $A = T_1 + 0.5\ T_2 = 160$.)

Velocity of belt, ft. per min.	500	1000	2000	3000	4000	5000
Initial tension, T_0.....	82	81	83	89	96	102
Tension on tight side, T_1...	140	141	140	134	125	114
Tension on slack side, T_2...	40	38	41	53	69	92
Effective pull, $T_1 - T_2$.....	100	103	99	81	56	22
Sum of tensions	180	179	181	187	194	206
H.p. per sq. in. of section...	1.51	3.12	6.04	7.36	6.79	3.33

Proper Size of Belt to Transmit a Given Amount of Power. — Using the same notation as in the preceding paragraph, the proper cross-section of the belt in square inches is approximately

$$wt = \frac{55{,}000\,P}{VT_1},$$

or exactly

$$wt = \frac{33{,}000\,P}{CVT_1\left(1 - \frac{mV^2}{9660\,T_1}\right)}.$$

The various "handy formulas" for determining the proper cross-section of belt are all of the form of the approximate formula, and differ only in regard to the proper value to assign to the tension T_1. A working tension, that is the difference between the tensions on the tight and slack sides of the belt, of 45 pounds for a single (thickness) belt 1 inch wide is commonly used, giving a nominal tension of $6 \times 45 = 270$ pounds per square inch. Taking the coefficient C at 0.6, the actual tension in a belt designed in accordance with this rule is 450 pounds per square inch. The value of C varies through a wide range, say from 0.25 to 0.90, chiefly due to the variability of the coefficient of friction.

The following table, deduced from Barth's curves, may be considered as representative of modern practice.

CROSS-SECTION OF LEATHER BELT PER HORSE-POWER TRANSMITTED, IN SQUARE INCHES

Speed, ft. per min.	500	1000	2000	3000	4000	5000	6000
Machine belts.....	0.44	0.209	0.107	0.079	0.072	0.082	0.111
Countershaft belts.....	0.662	0.320	0.166	0.136	0.147	0.300	....

All belts should have a contact area with the smaller pulley of at least 165 degrees. If this is not possible to obtain under normal conditions an idler should be provided to increase the belt contact.

Digitized by Google

Pulley Face and Belt Speed. — The following table may be used fo etermining the pulley face and best belt speed for moderate-speed machines or slow-speed machines the pulley sizes are the same as those used with moder te machines of the same frame dimensions.

PULLEY FACE AND BELT SPEED

Horse-power	Kilowatts	Belt width in inches	Pulley face in inches	Belt speed in feet per minute for moderate-speed machines

Relations of Driving and Driven Pulleys. — The maximum ratio betwee the diameters of the driving and driven pulleys should not exceed 6 : 1. Th ratio will determine the distance between the pulley centers, and good propor tions are given in the accompanying table.

Digitized by Google

CARE AND OPERATION OF BELTS. — The following is taken from an article by F. W. Taylor (*Trans. A.S.M.E., Vol. 15, p. 203*). See also an excellent article by C. J. Morreson (*Eng. Mag. 51, p. 567, July, 1916*).

The best distance from center to center of shafts is from 20 to 25 feet.

Idler pulleys work most satisfactorily when located on the slack side of the belt about one-quarter way from the driving pulley.

Belts are more durable and work more satisfactorily made narrow and thick, rather than wide and thin.

It is safe and advisable to use a double belt on a pulley 12 inches diameter or larger; a triple belt on a pulley 20 inches diameter or larger; a quadruple belt on a pulley 30 inches diameter or larger. As belts increase in width they should also be made thicker.

Approximate Ratio	Minimum Distance Between Centers in Feet
2 : 1	8
3 : 1	10
4 : 1	12
5 : 1	15
6 : 1	20

The ends of the belt should be fastened together by splicing and cementing instead of lacing, wiring or using hooks or clamps of any kind.

Belts should be cleaned and greased every five to six months.

Belt-clamps having spring-balances between the two pairs of clamps should be used for weighing the tension of the belt accurately each time it is tightened.

Double leather belts, when treated with great care and run night and day at moderate speed, should last for 18 years (the tension being adjusted in accordance with Barth's rules).

In figuring the total expense of belting, and the manufacturing cost chargeable to this account, by far the largest item is the time lost on the machines while belts are being relaced and repaired.

The total stretch of leather belting exceeds 6 per cent of the original length.

The stretch during the first six months of the life of belts is 15 per cent of their entire stretch (the tension being adjusted in accordance with Barth's rules).

A double belt will stretch 0.81 per cent of its length before requiring to be tightened (the tension being adjusted in accordance with Barth's rules).

The most important consideration in making up tables and rules for the use and care of belting is how to secure the minimum of interruptions to manufacture from this source.

The average double belt when running night and day in a machine shop will cause an interruption to manufacture not oftener than once in sixteen months (the tension being adjusted in accordance with Barth's rules).

The oak-tanned and fulled belts showed themselves to be superior in all respects except the coefficient of friction to either the oak-tanned not fulled, the semi-rawhide, or rawhide with tanned face.

Belts of any width can be successfully shifted backward and forward on tight and loose pulleys. Belts running between 5000 and 6000 feet per minute and driving 300 h.p. are now being daily shifted on tight and loose pulleys to throw lines of shafting in and out of use.

The best form of belt-shifter for wide belts is a pair of rollers twice the width of belt, either of which can be pressed onto the flat surface of the belt on its slack side close to the driven pulley, the axis of the roller making an angle of 75° with the center line of the belt.

Dressings for Leather Belts. — We advise that no belt dressing should be used except when the belt becomes dry and husky, and in such instances we recommend the use of a dressing. Where this is not used beef tallow at blood

warm temperature should be applied and then dried either by artificial heat or the sun. The addition of beeswax to the tallow will be of some service if the belts are used in wet or damp places. Our experience convinces us that resin should never be used on leather belting. (*Fayerweather and Ladew.*)

Some forms of belt dressing, the compositions of which have not been published, appear to have the property of increasing the coefficient of friction between the belt and the pulley, enabling a given power to be transmitted with a lower belt tension than with undressed belts. C. W. Evans (*Power, Dec., 1905*) gives a diagram, plotted from tests, which shows that three of these compositions gave increased transmission for a given tension, ranging from about 10 per cent for 50 pounds tension per inch of width to 100 per cent increase with 20 pounds tension.

Dressings for Rubber Belts. — Rubber belts will be improved, and their durability increased, by putting on with a painter's brush, and letting it dry, a composition made of equal parts of red lead, black lead, French yellow and litharge, mixed with boiled linseed oil and japan enough to make it dry quickly. The effect of this will be to produce a finely polished surface. If, from dust or other cause, the belt should slip, it should be lightly moistened on the side next the pulley with boiled linseed oil. (*From circulars of manufacturers.*)

Lacing of Belts. — In punching a belt for lacing, use an oval punch, the longer diameter of the punch being parallel with the sides of the belt. Punch two rows of holes in each end, placed zigzag. In a 3-inch belt there should be four holes in each end — two in each row. In a 6-inch belt, seven holes — four in the row nearest the end. A 10-inch belt should have nine holes. The edge of the holes should not come nearer than ⅝ inch from the sides, nor ⅞ inch from the ends of the belt. The second row should be at least 1¾ inches from the end. On wide belts these distances should be even a little greater.

Begin to lace in the center of the belt and take care to keep the ends exactly in line, and to lace both sides with equal tightness. The lacing should not be crossed on the side of the belt that runs next the pulley. In taking up belts observe the same rules as in putting on new ones.

Setting a Belt on Quarter-twist. — A belt must run squarely on to the pulley. To connect with a belt two horizontal shafts at right angles with each other, say an engine-shaft near the floor with a line attached to the ceiling, will require a quarter-turn. First, ascertain the central point on the face of each pulley at the extremity of the horizontal diameter where the belt will leave the pulley, and then set that point on the driven pulley plumb over the corresponding point on the driver. This will cause the belt to run squarely on to each pulley, and it will leave at an angle greater or less, according to the size of the pulleys and their distance from each other.

In quarter-twist belts, in order that the belt may remain on the pulleys, the central plane on each pulley must pass through the point of delivery of the other pulley. This arrangement does not admit of reversed motion.

BLOCKS AND TACKLE. — (*See also Ropes and Rope Drive; Chains and Chain Drive.*) A simple block used with rope tackle consists of one or more pulleys mounted in a casing or shell. They may be single, double, triple, etc., depending upon the number of sheaves or pulleys. In chain blocks, instead of simple pulleys, spur or worm and wheel gearing (*see Gears and Gearing*) or differential pulleys are used. In the triplex block, made by the Yale and Towne Co., the power is transmitted to the hoisting-chain wheel by means of a train of spur gearing operated by the hand chain. In the duplex block the power is transmitted through a worm wheel and screw.

Fig. 1 shows schematically a differential pulley. The two upper pulleys are rigidly fastened together and rotate as one piece. The rims of these pulleys are shaped to mesh with the links of the chain and prevent the latter from slipping. Let D_1 and D_2 be the respective diameters of the larger and smaller upper pulleys. Then if the diameter of the lower pulley is $(D_1 + D_2)/2$, the pull P' required to raise a load W, neglecting friction, is

$$P' = \frac{D_1 - D_2}{2D_1} \cdot W.$$

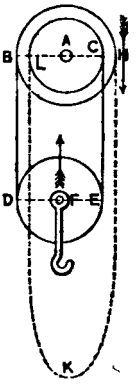

Fig. 1.

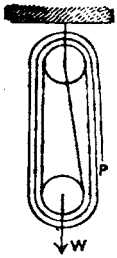

Fig. 2.

ACTUAL PULL REQUIRED; EFFICIENCY OF BLOCK AND TACKLE. — In the case of a simple block and tackle the pull P' required to raise a load W is, neglecting friction,

$$P' = \frac{W}{N},$$

where N is the number of lengths of rope shortened when the lower block rises (in Fig. 2 $N = 6$). The actual pull required is this theoretical pull P' divided by the efficiency expressed as a fraction, or

$$P = \frac{100\,W}{Ne},$$

where e = the per cent efficiency. The distance in feet through which the pulling rope must be pulled to raise the load 1 foot is equal to the number (N) of lengths of rope shortened.

In the case of a differential pulley the actual pull is

$$P = \frac{100\,(D_1 - D_2)\,W}{2D_1 e},$$

where e is the per cent efficiency and the other symbols as above. The distance through which the hand chain must be pulled to raise the load 1 foot is

$$\frac{2D_1}{D_1 - D_2}.$$

In any case, if the rope or chain pulls on the lower block at an angle, the block will be pulled out of the line drawn between the load and the upper block, and the effective pull will be less than the actual pull on the rope in the ratio of the cosine of the angle the pulling rope makes with the vertical, or line of action of the resistance, to unity.

Efficiency of Rope Blocks. — S. L. Wonson, *Eng. News*, June 11, 1903, es the following:

Number of rope lengths shortened, N	Manila rope, 1¼ to 2 in.		¾-inch wire rope	
	Ratio of load to pull	Efficiency, per cent, e	Ratio of load to pull	Efficiency, per cent, e
2	1.91	96	....	..
3	2.64	88	2.73	91
4	3.30	83	3.47	87
5	3.84	77	4.11	82
6	4.33	72	4.70	78
7	4.72	67	5.20	74
8	5.08	64	5.68	71
9	5.37	60	6.08	68
10	....	..	6.46	65
12	....	..	7.08	59

Pull Required with Chain Blocks. — The following table is taken from a catalogue of the Yale and Towne Co.

Capacity in tons, (2000 lb.)	Pull in pounds required on hand-chain to lift full loads			Feet of hand-chain to be pulled by operator to lift load one foot high		
	Triplex	Duplex	Differential	Triplex	Duplex	Differential
¼	...	...	72	...	...	18
½	62	68	122	21	40	24
1	82	87	216	31	59	30
1½	110	94	246	35	80	36
2	120	115	308	42	93	42
3	114	182	557	69	126	38
4	124	142	...	84	155	..
5	110	145	...	126	195	..
6	130	145	...	126	252	..
8	135	160	...	168	310	..
10	140	160	...	210	390	..

For loads from 10 to 20 tons two hand-chains are provided.

SAFE LOAD. — Blocks are usually designed to carry a load as great as that of the rope or chain which fits the grooves in the sheaves (*see Ropes and Rope Drive; Chains and Chain Drive*).

BLOWERS AND COMPRESSORS. — (*See also Draft, Mechanical; Fans.*) A blower is any kind of apparatus that is used for blowing or forcing air or other gas into or out of a room or other receptacle. When it is used to draw air from a room or vessel and discharge it into another vessel or into the external atmosphere it is commonly called an "exhauster." A fan is a blower in which motion is given to the air by means of thin blades or vanes (*see Fans*). A blowing engine is a large machine in which air is compressed in and discharged from a cylinder which is fitted with a reciprocating piston. When a blowing engine delivers air at high pressures, say 30 pounds per square inch and upwards, it is called an air compressor. Following is a brief description of the several kinds of blowers.

Displacement Blowers. — Into a closed tank containing air a stream of water is caused to flow, displacing the air and blowing it out through an opening provided for it. By using two tanks with suitable valves, the action may be made continuous.

Hydraulic Blowers. — A large tank is surmounted by a vertical pipe into the top of which water enters in such a way as to "entrain" or drag air along with it, which is separated from the water when it reaches the tank and is blown out through an air pipe while the water escapes through another opening. Tests of a compressor of this kind at Magog, P. Q., Canada, showed a capacity of from 967 to 1165 cubic feet of air per minute at a pressure of 53 pounds per square inch, and an efficiency of from 60 to 70 per cent. See paper by W. O. Webber, *Trans. A.S.M.E.*, Vol. 22, p. 599.

Jet Blowers. — A jet of water, compressed air, or steam flowing into a short pipe of a diameter greater than that of the jet will induce a current of air to flow through the pipe, which may thus be used as a blower or exhauster. The steam jet is in common use for blowing air into furnaces and gas producers, and is used as an exhaustor to increase the draft of chimneys. It is usually very wasteful of steam, and should be used only in emergencies, when blowing machines are not available, or when the steam used to drive the jet is also used for other purposes, as for combining with the carbon of the fuel in gas producers.

Positive Rotary Blowers. — These are built like rotary pumps, with two rotating shafts, geared together so as to turn in opposite directions, each carrying an "impeller," a casting approximating a figure 8 in section; the curve of the two impellers is so shaped that they touch or nearly touch on lines parallel to the shafts during the whole period of rotation, and also nearly touch the casing which surrounds them. A blower thus built delivers a constant quantity of air at each revolution, differing in this respect from centrifugal fans which deliver a varying quantity according to the resistance the air meets at the outlet. The economical range of these blowers is between 8 ounces and 1 pounds pressure per square inch. For higher pressures then 8 pounds the blowing engine is more economical.

Blowing Engines. — A cylinder with a reciprocating piston when used for blowing air is called a blowing engine, whether it is driven by a steam engine a water wheel or an electric motor. Blowing engines are commonly used to furnish air to blast furnaces and Bessemer converters, at pressures of from 4 to 30 pounds per square inch. They are simple in construction, but are usually large, heavy and costly relative to the quantity and pressure of air furnished by them, on account of their moderate speeds, and there is a tendency to supplant them by

High-speed Centrifugal Compressors. — These are built on the principle of steam turbines or high-pressure centrifugal pumps and are driven at very high

speeds, 1800 to 3500 r.p.m. The General Electric Co. makes a line of these compressors for pressures ranging from 1 to 3.25 pounds per square inch, and for delivering 800 to 28,000 cubic feet of free air per minute. By using several such compressors in series, one delivering into another, pressures of 100 pounds per square inch may be obtained.

POWER AND EFFICIENCY. — The useful work done by a blower is that equivalent to the isothermal compression of the air to the pressure in the receiver (or to the static plus the velocity pressure in the delivery main if the air were cooled to the atmospheric temperature) plus the work of delivering it against that pressure. If P_1 = absolute pressure at inlet in pounds per square foot; P_2 = pressure in the receiver; V_1 = volume of entering air at the pressure P_1, in cubic feet per minute, then useful work in foot-pounds per minute = $P_1 V_1 \log_e \frac{P_2}{P_1}$. The useful or "air horse-power" is this quantity divided by 33,000.

When P_2 is but slightly in excess of P_1 the work per minute is $(P_2 - P_1)V_1$ nearly, the error being less than 5 per cent when $P_2 = 1.1\ P_1$, and less than 1 per cent when $P_2 = 1.01\ P_1$.

When the air is compressed adiabatically, that is, without cooling during compression, the *useful* work is the same as in isothermal compression, but the actual work done in the cylinder (not including work lost by friction and leaking) is greater, or

$$3.463\ P_1 V_1 \left\{ \left(\frac{P_2}{P_1} \right)^{0.29} - 1 \right\}.$$

The efficiency of blowing machines (i.e., the ratio of the air horse-power to the horse-power required to drive the machine) ranges from 95 per cent in the case of a slow-moving engine with large inlet and outlet valves, down to almost zero in poorly designed rotating machines. Centrifugal compressors have an efficiency under normal load of from 40 to 60 per cent (*see Fans*). A 39 by 84-inch positive blower, made by the Connersville Blower Co., is reported to have given an efficiency ranging from 68.5 per cent at an air pressure of 0.5 pound per square inch to 86 per cent at a pressure of 3.5 pounds per square inch, the displacement of air in each case being approximately 18,000 cubic feet per minute. The efficiency of steam-jet blowers is very low.

SPECIFICATION FOR BLOWER. — The following memoranda are intended to assist in writing specifications. See also under *Fans* and article on *Specifications*.

Principal Characteristics and Conditions of Service.—Purpose of blowers.

Style and Description; Details of Construction. — Shall have horizontal, upward or downward discharge. Location of air outlet with reference to rotating parts. Hand or automatic closing of dampers when blower stops. How coupled to motor or engine, i.e., direct or belted. If direct driven, give details of coupler to disconnect blower from motor. Lubrication. Tools. Enclosure of moving parts to reduce danger.

Performance and Tests. — Cubic feet of air per minute. Air pressure, ounces or inches of water column at stated temperature.

ELECTRIC DRIVE OF COMPRESSORS. —(*See also Motors, Industrial Applications of.*) As compressors of the reciprocating type must be driven at a low speed, the synchronous motor is well adapted for driving them, chiefly because this motor operates normally at unity power factor and can be efficiently operated at leading power factors to counteract the lagging power factor

Digitized by Google

due to induction motors driving other apparatus on the system. Slow-speed induction motors must be built with a large number of poles and will then operate at very low power factors with a comparatively low efficiency. Other reasons favoring the synchronous motor drive for this service are the steady load and the new torque required in starting, as a by-pass is generally provided so that the compressor works only against atmospheric pressure when starting. The motor should be able to be started from the alternating-current side and should for this reason be provided with the usual "squirrel-cage" winding. There is usually sufficient flywheel effect in the machine itself to keep within a reasonable angle of displacement, so that no trouble is experienced from "hunting."

The centrifugal type of compressor operates at a comparatively high speed. For driving the smaller size compressors the squirrel cage induction motor is used, but for larger units where a low starting current is desirable the phase wound type of motor should preferably be selected. When design difficulties prevent the use of the induction motor for driving the larger size centrifugal compressors it has been the recent practice to use two-pole, 60-cycle synchronous motors built along the line of the turbo-alternator.

For direct-current installations compound-wound motors are generally used for driving reciprocating compressors and shunt-wound motors for the centrifugal type.

DIMENSIONS, WEIGHTS AND COSTS. — There is so great a variety of blowers and compressors that it is impossible in the space available to give a representative table of dimensions, weights and costs. The reader is referred to the manufacturers' catalogues and price lists. Representative manufacturers are the Ingersoll-Rand Co., the American Blower Co., the Sturtevant Co., and the Connersville Blower Co. (*See also Kent's Mechanical Engineers' Pocket-book.*)

BOILERS, STEAM. — (*See also Chimneys; Condensers, Steam; Conveyors; Lift, Mechanical; Feed-water Heaters; Fuels; Pipes and Piping; Power Stations; Pumps; Separators, Steam; Steam.*) The simplest form of boiler is a closed metal cylinder partly filled with water, with a pipe for the introduction of feed water, another pipe for the escape of steam and means for maintaining a fire under the boiler. Modifications of this elementary form are made: (1) for the purpose of insuring that as large a fraction as possible of the heat energy generated by the burning fuel shall be absorbed by the water and as small a fraction as possible shall be lost in the escaping hot gases and by radiation; and (2) for the purpose of increasing the heating surface and therefore the evaporative capacity of the boiler, with as great an economy of space occupied and of cost in the metallic structure as possible, without at the same time endangering the safety of the boiler, or decreasing its durability, facility for cleaning or other desirable qualities.

DEFINITIONS. — Certain special terms used in reference to boilers are defined below.

Boiler Horse-power. — This term was originally introduced to indicate the size of boiler required for an average reciprocating engine, the boiler being said to have the same horse-power as that of the engine. Due to improvements in the design of steam engines a boiler of a given horse-power rating may be made to supply an engine (e.g., a compound condensing engine) of 3 times the rating of the boiler. The American Society of Mechanical Engineers has adopted the following definition:

"A boiler horse-power is equivalent to the evaporation of 34.5 pounds of water per hour from feed water at 212° F. to saturated steam at the same temperature."

Adopting Marks and Davis's figures for the properties of steam (*see Steam*) 34.5 pounds of steam from and at 212° F. is equivalent to 33,479 B.t.u. per hour, or to an evaporation of 30.018 pounds from 100° F. feed-water temperature into steam at 70 pounds gage pressure.

It is customary in the trade to consider 10 square feet of heating surface as equivalent to a boiler horse-power, for stationary boilers. The term boiler horse-power is not used in connection with locomotive or marine boilers, and there is a tendency to discontinue its use for stationary boilers, expressing their size in square feet of heating surface, and their evaporative capacity in pounds of water evaporated from and at 212° F. per hour.

Equivalent Evaporation. — Factor of Evaporation. — For the purpose of reducing the results of a boiler test made under certain conditions of feed-water temperature and steam pressure and quality to a common standard, it is customary to use the equivalent evaporation from and at 212° F. as that standard. The pounds evaporated under actual conditions are multiplied by a "factor of evaporation," F, which is determined by the formula

$$F = \frac{H - h}{970.4},$$

in which H = total B.t.u. above 32° F. in 1 pound of steam at the actual pressure and degree of superheat, and h = total B.t.u. above 32° F. of 1 pound of the feed water. The values of H and h are given in steam tables (*see Steam*). If the steam contains x per cent of moisture, use for H in the above formula

$$H = H'\left(1 - \frac{x}{100}\right) + \frac{h'x}{100},$$

where H' is the total heat of saturated steam at the given pressure and h' is the heat of the liquid at the given pressure, as given in steam tables.

Digitized by Google

Boiler Efficiency. — The efficiency of the boiler alone is usually defined as the ratio of the number of B.t.u. absorbed by the water per pound of combustible *actually* burnt, to the number of B.t.u. in one pound of the combustible. The over-all efficiency of the boiler and grate is the ratio of the B.t.u. absorbed by the water per pound of *coal as fired* to the number of B.t.u. in one pound of this coal. This over-all efficiency differs from the efficiency of the boiler alone according to the amount of coal lost through the grates.

"Economy" or Water Rate. — Boiler efficiency is also frequently expressed in terms of the number of pounds of water evaporated from and at 212° F. per pound of combustible in the coal actually burnt (this corresponds to the efficiency of the boiler alone), or per pound of coal as fired (this corresponds to the efficiency of boiler and grate). The number of pounds of water evaporated from and at 212° F. per pound of coal is frequently referred to as the "economy" of the boiler, or its "water rate."

The relation between efficiency and economy may be expressed as follows:

Let e = boiler efficiency, in per cent,
B = B.t.u. per pound of coal,
w = economy, i.e., the equivalent number of pounds water evaporated per pound of coal.

Then

$$w = \frac{Be}{97{,}040}.$$

For example, if the coal contains 10,000 B.t.u. per pound and the boiler efficiency is 70 per cent, then the economy is $10{,}000 \times 70/97{,}040 = 7.2$ pounds water per pound coal.

CLASSIFICATION OF BOILERS. — Boilers may be classified as *externally* and *internally fired*, *water tube* and *fire tube*, *through tube* and *return tube*, *horizontal* and *vertical*. An *internally fired* boiler is one in which the furnace is built inside of the boiler, and its roof and sides form a part of the heating surface of the boiler; the locomotive and Scotch marine, the Lancashire and the vertical-tubular boiler are of this type. An *externally fired* boiler is one in which the furnace is separate from the boiler itself and is usually placed underneath it, but sometimes at the side of it in a structure lined with fire-brick. A *fire tube* boiler is one in which the hot gases pass through the tubes, whereas the water is contained in an external shell through which the tubes pass. A *water tube* boiler is one in which the water is contained in the tubes and the hot gases pass around them. A *through tube* boiler is one in which the hot gases pass directly through the tubes from the fire to the smoke flue, whereas in a *return tube* boiler the gases are caused to pass under the shell containing the tubes to the farther end, thence upward through the "back connection," or rear of the setting and return through the tubes to the "breeching" or flue connection to the chimney. The term "return tubular" is applied only to fire tube boilers.

APPLICATIONS OF VARIOUS TYPES. — Externally fired *return tube* boilers in sizes up to 200 horse-power and for pressures up to 150 pounds per square inch are very commonly used. Boilers of this type are comparatively cheap and do not require expensive setting. In large power stations externally-fired *water tube* boilers are almost invariably used in this country. These boilers are built in sizes up to 2300 horse-power and for all practicable pressures. Babcock and Wilcox, Heine, Sterling and Wickes boilers are of the water tube type. In the first two makes the tubes are slightly inclined, in the third they are quite steeply inclined, and in the last they are vertical.

Digitized by Google

Selection of Type of Boiler. — In selecting the type of boiler to be used in any particular case the following points should be taken into consideration: (1) steam pressure desired; (2) space available; (3) danger of explosion; (4) liability to minor troubles which cause temporary stoppage; (5) durability; (6) ease of making repairs; (7) facilities for cleaning and removing scale and for inspection; (8) water-storage capacity; (9) rapidity at which steam can be raised; (10) steadiness of water level; (11) dryness of steam; (12) cost, including setting.

The question of economy of fuel is not generally dependent on the type of boiler as the same economy may be obtained with all types provided each is so designed that (1) there is sufficient heating surface; (2) the fuel can be thoroughly burned in the furnace, so that no unburned gases are allowed to reach the heating surface, and (3) the path of the gases through the boiler is properly baffled so that they are not "short-circuited," leaving part of the heating surface out of the current.

DESIGN AND CONSTRUCTION. — The essential parts of the boiler in the case of a water tube boiler are the tubes, steam drums and mud drums, grates and setting. The tubes are usually 4 inches in diameter in large stationary boilers, and are usually more or less inclined. The steam drums are large cylindrical vessels which serve as a reservoir for the water and steam. The mud drums are arranged to collect a considerable part of the sediment formed by evaporation of the water. Suitable blowpipes are provided for draining off the water and for discharging the sediment and scale-forming material. The water level in the boiler is usually indicated by a gauge glass or try cocks, or both, connected either directly to the boiler shell or to a water column. Suitable manholes and handholes are provided to give access to the various parts of the boiler.

Heating Surface. — For maximum fuel economy with any kind of boiler it should be proportioned so that at least one square foot of heating surface should be given for every 3 pounds of water to be evaporated from and at 212° F. per hour. Still more liberal proportions are required if a portion of the heating surface has its efficiency reduced by: (1) tendency of the heated gases to short-circuit, that is, to select passages of least resistance and flow through them with high velocity, to the neglect of other passages; (2) deposition of soot from smoky fuel; (3) incrustation. If the heating surface is clean, and the heated gases pass over it uniformly, little if any increase in economy can be obtained by increasing the heating surface beyond the proportion of 1 square foot to every 3 pounds of water to be evaporated, and with all conditions favorable but little decrease of economy will take place if the proportion is 1 square foot to every 4 pounds evaporated; but in order to provide for driving of the boiler beyond its rated capacity, and for possible decrease of efficiency due to the causes above named, it is better to adopt 1 square foot to 3 pounds evaporation per hour as the minimum standard proportion.

For maximum commercial economy, taking into consideration not only the cost of fuel but also the interest, depreciation and taxes on the cost of the plant, a higher rate of driving may be required, even as high as 6 or 8 pounds per square foot of heating surface per hour at the time of maximum or peak load, if the high loads last only a few hours each day.

Measurement of Heating Surface. — The usual rule is to consider as heating surface all the surfaces that are surrounded by water on one side and by flame or heated gases on the other, using the external diameter for water tube boilers and the internal diameter for fire tube boilers.

Grates. — Three kinds of grates are employed, the stationary, the rocking or shaking, and the traveling grate. The grate bars are made of cast iron. Rock-

ing grates have the advantage of permitting clearing the fire-bed of ash and clinker without opening the fire door and require less manual labor than the stationary grate. A traveling grate is one form of a mechanical stoker (*see Stokers, Mechanical*).

Grate Surface. — The amount of grate surface required per horse-power and the proper ratio of heating surface to grate surface are extremely variable, depending chiefly upon the character of the coal and upon the rate of draft. With good coal, low in ash, approximately equal results may be obtained with large grate surface and light draft, and with small grate surface and strong draft, the total amount of coal burned per hour being the same in both cases. With good bituminous coal, like Pittsburgh, low in ash, the best results apparently are obtained with strong draft and high rates of combustion, provided the grate surfaces are cut down so that the total coal burned per hour is not too great for the capacity of the heating surface to absorb the heat produced.

With coals high in ash, especially if the ash is easily fusible, tending to choke the grates, large grate surface and a slow rate of combustion are required, unless means, such as shaking grates, are provided to get rid of the ash as fast as it is made.

The following table is adapted from a more extensive one given in Gebhardt's *Steam Power Plant Engineering*.

Nature of plant	Number of plants	Character of fuel	Average ratio of heating surface to grate surface
Central stations	10	Illinois screenings, 15 to 20% ash	65
Central stations	14	Bituminous	60
Central stations	1	Bituminous	31
Central stations	9	Anthracite	40
Mfg. plants	20	Anthracite	35
Office building	6	Bituminous	48

Calculation of Required Heating Surface and Grate Area. — From the data given above the proper grate area and heating surface may be calculated as follows:

Example 1. — Steam required per hour at the "peak of the load," 6000 pounds; 3000 pounds ordinarily. Steam per pound of the poorest coal under the given conditions of feed-water temperature and steam pressure at maximum rate of driving, 6 pounds. This corresponds to 6000/6 = 1000 pounds of coal per hour. Maximum rate of combustion under worst conditions 25 pounds of coal per square foot of grate per hour. The required grate surface is then 1000/25 = 40 square feet. Heating surface for maximum economy at ordinary driving will be 3000/3 = 1000 square feet, requiring 6000 × 3/3000 = 6 pounds of steam per square foot of heating surface per hour at highest rate. Ratio of heating to grate surface, 1000/40 = 25 to 1.

Example 2. Let 3000 pounds of steam be required per hour uniformly. The coal is of good quality so that 9 pounds of water will be evaporated per pound

f coal when the rate of driving does not exceed 3 pounds of evaporation per quare foot of heating surface per hour. The rate of combustion of this coal ay be as high as 30 pounds per square foot of grate per hour, but to have ore easy firing, 20 pounds is chosen. Then,

Heating surface = 3000/3 = 1000 square feet;
Coal per hour = 3000/9 = 333 pounds;
Grate surface = 333/20 = 16.7 square feet;
Ratio of heating to grate surface = 1000/16.7 = 60 to 1.

Air Passages through Grates. — The usual practice is to make the ir opening 30 to 50 per cent of the total grate area. With coal free from finker much smaller openings may be used.

Flues and Other Gas Passages. — Rules are usually given making the rea of gas passages bear a certain ratio to the area of the grate surface; thus a ommon rule for horizontal tubular boilers is to make the area over the bridge all 1/7 of the grate surface, the flue area 1/8, and the chimney area 1/8.

For average conditions with anthracite coal and moderate draft, say a rate f combustion of 12 pounds of coal per square foot of grate per hour, and a atio of heating to grate surface of 30 to 1, this rule is as good as any, but it is vident that if the draft were increased so as to cause a rate of combustion f 24 pounds, requiring the grate surface to be cut down to a ratio of 60 to 1, the reas of gas passages should not be reduced in proportion. The amount of oal burned per hour being the same under the changed conditions, and there being no reason why the gases should travel at a higher velocity, the actual reas of the passages should remain as before, but the ratio of the area to the grate surface would in that case be doubled.

Mr. Barrus states that the highest efficiency with anthracite coal is obtained when the tube area is 1/6 to 1/10 of the grate surface, and with bituminous coal when it is 1/6 to 1/7, for the conditions of medium rates of combustion, such as 10 to 12 pounds per square foot of grate per hour, and 12 square feet of heating surface allowed to the horse-power.

Boiler Settings. — The boiler proper is usually mounted in a brick setting with suitable iron buckstays. The setting also forms the walls of the furnace. Common red brick is usually employed for the setting except for those parts which are exposed to a sufficiently high temperature to require the use of fire brick. Sometimes a separate furnace, or "Dutch oven," directly in front of the boiler, is used.

OIL BURNERS AND FURNACES. — In burning liquid fuel in steam-boiler or other furnaces it is of the utmost importance that the fuel be completely atomized and that each minute particle be surrounded by sufficient air for its complete combustion. Failure in this results in the formation of smoke and soot. The following methods of injecting the oil and air into the furnace are used in connection with steam boilers:

(1) *Steam injection.* A fine jet of steam at high pressure is employed to inject both oil and air into the furnace. Furnaces fired by this method are very successful in burning oil without smoke, if the oil is not fed to the furnace at a rate faster than that for which the burner is designed. (2) *Air injection.* Air at about 40 pounds pressure per square inch is used to inject and atomize the oil. Burners of this type are very successful, and they give higher temperatures than steam injectors. The objection to them is the cost of the air-compressing machinery. (3) *Mechanical injectors.* The oil under pressure operates a revolving device in the nozzle of the burner which causes the oil to be delivered in a very fine spray. Some burners of this type have given excellent results. With these burners it is necessary to supply the oil under a high pres-

sure, say from 50 to 80 pounds per square inch and to heat it before reaching the burner to a temperature of from 120° to 180° F. in order to reduce its viscosity.

More important than the burner is the furnace. It must be of sufficient size to give ample room for complete combustion of the gases formed by decomposition of the oil before these gases are allowed to be chilled by contact with the heating surfaces of the boiler. For economy of oil the air supply should be regulated so that the excess of air is not more than 50 per cent above that theoretically required for complete combustion.

POWDERED FUEL BURNERS AND FURNACES. — In burning powdered fuel, it is necessary that the coal be dried to a moisture of 1 per cent or less. The coal must be ground to such fineness that 95 per cent will pass through a 100-mesh screen and 80 to 85 per cent through a 200-mesh screen. Reliable regulation of the coal and air supply seems to be the principal requirement of a good burner. John V. Cullney specifies the essentials as: (*a*) uniform feed; (*b*) proper mixture of coal and air; (*c*) proper control and ability to vary coal supply; (*d*) simplicity; (*e*) compactness. The life of furnaces using pulverized coal varies with the type of furnace. Information available at the present time indicates that the life of such furnaces is about the same as for furnaces using oil. The working temperatures of powdered fuel furnaces seem to range from 1800 to 3000° F.

Cost of Grinding and Handling, including Upkeep (Pre-war figures). — These items vary considerably with plants of different size and under different operating conditions. The cost of grinding, drying, handling, etc., per ton of fuel, as reported by four companies is as follows:

For Plant (*a*) about 45 cts. per ton, subdivided as follows:

Labor	15 cts.
Power	10
Repairs	14.5
Coal for drying	5.5
	45 cts.

For Plant (*b*), based on 200 tons in 24 hours, excluding overhead charges, interest, and depreciation.

Price of coal	Cost of grinding, handling, etc.
$1	17.6 cts.
2	21.8
3	23.9

For Plant (*c*), 140 tons per 24 hours in plant built 16 years ago.

	Cost per ton.	
Labor, operating	15.64 cts.	
Labor, repairs	1.70	
Supplies, fuel, power, etc.	14.71	
Oil and waste	1.25	
Repairs	4.54	
		37.84 cts.
Interest, depreciation and obsolescence		1.35
		39.19 cts.

For Plant (*d*), from 11.4 cts. per ton to 49.2 cts., depending upon the degree of pulverization, amount of coal consumed, etc.

Digitized by Google

SUPERHEATERS. — To obtain the advantages of superheated steam (*see* ...am), various forms of superheaters are employed. A superheater consists ...entially of a number of small tubes, through which the steam is passed, ...anged to be heated by the hot gases in the boiler or from some external ...rce. In this country the superheater is nearly always placed within the ...iler setting. Frequent cleaning of the exterior walls of the superheater tubes ...th steam is necessary to prevent the accumulation of soot. It is customary ...provide for the flooding of the superheaters when the boiler is banked and ...en steam is being raised; this procedure may be undesirable when the feed ...ter contains much scale-forming impurity, as superheater tubes are not ...dily cleaned internally.

PERFORMANCE OF BOILERS. — The number of boiler horse-power ...., the number of pounds of steam from and at 212° F. divided by 34.5) which ...n be obtained from a boiler depends upon the heating surface of the boiler, ...e grate area of the furnace, the quality of coal used, the method of firing, etc. ...nsequently the horse-power rating of a boiler is at best but an exceedingly ...gh indication of its capacity, and therefore the modern tendency is to rate ...oiler in terms of the number of square feet of heating surface. If the horse-...wer rating is also given, this is usually taken arbitrarily for water tube boilers ...the number of square feet of heating surface divided by 10; that is, 1 boiler ...se-power is taken as equivalent to 10 square feet of heating surface. Some ...ge modern boilers, however, are operated normally under conditions such ...t the boiler horse-power actually developed is twice the rating on this basis. ...ilders of fire tube boilers usually rate them on the basis of 11 to 12 square ...et per boiler horse-power.

Boiler Capacity. — The capacity of a boiler may be expressed in terms ...the boiler horse-power which may be obtained from it, or, more definitely, ...terms of the number of pounds of water which can be evaporated in it. The ...pacity of a boiler, by which is meant the quantity of steam it will make in a ...ven time, depends (1) upon the quantity of heat that can be generated in ...e furnace, and (2) upon the percentage of this heat that is absorbed by the ...iler and not wasted in the chimney gases or by radiation.

The first essential of boiler capacity for a given heating surface is furnace ...pacity, and this depends chiefly upon three things, area of grate surface, ...uality of fuel and force of draft. It may also depend upon the kind of grate, ...plain or shaking grate, or mechanical stoker; upon the roof of the furnace, ...hether formed of the heating surface of the boiler, or of fire brick; and upon ...e introduction of air above the fire in addition to that which passes through ...e grate. The second essential of boiler capacity is boiler efficiency. Other ...hings being equal, anything that increases the efficiency of a boiler increases ...s capacity in the same ratio.

Factors Affecting the Efficiency of a Boiler. — Boiler efficiency de...ends: (1) on the quality of the coal (or other fuel) as regards its content of ...oisture and volatile matter (*see article on Fuels*); (2) on the completeness ...ith which the coal is burned in the furnace, before the gases of combustion ...ach the heating surface; (3) on the combustion being effected with the least ...ossible excess of air, above 20 per cent excess being necessary to avoid imperfect ...mbustion; (4) on the cleanness of the heating surface, inside and out; (5) on ...e proper baffling of the gases, so as to avoid short-circuiting; (6) on the heat ...st by radiation; and (7) on the extent of the heating surface relative to the ...uantity of heat generated, or to the rate of driving of the boiler, as measured ...y the heat absorbed in a given time per square foot of heating surface (*see ...ction on Heating Surface, below*). In general the efficiency of a boiler may be ...epresented approximately by the equation

Digitized by Google

$$e = \frac{T_1 - T_2}{T_1},$$

in which T_1 is the temperature of the fire and T_2 the temperature of the chim gases. The temperature T_1 is proportional to the heat generated in the furn assuming the specific heat of the gases to be constant, and T_2 to the heat in the chimney. The loss by radiation is not considered in the formula. this is generally not over 2 to 3 per cent when a boiler is driven at a normal r

Values of Boiler Efficiency. — The *highest* efficiency that is obtai with ordinary boilers and furnaces, fired by hand, is about 79 per cent v anthracite and 76 per cent with bituminous coal. As high as 81 per cent s possibly be obtained with bituminous coal with very large boilers, provi with mechanical stokers, and 82 per cent with oil fuel. With economiz heating the feed water by the waste heat of the gases from the boiler, the c bined efficiency of boiler and economizer may be as high as 90 per cent.

The necessary conditions for obtaining these high figures of efficiency (1) that the coal is of good quality, low in moisture; (2) that the coal is bur uniformly and with uniform conditions of air supply, so that the grate is obstructed by clinker or imperfectly covered by coal; (3) that the rate of dri does not exceed 3 pounds evaporation per square foot of heating surface hour; (4) that the air supply does not exceed 20 pounds per pound of coa burned; (5) that the combustion of the gases is completed in the furnace that no unburned gases touch the heating surface of the boiler and bec chilled below the point of ignition; (6) that the path of the gases through boiler is so baffled as to cause them to traverse uniformly all parts of the hea surface; (7) that the heating surface is free from soot and dust on the out and from scale or grease on the inside.

The conditions of high efficiency above described are obtained only in best-managed plants, where the chimney gases are constantly analyzed a check on the air supply (*see below under Tests of Boilers*). In the average p in everyday practice the efficiency may be anywhere from 10 to 30 per c below the best possible.

Boiler efficiencies are usually graded as follows: 50 to 60 per cent, poor; 6 70 per cent, fair; 70 to 75 per cent, good; over 75 per cent, excellent.

Effect of Rate of Evaporation on Efficiency. — On the basis o square feet of heating surface per boiler horse-power (34.5 pounds of steam f and at 212° F.) approximately 3 pounds of steam are evaporated per square of heating surface when the boiler is developing its rating at normal steam pres and temperature. If there is sufficient grate surface and draft the evapora may be increased to 6 or in emergency to 15 pounds of steam per square of heating surface. The efficiency, however, falls off with increased rat driving. The following figures are taken from a test by D. S. Jacobus (*Tr A.S.M.E., 1911*) on a large Stirling boiler (23,650 square feet of heating surfa

Equivalent evaporation per square foot =	3.24	3.40	3.72	4.18	5.22	5.62	6.40	6.67	6.75
Over-all efficiency =	81.2	81.0	80.3	79.2	77.1	77.9	76.4	76.7	75.6

Still higher rates of driving and the corresponding efficiencies are given be these figures being taken from a test of Babcock & Wilcox boilers designed the United States warships "Cincinnati" and "Wyoming" (*Industrial E neering, March, 1911*). The results are as follows:

Equivalent evaporation per square foot =	8.42	8.75	9.03	9.58	10.1	10.5	13.7
Over-all efficiency =	70.4	70.6	72.1	68.2	70.1	71.0	64.5

These efficiencies are all exceptionally high for the given rates of driving, t the relative efficiencies for the different rates are representative of good rage practice.

Thickness of Fire and Efficiency. — Too thin a fire results in excess air and too thick a fire in a deficiency, unless sufficient draft is provided by ans of fans or tall chimneys (*see Draft, Mechanical*). There are so many tors to be considered that the proper thickness for maximum economy in any rticular case can be determined only from actual test. Under ordinary con- tions of hand-firing the thickness of fire for best efficiency ranges from 6 to 12 ches.

Air Supply and Efficiency. — The air supply for maximum efficiency, l other conditions remaining constant, is about 17 or 18 pounds per pound of rbon.

With an air supply lower than 17 pounds the efficiency is likely to fall off, i account of imperfect combustion. If the air supply is greater than 20 pounds e efficiency falls off very rapidly, the excess air supply causing a reduction temperature in the furnace and an increase of heat carried into the chimney.

Heat Balance and Distribution of Losses. — By the "heat balance" is ant a statement accounting for ultimate distribution of the B.t.u. in the el supplied to the boiler. Such a statement is usually made up as follows. he figures given illustrate the ordinary range for the various items.

HEAT BALANCE PER POUND OF COMBUSTIBLE

Item	B.t.u.	Per cent
1. Heat absorbed by the boiler	.....	80–50
2. Loss due to heating moisture in coal	.....	0.2–2.0
3. Loss due to heating moisture formed by the burning of hydrogen	.....	0.5–4.0
4. Loss due to heat carried away in the dry chimney gases	.....	12–30
5. Loss due to incomplete combustion of carbon (CO in flue gas)	.....	0.0–3.0
6. Loss due to		
a. Unconsumed hydrogen and hydrocarbons (smoke and soot)	.....	0.0–1.5
b. To heating the moisture in the air	.....	0.2–1.5
c. To carbon lost through grate	.....	0.5–3.0
d. To radiation	.....	1.0–3.0
e. Unaccounted for	.....	1.0–10.0
Total	11,000 to 15,500	100

The five items under 6 are frequently given as a single item.

TESTING OF BOILERS. — The principal observations made during an evaporation" test of a boiler are pounds of water evaporated, pounds of coal red, steam pressure and feed-water temperature. Records of the water aporated and the coal fired should be made for each hour of the test if possible. he steam pressures and feed-water temperatures are recorded every half-hour r oftener, and averaged for the whole test. All conditions should as nearly s possible be the same at the end as at the beginning of the test. When the rnaces are hand fired, tests of 8 to 10 hours duration are usually sufficient, but hen mechanical stokers are used it is difficult to obtain an equal quantity and ndition of the coal in the furnace at the beginning and end of the test, and a

large error in the results may be made if the test is much shorter than 24 hour The average moisture in the coal should be determined and the ash and refu should be weighed.

In all important tests the code of the American Society of Mechanical Eng neers (new code to be published shortly, 1922) should be followed. The princip data and results given in this code are as follows:

PRINCIPAL DATA AND RESULTS OF BOILER TEST.

1.	Grate surface (width ...., length ....)	sq. ft.
2.	Total heating surface	sq. ft.
3.	Date	
4.	Duration	hr.
5.	Kind and size of coal	
6.	Steam pressure by gauge	lb.
7.	Temperature of feed water entering boiler	° F.
8.	Percentage of moisture in steam or number of degrees of superheating	per cent or ° F.
9.	Percentage of moisture in coal	per cent
10.	Dry coal consumed per hour	lb.
11.	Dry coal consumed per sq. ft of grate surface per hour	lb.
12.	Equivalent evaporation per hour from and at 212°	lb.
13.	Equivalent evaporation per hour from and at 212° per sq. ft. of heating surface	lb.
14.	Rated capacity per hour, from and at 212°	lb.
15.	Percentage of rated capacity developed	per cent
16.	Equivalent evaporation from and at 212° per lb. of dry coal	lb.
17.	Equivalent evaporation from and at 212° per lb. of combustible	lb.
18.	Calorific value of 1 lb. of dry coal by calorimeter	B.t.u.
19.	Calorific value of 1 lb. of combustible by calorimeter	B.t.u.
20.	Efficiency of boiler, furnace and grate: $100 \times \left(\frac{\text{Item } 16 \times 970.4}{\text{Item } 18}\right)$	per cent
21.	Efficiency of boiler and furnace: $100 \times \left(\frac{\text{Item } 17 \times 970.4}{\text{Item } 19}\right)$	per cent

Flue Gas Analysis and Heat Balance. — See Kent's *Mechanical Engineer Pocket-Book* and Gebhardt's *Steam Power Plant Engineering*.

SPECIFICATIONS FOR STEAM BOILERS. — As nearly all stea boilers are now made by large manufacturing concerns who have their ow specifications as to details of construction, quality of material, etc., it is rare the case that an engineer of a power plant or a consulting engineer is called o to make an original design of a boiler or to furnish detailed specifications fo one. What is usually done is to call for bids on general specifications, namin the quality of coal to be used, the kind of furnace or stoker, the horse-power t be developed (34.5 pounds of water evaporated from and at 212° F. = 1 h.p. when the boiler is driven at a rate not to exceed 3.5 pounds per square foot o heating surface per hour, evaporated from and at 212° F., and the overload capa

y desired for higher rates of driving, or " the peak of the load." The bids re-ved are then tabulated as to the details, such as heating surface, grate surface, e of combustion chamber, size of tubes, diameter of shell, quality of steel, le of riveting, factor of safety, space occupied, guarantees of capacity and nomy, etc., and a selection made of the boiler that appears to be the most itable for the location. Of two boilers that have the same heating surface e one that has the largest grate surface is the one that has the greatest over-ad capacity, if the draft is the same in both cases. Guarantees of capacity id economy may be disregarded when bids are for ordinary forms of boilers id furnaces, for the capacity and economy of two boilers of the same size of ate and heating surface will be practically the same whatever the type or rm of the boiler, but they will vary greatly from causes independent of the ilers themselves, such as quality of coal, method of firing, kind of furnace, e of combustion chamber, etc.

OPERATION OF BOILERS. — To obtain the best results from boilers, nsiderable care must be paid to the firing and regulation of air supply.

Firing. — There are three common methods of hand firing: (1) the alternate which fresh coal is fired on one side of the grate at a time, the combustion of olatile matter being assisted by the heated air passing through the other side; 2) the spread-firing, in which small amounts are spread thinly over the entire re bed; and (3) the coking, in which a thick bed of fresh coal is fired directly n front of the door and allowed to coke, after which it is pushed back into the urnace. The best method for any particular kind of fuel, style of furnace nd rate of driving should be determined by experiment.

Mechanical stokers (*see Stokers, Mechanical*) afford the following advantages: ix., the uniform feeding of coal, the close regulation of the air supply at all imes, and consequently smokeless and efficient combustion with a wide range f loads, and a great reduction of labor cost in handling and firing fuel. In mall plants with poor load factors the expense of installation is generally con-idered prohibitive, but in plants of 1500 kilowatts or more a considerable net nnual saving can usually be obtained.

Air Supply. — (*See also Chimneys; Draft, Mechanical.*) The extent of the ue losses is determined by the amount of gas discharged, the temperature at hich it is discharged, the amount of incompletely burned gas discharged and he amount of latent heat carried away in water vapor. The minimum economic mount of flue gas would obtain with the amount of air supplied to the fire xactly equal to the theoretical requirements of complete combustion. The dmission of less air tends to the production of CO. More air dilutes the flue as, increases the total amount of gas rejected and, in the same ratio, increases he amount of heat rejected, the stack temperature remaining the same. The heoretical air supply per pound of combustible (*see Fuels*) is approximately .2 pounds, but since the air and fuel cannot be mixed with perfect intimacy it s necessary to considerably increase this amount to prevent the formation of CO. See above under *Air Supply and Efficiency.*

CO_2 Recorders. — The per cent of CO_2 in the flue gas is an index of the ir excess, provided combustion is complete. With perfect combustion and no xcess air 20.9 per cent CO_2 should be obtained with pure carbon as fuel, or 18.6 per cent with a fuel composed of 95 parts C and 5 parts H. In practice nore air must be supplied and 14 per cent CO_2 represents about the upper limit which should be attempted. 12 per cent CO_2 is good, 10 per cent fair and 8 per cent poor. Several types of CO_2 recorders have been devised. If prop-rly maintained and interpreted they form a valuable check on the regulation f the air supply. Their indications, however, give no clue to the presence of CO, and are directly significant only when the formation of CO is prevented.

Flue-gas Temperature. — Because of the great heating surface wh would be required it is not practicable to reduce flue-gas temperature to l than 75 degrees above the feed water. Economizers or flue-gas feed-wa heaters (*see Feed-water Heaters*) assist in lowering the temperature of disch but add considerably to the space required, increase the cost of installation a maintenance and increase the total draft required. Without economizers it seldom economical to attempt to reduce the gas temperature below 450° F.

Smoke represents a minor element of loss *per se*, seldom exceeding 1 per ce but it is generally an index of inefficient combustion. Smoke is usually due a poorly regulated air supply, an imperfect mixture of air and fuel, or the u rapid volatilization of hydrocarbons and their premature chilling in a h burned state. The absence of smoke, however, is not a final index of efficien for the air supply may be excessive. See also article on *Smoke Prevention*.

Feed Water. — (*See Feed-water Heaters; Pumps and Pumping Engines.*)

Cleaning Tubes. — The tubes of a boiler should be kept clean, both int nally and externally. For blowing the soot off the external surface the tu of water tube boilers or off the internal surface of the tubes of fire tube boil a steam jet blower is ordinarily used. For removing scale from the interior water tubes different forms of scrapers or chippers are used, also rotary cutti devices driven at a high speed by steam, water or other power. For removi scale from the water side of fire tubes of horizontal tubular boilers the usu method is the operation of chipping and hammering by a man working insi of the boiler. Sometimes the scale is softened by the use of soda or other chem cals, before chipping, and a strong jet of water from a hose assists in detachi the scale. In locomotive practice it is often necessary to cut the tubes out the boiler and run them through a cleaning machine, and then to weld a pie of each tube on one end to restore its original length, and to reset the tubes i the boiler.

DIMENSIONS OF BOILERS. — An ordinary fire tube boiler occupi a floor space of from 1.5 to 2.0 square feet per boiler horse-power (on th basis of 12 square feet of heating surface per horse-power). A water-tub boiler occupies from 0.5 to 1.0 square foot of floor space per boiler horse-p wer (on the basis of 10 square feet of heating surface per horse-power). Wit either type the height ranges from as low as 7 to as high as 30 feet dependin not only on the horse-power but also on the style, whether horizontal o vertical. One boiler is sometimes placed directly on top of another, making "double-deck" arrangement. For complete dimensions see the manufacturer catalogues.

COST OF BOILERS (Pre-war figures). — The selling price of boilers pe rated horse-power (10 square feet of heating surface = 1 horse-power) rang from about $8 to $25, depending upon the size, the pressure they are to sustain the style and design, etc. The lowest prices named are for large-sized ordinar horizontal tubular boilers (fire tube) for low pressures. For power plants o 1000 horse-power and over the price will range usually between $10 and $15 fo pressures not over 150 pounds per square inch. For higher pressures and in boilers provided with superheaters the prices will be higher. For boilers of les than 100 horse-power the price per horse-power increases as the size decreases The prices named are for the boilers with the usual fittings of grates, steam an water gauges, blow-off and stop valves, on board cars at the boiler works, an do not include the cost of erection nor of brickwork, flues or chimneys. (*See also Power Station.*)

The following approximate rules, in which P = boiler horse-power, may b used for determining the cost of boilers:

Digitized by Google

) Horizontal return tubular boilers.
Cost f.o.b. factory ($) = 180 + 6.4*P*
Cost of setting ($) = 140 + 2*P*.

) Horizontal water-tube boilers, 125 lb. pressure.
Cost f.o.b. factory ($) = 425 + 9*P*.
Cost of setting ($) = 140 + 2*P*.

) High grade water-tube boiler, 160 lb. pressure.
Cost f.o.b. factory ($) = 1000 + 10*P*.

) High grade water-tube boiler, 200 lb. pressure.
Cost f.o.b. factory ($) = 1300 + 12*P*.

BONDS, RAILWAY TRACK. — (*See also Third Rail Systems; Trolley Systems; Wires and Cables.*) Rail bonds are electrical conductors for bridging the joints of rails. They consist either of a series of thin strips of annealed copper, or of one or more cables of copper wire, the ends of which are usually pressed or cast into solid copper terminals. Ribbon is more compact, but stranded wire is more flexible; the latter should always be used if space permits. Sometimes the terminals are made by upsetting the ends of a stranded conductor, so as to form a crude bond head. The terminals of the headed bonds are then heated to a welding heat in furnaces, and pressed to the proper size and shape, the separate wires in the terminals becoming a solid mass of homogeneous copper. After being cleansed of all foreign substances the terminals are shaved to the proper size.

TYPES OF BONDS. — Bonds may be classified, according to the method of fastening them to the rail, as soldered bonds, brazed bonds and bonds applied by mechanical pressure.

Soldered Bonds (Figs. 1 and 2) usually consist of a series of thin strips of annealed copper with tinned terminals as shown in Figs. 1 and 2. They are

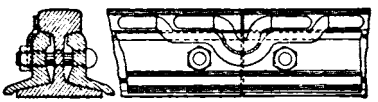

Fig. 1.

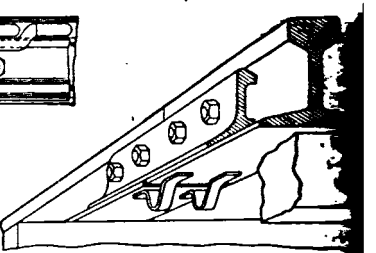

Fig. 2.

soldered direct to the head, foot or web of the rail. One or more bonds per joint may be used. A few companies employing well-trained workmen continue to install bonds of this type, but they have generally been abandoned.

Brazed Bonds resemble soldered bonds except that the terminals are enveloped in brass. They are brazed or welded to the rail by heat generated electrically in a carbon which constitutes one jaw of a clamp holding the bond against the rail. These are sometimes known as "electrically welded" bonds.

Expanded and Compressed Terminal Bonds. — Bonds fastened to the rail by mechanical pressure may be divided into two general classes, expanded terminal and compressed terminal bonds. Both kinds are called "stud terminal" bonds. The number of stud terminal bonds in use greatly exceeds that of any other kind, brazed bonds being second.

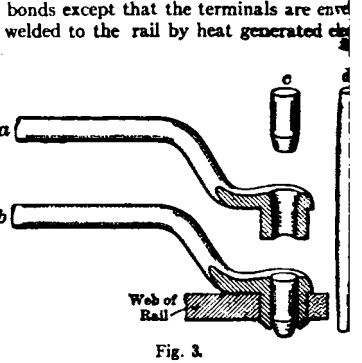

Fig. 3.

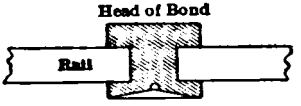
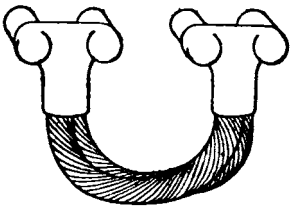
Pin-expanded Terminal Bonds (Fig. 3) have their heads drilled with an axial hole, through which a tapered steel pin *d* is driven, forcing the copper

tward and against the steel. This type of bond is fastened to the web of th
l.

Compressed Terminal Bonds (Figs. 4 and 5). — There are two kinds compressed terminal bonds, in one of which direct pressure is applied at both ds of the head, and in the other, at one end only. The first type of bond is ually applied to the web of the rail by means of a heavy screw or hydraulic ss (Fig. 8) which engages the bond head and causes it to compress longitudi-lly and expand laterally as the pressure is applied, bringing the copper into





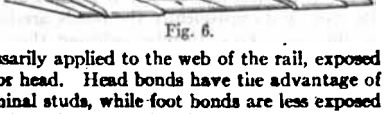


Fig. 4.

Fig. 5.

m contact with the steel and spreading the projecting end of the terminal into button-shaped rivet-head, as shown in Fig. 4. The second type of bond (Fig.) is applied only to the head of the rail, the terminal lugs being set in holes herein and expanded into contact by means of hammer blows.

Compressed Terminal Soldered Bond. — A type of bond which has been ound very successful at the Detroit River Tunnel for third-rail work is a com-ressed terminal head bond soldered to the rail. The combination of mechani-l adhesion and soldering has resulted in a bond of unusual durability. *J. B. P. Wrenn.*)

Exposed Versus Concealed Bonds. — Whether soldered, brazed, expanded r compressed, bonds may be either exposed or concealed (Fig. 6) under the ab-plates. The former condition is preferable, if there is no likelihood of heft, as it permits inspection to be asily made. Where the bonds are xposed to theft, as, for example, a track rails unprotected by pav-ng, concealed bonds are almost a ecessity.

Fig. 6.

While concealed bonds are necessarily applied to the web of the rail, exposed onds may be applied to the foot or head. Head bonds have the advantage of reater contact surface at the terminal studs, while foot bonds are less exposed o mechanical violence. Web bonds, unless concealed, have to be excessively ong in order to span the fish-plates.

USES OF VARIOUS TYPES OF BONDS. — Bonds are used for track ails, third rails and girders of elevated and subway lines. Soldered bonds and ompressed terminal head bonds find their best application in third-rail work, here good electrical contact is of greater importance than mechanical strength. Expanded terminal web bonds, especially of the concealed type with two stranded onductors, are regarded as the best for heavy track work, where mechanical trength and ease of installation are of the utmost importance.

SUBSTITUTES FOR BONDING. — Several efficient substitutes for bond-ng are now in use, such as electrical welding, cast welding and Thermit welding.

Electrical Welding is performed by clamping an iron bar to the web of the ails, and bringing the bar and the neighboring part of the rail to a white heat by

means of an electric current. Another process accomplishes the welding by means of a carbon electrode. A modification of the latter process makes use of a composition bar which is clamped against the fish-plate. A soft steel rod is placed in a groove between the rail and composition bar supplies the welding material.

Cast Welding is accomplished by setting a mold around the rail joint and pouring molten iron around it. The Thermit process is a modification of this, the iron being liberated at a white heat from a mixture of iron oxide and aluminum, which is ignited in a crucible.

SELECTION OF TYPE AND SIZE OF BOND. — Considerations determining the choice between concealed and exposed bonds are liability of theft, electrolytic corrosion, facility of inspection and injury to fish-plate bolts of old rails.

The choice between mechanical adhesion and soldering depends largely upon the importance of rapid installation, the mechanical stresses to be withstood in service, the type of labor available and the facilities for the use of drills, presses, etc.

Single vs. Double Bonding. — Joints are sometimes bonded with one bond, sometimes with two bonds. Double bonding has the advantages of less chance of complete failure and greater carrying capacity for a given cross-section of copper. It, however, has the disadvantages of being more expensive and giving uncertain results in testing.

Selection of Cross-sectional Area of Bond. — The cross-sectional area of a rail bond should, as a rule, be not greater than is necessary to keep its temperature at a safe working amount, unless greater area is required for mechanical strength. The resistance of the bonded joint is of secondary importance unless very high, because the resistance of the joints is usually a mere fraction of the total track-rail resistance (*see below*).

Carrying Capacity of Bonds. — The carrying capacity of rail bonds is not very well known as the manufacturers do not supply any data on this subject for their various products. The excellent heat conductivity of copper and the large heat storage capacity of steel rails tend to make the carrying capacity of bonds in cold weather considerably greater than that of free wire of the same size, especially if the bonds are short. In hot weather, however, the rails and consequently the bonds are likely to become hot from exposure to the sun's rays, thereby reducing the effective carrying capacity of the bonds.

Tests to determine the ultimate carrying capacity of soldered bonds indicate that a 500,000 circular mil bond of the type shown in Fig. 1 will carry 3500 amperes continuously without injury, but will melt in 5 or 10 minutes at 10,000 amperes. On the basis of this test assuming the cooling surface per unit length of a bond to be proportional to the square root of its cross-section, the safe carrying capacity of a bond of A circular mils cross-section is

$$I = \frac{A}{5.6\sqrt[4]{A}}.$$

Or, the cross-section required for a given current is

$$A = 10\, I \sqrt[3]{I}.$$

Resistance of Bonds. — The total resistance of a bond is the sum of the resistances of the copper in the bond and the contact resistance between the body of the bond and the terminals and the contact resistance between the

minals and the rail. The following table gives the resistance of a well-bonded nt at 75° F., including the body resistance and the two contact resistances each end.

RESISTANCE OF BONDED JOINT IN MICROHMS (10^{-6} OHMS)

Size . W. G. r B. & S. nd C. M.	Diameter of terminals, inches	Length of bond in inches, between centers of terminals							
		9	12	15	18	24	30	36	42
500,000	1	28	33	39	44	55	65	76	87
400,000	1	32	39	46	52	66	80	93	106
300,000	1	38	46	55	63	80	97	114	131
250,000	7/8	44	54	65	75	95	116	136	157
0000	7/8	50	62	75	87	111	136	160	185
000	3/4	60	75	91	107	137	169	200	230
00	5/8	72	91	112	131	171	210	250	290
0	5/8	87	112	137	162	211	260	310	360

Bonding Efficiency and "Equivalent" Length of Joint. — The onding efficiency* of a bonded rail system (having one bonded joint to ch rail length) is the ratio of its conductance to that of an equal length of rfectly continuous rail without any breaks or joints. By "equivalent" ngth of a joint is meant the length of continuous rail having a resistance ual to that of the bonded joint. Let

B = bonding efficiency,
l = distance in feet measured along the rail between centers of bond terminals,
l' = equivalent length of bonded joint in feet,
L = length in feet of a full rail section,
r = resistance of rail per foot,
R_j = resistance of bonded joint.

hen

$$l' = \frac{R_j}{r},$$

$$B = \frac{1}{1 + \frac{l' - l}{L}}.$$

For values of r see article on *Rails*. The equivalent length of a properly nded joint ranges from 1 foot to 6 feet, depending upon the size of rail, number nd cross-section of bonds, length of bond, etc. (See also section on *Rebonding*, elow.)

It is common practice to bond a joint with a bond having one-half the conductance of the rail. Hence for a 12-inch bond, and 30-foot rail section, assuming inches between terminals measured along the rail, $l = 0.75$ and $l' = 2$, giving a onding efficiency of 96 per cent.

Selection of Length of Bond. — The length of concealed bonds is necessarily determined by the dimensions of the rail and fish-plate, and by the bolt-ole drilling. The length should never be less than ten inches for single bonding

* The efficiency of individual bonds is sometimes stated as the ratio of the distance long the rail between centers of bond terminals to the equivalent length $= l/l'$.

and should generally be greater, it being usual practice to place the termina between the first and second bolt holes. In double bonding it is customa to place one terminal of each bond between the first and second bolt holes each rail, and the other terminals beyond the second bolt holes. It is n unusual to use concealed bonds 2 feet long for double-bonded rails on electr fied steam roads. Exposed bonds are usually made as short as is consiste with the flexibility requisite to withstand vibration and other rail movements.

Tests by H. H. George (E.R.J., 1914, Vol. 44, p. 487) on No. 0000 strande wire bonds showed the following relative number of vibrations to produce fra ture.

Length of Bond inches	Relative number of vibrations
7	1.0
8	5.2
10	31.2
14	194.0

Effect of Vibration and Expansion of Rails. — The continu bending of a copper wire or ribbon will cause local hardening and crystallizati of the metal, and eventually lead to fracture. It is, therefore, important save track bonds from vibration as much as possible, and they should be initial designed to withstand the vibration they are likely to experience in use. T best way to accomplish this is to use long thin wires of soft annealed copp entirely free from surface imperfections.

According to the A. S. W. Co., Cat. No. 3, wires of from 0.040 to 0.045 in diameter give the best general service for short bonds.

Concealed ribbon bonds, and to a less extent wire bonds, frequently bre at the loop between rail bolts, first, because the operation of crimping slight hardens the copper in the loop, and second, because the travel of the rails, d to their expansion and contraction, is wholly taken up in the loops, causing t copper to crystallize and break at this point. Of course this action is aggravat by any severe jarring or vibration of the joint.

SPECIFICATIONS. — (*See also article on Specifications and Contract*) Specifications for rail bonds should state the exact service conditions und which the bond is to be used, the style of adhesion desired, the part of the r they are to be applied to, the style of conductor (ribbon, solid wire or cabl the cross-sectional area, the contact area of the stud, the formed length betwe centers of terminals, and the fish-plate and bolt layout, if the bonds are to concealed.

INSTALLATION. — The foremost consideration in the installation bonds is the cleanliness of the bonds and bond holes, or other adhesion surfa Unless this is secured the bonds will be electrically defective whatever th mechanical strength may be.

Soldered Bonds. — The rail surface is brightened by means of a carboru dum or emery wheel, then tinned, using an acid flux. The bond is then clamp in place and the rail and bond heated by means of a blow-torch, to a temper ture at which the solder will melt and cause the bond to adhere firmly to the ra

Brazed Bonds. — The preliminary processes are the same as for solder bonds except that a special clamp is used, the terminals of which are the el trodes of an electrical circuit, one being of copper and the other of carbon.

The surface of the rail being previously ground bright at the point whe the weld is to be made, the brass-enveloped bond terminal is placed in positi against the rail at this point, held there and pressed against the rail by the carb

lectrode, the copper electrode being in contact with the opposite side of the ail. The current, on passing from one electrode to the other, traverses the ond terminal and rail, the carbon becoming incandescent. The incandescent arbon pressing the copper against the rail quickly transmits sufficient heat exactly the point where it is required, to produce the weld. To make a weld, he current is applied for a period of from 45 seconds to two minutes, depending n conditions.

Welding Outfit. — It is claimed by the manufacturers of one type of elding outfit that an average of over 100 bonds per day is readily installed y their car operating with four men, a bonder and three helpers. This car about 6 feet, 10 inches long by 5 feet, 10 inches wide, and carries an 18-kilowatt otary converter and transformer, with the necessary apparatus for their safe peration. To weld an average-size rail bond to the rail, an alternating current f about 2000 amperes at 5 volts is employed. On d-c. railways this is obtained y converting and transforming about 20 amperes at 500 volts taken from the rolley wire.

Pin-expanded Bonds. — The rail is drilled, usually through the web, with r without lubricant, using some form of drill especially adapted to this service.

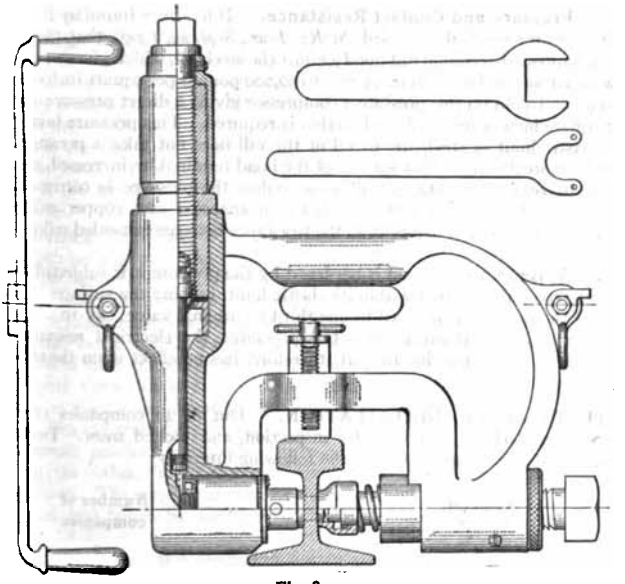

Fig. 8.

Drilling without lubricant has the advantage of giving a perfectly clean hole, nd is now generally preferred. Holes are drilled to the same diameter as the ond studs, and rust or scale on the web of the rail is removed around the hole. The bond head is then inserted into the hole, and a long taper punch lubricated with grease is driven entirely through the terminal. Then a short drift pin is driven home, as shown in Fig. 3. The diameter of the hole is usually increased

about ⅛ inch by the expansion process. From 100 to 200 bonds may be inst with one taper punch before it is worn down to an appreciable extent.

This type of bond requires a smaller equipment in tools and materials t most other types and does not necessitate the use of any apparatus w obstructs the track and thereby endangers traffic.

Compressed-terminal Web and Foot Bonds. — The drilling and cleaning having been performed as for a pin-expanded bond, and the bond h inserted into their respective holes, a screw or hydraulic compressor, as sho Fig. 8, is applied at both ends of the bond head, the conical point of the p fitting into the conical depression of the bond. Pressure is applied, either u collar on the ram touches the rail, or until the head of the bond acquires proper shape. Where no collar is used the point of the press (if of the s type) sometimes cuts into the bond head; this may be avoided by placi small amount of flake graphite mixed with oil in the depression of the bond h

Compressed-terminal Head Bonds. — A four-spindle drill is used to four holes simultaneously in the rail heads. It is important to avoid dri the holes too deep lest the copper should not touch bottom and therefore unable to expand laterally. If, on the other hand, the hole is too sha expansion will occur too soon.

Pressure and Contact Resistance. — It has been found by P. M. H P. C. Smith and C. B. Starbird (*St. Ry. Jour., Sept. 14, 1907*) that the pres of a compressed-terminal rail bond against the steel rail, which gives a reaso low-resistance value, is from 25,000 to 30,000 pounds per square inch of co surface. To obtain this pressure a compressor giving a direct pressure of 25 per square inch of terminal steel section is required. This pressure being w the elastic limit of steel, the metal of the rail does not take a permanent Furthermore, if the contact surface of the bond terminal be increased, no ap ciable decrease of resistance will occur unless the pressure is correspondi increased. The contact resistance between annealed cast copper and ste from 30 to 60 per cent higher than the resistance between annealed rolled cop and steel.

The copper of a bond head is hardened by the pressure it is subjected to, a like the steel, is distorted within its elastic limit, causing the surfaces to ad even if the pressure is reduced to one-third its original value, say 10,000 po per square inch. Between these two pressures, the electrical resistance d not vary. Expansion due to heat, therefore, has no effect upon the resista of bonds.

TESTS AFTER INSTALLATION. — Out of 42 companies 15 do inspect regularly, 6 test only by inspection, and melted snow. Twenty- companies which inspect, test at the following intervals

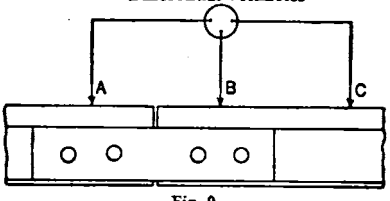
Interval, months	Number of companies
3	2
6	10
12	12
18	1

Twenty-three of these companies use portable bond testers; four use a graphic test cars.

Resistance Test. — The usual method of testing is to measure the drop potential across the bonded joint and find simultaneously the length of c tinuous rail in which the same drop occurs, i.e., the "equivalent" length of t

led joint. Several ingenious instruments have been devised for making comparison with ease and accuracy.

Differential Voltmeter Method. — The most accurate type consists differential voltmeter and three contact pieces for attachment to the rail. winding of the differential voltmeter is connected to a pair of contact es *A* and *B*, which are placed ntact with the rail just over centers of the bond termi-, see Fig. 9, and the other ding to a pair of contact es *B* and *C*, which span a able length of continuous The distance *BC* is varied moving the contact *C* until voltmeter shows no deflec-. This indicates that the ential drop between *A* and *B* qual to that between *B* and *C*, or in other words, that a length of continuous has been found which has the same resistance as the bonded joint. The ter should make sure that there is current in the rail while he is making test.



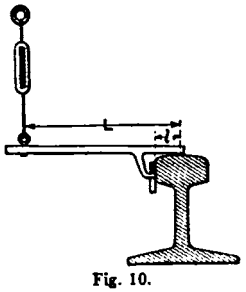


Fig. 9.

Conant Bond Tester. — R. W. Conant (Cambridge, Mass.) makes a nd tester in which the balancing is done by sound. A clockwork interrupter, induction coil, and a telephone receiver is connected across a Wheatstone dge (*see Bridges, for Electric Measurements*). The interrupted current causes nds in the telephone receiver, which sounds diminish and disappear when drop in the rail is balanced, by the bridge adjustment, to equal the drop oss the joint. This type of apparatus has the advantage of being indeident of the traction current in the rails, and is, therefore, constant in its sitiveness.

Herrick Test Car. — A. B. Herrick has devised a recording instrunt, which being placed on a car, is able to test the bonding of a railroad while ning the car over it. The Herrick test car carries autographic recording aratus, which measures by means of millivoltmeters, the potential drop oss each joint, recording on sensitized paper by an electric spark, the scale the record being usually about 1 inch to 60 feet of track. Wire-brush conis made of steel of composition similar to that of the rail measure the drop ss joints through which low-voltage current irculated from a small motor generator set on car The car trucks are insulated from each er. current passing through the rail from one ck to the other, while the bond is under asurement. The apparatus can also automatly mark bad bonds by squirting paint on the

Fig. 10.

The advantages of this method of testing are follows: 1. Uniform impressed low-voltage rent through joints while testing; 2. Heavy passing over joint breaks any transient conion made by fish-plate; 3. Autographic record duced by the bonds themselves of their conion.

Mechanical Strength. — The mechanical adhesion of soldered bonds may tested by means of a lever as shown in Fig. 10. It may be used as soon

as the terminals are cool. The operation of testing consists simply in s mitting each bond terminal to a predetermined pull. A properly solde bond should stand a shearing force of 1200 pounds per square inch of cont Calling S this shearing force per square inch, A the square inch of cont and P the pull, as registered on the balance, then

$$P = \frac{ASl}{L}.$$

REBONDING. — The resistance at which a joint should be rebon depends upon how much potential drop is permissible in the tracks, and up the relative cost of the energy loss and the cost of rebonding. The latter, turn, depends upon the probable life of a new bond. If the energy loss is t primary consideration, the resistance at which rebonding becomes economic is given by the formula below.

Let

R = amount by which the resistance of the existing bond has increas over that of a new bond, ohms,

B = cost of rebonding once, dollars, allowing credit for scrap material,

I = root-mean-square current in the bond, amperes,

C = cost of an increment of energy, dollars per kw. hour,

T = expected life of the bond in days, i.e., the number of days in wh its resistance is expected to increase R ohms, or in which it is be removed for any reason whatsoever. This may be estimat from previous experience on the railway under considerati the usual limitations being the life of the rails to which they a attached, corrosion by electrolysis, fracture due to crystalli tion and loosening of the terminals.

Then it is economical to rebond if R is equal to or greater than

$$\frac{B}{0.024\,I^2CT}.$$

It is usual to state the resistance of bonds in terms of the number of feet rail having the same resistance. Let r be the resistance of the rail in ohms p foot; then the increased resistance R will be represented by an increased leng expressed in feet, equal to $\frac{R}{r}$.

It should also be noted that bonds in different parts of a railway system car different amounts of current, those nearer the station bus carrying more th those at comparatively remote points. Hence, the economical resistance which to rebond is less the nearer the bond is to the bus, a consideration th complicates the use of the above formula. Furthermore, as the economic resistance is inversely proportional to the square of the current, a slight err in the estimation of the root-mean-square current will lead to a considerabl error in the resistance. Such errors are unavoidable, a circumstance that, take in conjunction with the probable error in the estimated life, renders the abov formula a mere approximation. It is, therefore, usual for railway companie to select some arbitrary total resistance at which to replace their bonds, th resistance being expressed in terms of equivalent length of rail. For urba lines this length varies from 3¼ feet to 20 feet with an average of about 8 feet for suburban lines, a length of 12 feet or more is common.

REPAIRS. — If a soldered bond becomes loose, it may often be resoldered but defective bonds of other types are usually scrapped, unless the defect is o a very trivial nature. Pin-expanded bonds may, however, be reexpanded int

ger holes, but with some loss in efficiency. Soldered bonds entail a comratively large and increasing expense for repairs when applied to track rails, spite of the fact that no failures may occur for several months after installation. ost bond failures are due to loose rail joints.

COSTS. — The cost of bonding is extremely variable, depending upon the pe and size of bond, cost of labor, etc. The following cost data should therere be used with caution.

COST OF BONDING

	Cost per joint		
	Labor	Material	Total
a. 2-500,000 C.M. bonds soldered to head of third rail	$0.66	$1.23	$1.89
b. 2-500,000 C.M. pin-expanded concealed bonds applied to track rail.	0.69	2.05	2.74
c. 2-400,000 C.M. compressed terminal concealed bonds applied to track rail	....	....	1.90
d. 2-0000 bonds of same type as *c*	0.50	1.00	1.50

Note.—In *a* and *b* the item for material includes inspection and the labor item includes foreman's salary; solder, acids and tools, not included.

BRAKES AND BRAKING SYSTEMS. — (*See also Cars, Electric; Railways, Energy Requirements for.*) In order to stop a car or train a torque must be applied to the wheels in a direction opposite to the direction of motion of the car. This may be accomplished by applying a frictional retarding force to the wheel rims, by applying a retarding force to the axle by means of a magnetically operated friction clutch, by applying a reverse torque to the axles by operating the motors as generators, or by applying a frictional force to the rails directly by a "track brake." The method of applying a retarding frictional force to the wheel rims is the most general one and lends itself most readily to the system of manipulating the brakes by compressed air. This system has done much to improve the safety of travel on railroads. The other methods have all been tried and some have been put into practical operation, but only to meet special local conditions.

FRICTIONAL RESISTANCES IN BRAKE-SHOE SYSTEM. — The application of the usual brake-shoe system makes use of the frictional adhesion between the wheels and the track and between the brake shoes and the wheels. Both these quantities vary throughout a considerable range and it is therefore necessary to adjust the pressure between the various members so that it is possible to rely on a definite minimum value.

Adhesion between Wheel Rim and Rails. — The coefficient of adhesion between the wheel rims and rails varies from less than 15 per cent to over 30 per cent depending upon the condition of the track and the relative motion between the track and wheel rim. (*See Railways, Energy Requirements for.*) An adhesion of 15 per cent can usually be depended upon with normal track, and this can be increased to 25 per cent by the use of sand. But these values only obtain while the wheels are rolling on the track. If they begin to slide the coefficient decreases considerably. For this reason the braking effort must always be controlled so that the wheels do not slip.

Adhesion between Brake Shoe and Wheel Rim. — When the brakes are applied, the retarding force is applied below the center of gravity of the car body. The latter is therefore subjected to a couple and tends to press downward at the forward end and upward at the rear end, thus changing the distribution of weight on the axles and decreasing the adhesion on some axles or trucks. It is therefore not possible to figure on using for braking purposes the same weight per axle as exists at standstill. For this reason the brake-shoe adhesion must be less than the track adhesion. The coefficient of adhesion between the customary cast-iron brake shoe and the steel tire of the wheel varies with the speed, and decreases as the time of application increases. As the speed increases the coefficient drops off, being a maximum of from 30 to 25 per cent at speeds from 0 to 5 mi. per hr., 20 per cent at 20 mi. per hr., 14 per cent at 40 mi. per hr., and 7.5 per cent at 60 mi. per hr. Thus at high speeds a heavy pressure may be applied without stopping the wheels, while as the speed of the car diminishes the pressure on the brake shoes must be decreased in order to prevent gripping the wheels and causing them to slide on the track.

Effect of Angular Momentum. — In addition to overcoming the linear momentum of the cars the brakes must overcome the angular momentum of the gears and motor armatures. The effect of the latter is to introduce a tendency of the whole motor to rotate around the car axle and introduce additional strains on the gears and on the trucks. For this reason brake shoes hung between the wheels of a truck are better than those hung on the outside of the wheels.

HAND BRAKES are always provided on cars and locomotives whether power brakes are employed or not, as they are necessary to hold a car left out of service on a grade, because the air brakes will not hold a car standing idle for any

Digitized by Google

ngth of time. When a car is descending a very steep grade it is customary
set the hand brakes to hold the speed of the car and reserve the power brakes
emergency or for stopping the car. In hand braking equipment the "foun-
ation" brakes (*see next paragraph*) are actuated through a drum or lever
stem which is hand operated.

POWER BRAKES. — The "foundation" brakes are that part of the brake quipment usually furnished separately from the power-braking equipment, and onsist of the brake shoes, hangers, equalizers, levers, etc., back to the brake ylinder. To this is attached the desired form or make of power brake. Of he various forms of power brakes in use, viz., air, electric, regenerative and lectro-pneumatic, the air-brake is the most generally used.

Air-Brakes. — In electric railway practice there are three systems of air-rakes in use, each of which is best suited to a definite type of service and has its articular field, as follows: (1) straight air-brake system for cars always operated ingly; (2) emergency straight air-brake system for cars operated in trains of wo or three but never more than three cars; (3) automatic air-brake system or cars operated in trains of any number of cars.

Straight Air-brake System. — The equipment for the straight air-rake system consists essentially of a motor-driven compressor, a reservoir, a brake cylinder, a motorman's valve, a train pipe, and the foundation brakes. The brakes are applied by direct pressure, that is by admitting air from the reservoir directly to the cylinder. The advantages of the system are that it is quick-acting and the braking effort is easily controlled to any value desired. Its disadvantage is that in trains a leak in the train pipe renders the brakes ineffective so that there is no means of applying the brakes on the trail-cars if the train should break apart. Sometimes instead of a compressor the motor-car carries a large reservoir which is charged at stations.

Emergency Straight Air-brake System. — This system involves a special valve and an extra pipe on each car so arranged that if the air pressure in the train pipe drops, due to cars breaking apart, this valve automatically turns the pressure of the reservoir into the brake cylinders and applies the brakes. The equipment of the motor car includes an extra pipe and each trail car has a reservoir, two pipes, automatic valve, brake cylinder and foundation brakes. The usual operation in service is like that of the straight air-brake.

Automatic Air-brake System. — This system involves the use of an auxiliary reservoir and a "triple valve" on each car. Whenever the air pressure in the train pipe is reduced, either intentionally or accidentally, this triple valve turns the air pressure of the auxiliary reservoir on each car into the brake cylinders. The brakes are applied by the motorman by opening the service pipe to the air by means of the engineer's valve. The engineer's valve has three positions, "off," "lap," and "on." By turning the handle to the "on" position the train pipe is opened to the atmosphere and the air continuously escapes. This applies the brakes with a continuously increasing pressure. When the desired pressure has been reached the handle is turned to the "lap" position, when the pressure of air in the train pipe and the pressure of the brakes on the wheels remains constant. By turning the handle to the "off" position pressure is restored in the train pipe, the brakes are released, and the reservoirs recharged.

Quick-action Triple Valve. — In any air-brake system an appreciable time elapses between the action of turning the engineer's valve and the actual application of the brakes. If there are many cars in a train the brakes may be applied on the leading cars sometime before they are applied on the rear cars and the result is that the rear cars bump into the forward cars, and may cause a derailment, particularly if this happens on a curve. To guard against this, the

"quick-action triple valve" is used on long trains. This consists of a special form of valve which causes a local intensification of the change in pressure in the train pipe on each car. The action is somewhat similar to a relay which is affected by slight changes in pressure and causes greater changes, and thus applies or releases the brakes more quickly.

Electromagnetic Brakes. — Any braking system making use of the electric current is not as reliable as the air system since if either the trolley comes off or the motors fail to pick up as generators the brakes are inoperative. Electromagnetic braking may be applied either to the axles or directly to the track.

Disc Brakes. — This system comprises two cast-iron discs mounted concentrically on the car axle. One is keyed to the axle and the other anchored to the truck frames. A coil is placed in one of these discs and when a current flows in the coil the two discs are attracted to each other by the magnetism and the friction between them retards the car. The current for the coils may be taken from the trolley or from the motors operating as generators. In the latter case the motors supply an additional retarding force. The braking effort is controlled by resistance in series with the magnet coils.

Track Brakes. — The principle of electromagnetic braking may also be applied to a track brake in which a magnet coil when energized draws a shoe against the rail, the pressure being regulated by a resistance in series with the magnet coil.

Regenerative Braking. — By supplying the field circuits of the motors with a current of proper value and direction by means of separate excitation they may be operated as generators and made to exert a strong retarding effort on the car axles. This separate excitation may be obtained by connecting the field windings of all the motors on a car in series with themselves and with a regulating resistance to the trolley, or by means of a motor generator set (on a locomotive) supplying a low potential of the proper value. The energy developed by the motors when acting as generators may be dissipated in rheostats or may be returned to the distributing system. In the latter case the voltage generated by the motors must be accurately controlled. Ordinarily, if the energy is returned to the line, the braking effort can only be obtained at speeds in the proximity of full speed. Very special means must be provided to make it possible to return energy to the line at low speeds.

This system has had its most elaborate application in the locomotives of the C. M. & St. P. Ry. of U. S. A., where experience over a considerable period of time shows a saving of approximately 15 per cent in the energy consumption with grades varying from 0.7 per cent to 2 per cent. Of greater importance than the saving of energy, is the saving in wear on wheel tires, brake shoes and track and the ease of control, as these features have reduced the number of derailments to a marked extent. In the early St. Paul locomotives, a special motor generator was provided to serve as an exciter. In the later locomotives, two of the main traction motors are used to supply the exciting currents for the rest of the motors when they act as generators.

Three-phase induction motors will provide regenerative braking at rated speed without auxiliary devices.

Electro-pneumatic Brakes. — This system has been proposed as an improvement over the quick-acting air-brake system. It involves controlling the application of the brakes on each car by means of an electromagnet receiving current from the locomotive cab. By energizing this circuit the motorman can set the air brakes on all cars practically simultaneously. Each car would be equipped with the usual brake cylinders and reservoir and merely the application of the brakes would be controlled electrically.

BRICKS AND BRICK MASONRY. — (*See also Buildings, Allowable Unit Stresses in; Cement; Concrete.*) Brick construction may be made more ornamental than concrete, but is generally more expensive to place on account of the necessity of handling each brick as an individual unit. The proportion of building and engineering construction in which bricks are used, although still extensive, has been falling off in recent years with the increasing use of plain and reinforced concrete.

Kinds of Bricks. — Ordinary or clay bricks are made by moulding a rectangular block of nearly pure clay, or clay and clean sand, and subsequently burning it in a kiln for from one to two weeks. Pressed bricks are machine molded clay bricks used for facing work in high-class construction. Sand lime bricks are also used to some extent. They are made from sand cemented by lime and are hardened by being subjected to steam pressure at from 100 to 150 pounds per square inch for about one-half a day. Fire bricks are a special kind of clay bricks, which are made to stand high temperatures. The refractory properties of fire bricks depend chiefly upon the amount of silicon contained. The amount of iron oxide in fire bricks should not exceed 6 per cent. Vitrified bricks are very hard burned clay bricks which have been annealed by slow cooling; used in pavement work.

Physical Properties. — A common, practical test for a good brick is that it will give a clear, ringing sound when struck with a hammer. The color of a brick is not a reliable indication of its strength or properties. The water absorbed in a specified time by a number of bricks is sometimes considered to indicate their relative strengths, as water acts as a lubricant on the material and causes crushing to occur more readily than when dry, but there is considerable difference of opinion as to the value of this test.

The compressive strength of dry bricks ranges from 500 pounds per square inch for soft bricks to over 10,000 pounds per square inch for pressed bricks. The strength of the individual bricks, however, is of little importance except for comparing various kinds, as the strength of brick masonry is usually limited by the strength of the mortar used.

The specific gravity of bricks ranges from 1.6 to 2.6. See also paragraph below on *Brick Masonry* and article on *Weights of Materials*.

Several foreign countries have adopted legal standard sizes for brick, but the only standard sizes in the United States are those specified by the National Brick Mfg. Assoc. as follows:

Common brick	8¼ by 4 by 2¼ inches
Pressed brick	8⅛ by 4 by 2⅛ inches
Paving brick	8½ by 4 by 2½ inches

BRICK MASONRY. — Bricks are laid in lime or cement mortar, the mortar forming a cushion which fills the interstices and keeps out water. Joints, i.e., the spaces between adjacent bricks which are filled with mortar, are usually made from ¼ to ⅝ inch thick in outside walls, and from ⅜ to ½ inch thick in inner walls. In ordinary building work, where the weight of the wall itself is the greater part of the load, lime mortar is usually used because it is cheap. Where strength is required of brickwork, a rich Portland cement mortar should be used; see article on *Cement*. Tests upon the ultimate compressive strength of brick piers are quoted in detail in Johnson's *Materials of Construction*, and Baker's *Masonry Construction*. The values of loads allowed upon brick masonry in various localities range from 100 to 300 pounds per square inch; see *Buildings, Allowable Unit Stresses in*. A brick wall itself weighs from 100 to 145 pounds per cubic foot, depending somewhat upon the quality of the brick and the thickness of joints.

Digitized by Google

Measurement of Brickwork. — Bricks are usually sold by the thousand. Brickwork is commonly measured by the cubic yard in place, but the units of per thousand brick and per square yard of surface area are also used. The relation between the number of bricks used and the volume of finished brickwork depends upon the size of brick, thickness of joints and shape of the structure. For solid brick walls the number of bricks per cubic yard ranges from about 400 with $\frac{3}{8}$-inch joints to about 500 with $\frac{1}{4}$-inch joints. An allowance of 3 or 4 per cent excess should be made in estimating to provide for waste and breakage.

Cost of Brickwork (Pre-war figures). — Hudson River common bricks cost prior to the war about $6.00 per thousand. Lime for mortar was quoted at $0.97 to $1.10 per 200-pound barrel. The total cost of brick masonry including labor and materials was from $6.00 to $15.00 per cubic yard, depending upon the locality, type of construction and quality of brick and mortar. An average figure for ordinary brick walls was from $8.00 to $10.00 per cubic yard.

BRIDGES FOR ELECTRICAL MEASUREMENTS. — (*See also Inductance and Inductive Reactance; Resistance and Conductance, Electric; Resistors, Standard; Wires and Cables, Insulated.*) Numerous arrangements of electric circuits, known under the general term of "bridges," are used for the comparison of unknown with known resistances, capacities and inductances. The fundamental principle of an electric bridge is the adjustment of the component circuits or arms of the bridge in such a manner that the drop in potential V in the arm formed by the circuit to be tested is to the drop of potential V_r in an arm having known constants as the drop of potential V_a in one "ratio" arm is to the drop V_b in the second "ratio" arm.

A bridge may be made up of separate resistance boxes (*see Resistors, Standard*), but where frequent tests are to be made it is more desirable to have all the resistances, keys, etc., mounted together in a single box. Complete bridges of this kind can be obtained from instrument manufacturers.

SLIDE-WIRE BRIDGE (Fig. 1). — This is the simplest form of bridge but is seldom used in commercial testing, as its range is limited. In principle it is the same as a Wheatstone bridge (*see below*), the difference being a structural one only, in that a wire is used for the "ratio" arms.

The slide wire, AB in Fig. 1, is generally a wire of uniform cross-section stretched along a meter scale which is divided into millimeters. All connections in the X and R circuits are made of heavy low-resistance material. A slider is provided for sliding over and making contact on the wire. When the bridge is balanced (i.e., no current through the galvanometer),

$$X = \frac{AR}{1000 - A},$$

where A is the distance in millimeters between the slider and the left-hand end of the bridge. The slide wire can be made uniform to $\frac{1}{10}$ per cent and the error in observation may be even smaller than this. When using a ratio greater than 1 to 1 and when a low resistance is being measured, the errors are greater. It is possible when using an even ratio to make very exact comparisons of the standard and unknown resistances by reversing them and taking the mean of the two measurements.

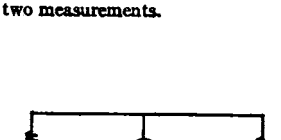

Fig. 1. Slide-wire Bridge

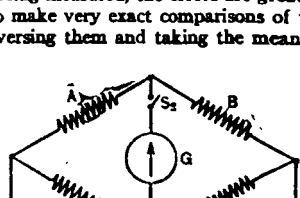

Fig. 2. Wheatstone Bridge

WHEATSTONE BRIDGES. — Fig. 2 shows the arrangement of resistances in the ordinary type of Wheatstone bridge used for comparing resistances. A and B represent two coils or sets of coils, usually referred to as the "ratio" coils, whose relative resistances must be known but whose actual resistance values are unnecessary; R is a standard variable resistance, or resistance box (*see Resistors, Standard*); X is the unknown resistance; G is a sensitive galvanometer connected across two points of the diamond and B is a battery connected across the other two points of the diamond.

For no deflection of the galvanometer when the switches S_1 and S_2 are closed, i.e., when the bridge is balanced,

$$X = \frac{A}{B} \cdot R,$$

where the letters represent the resistances of the four arms.

Construction. — Wheatstone bridges having the various parts mounted in one box may be divided into three classes: (1) **portable bridges**, in which not only the resistance coils and keys but also the battery and galvanometer are mounted in one box; (2) **laboratory bridges**, in which the coils and in some cases the keys are mounted in one box, but for which separate galvanometers and batteries must be provided; and (3) precision bridges, arranged in the same manner as laboratory bridges but made with greater care and capable of greater precision.

Since the construction of the resistance coils, blocks, plugs and other minor details of bridges is practically the same as for resistance boxes (*see Resistors, Standard*); only the arrangement of coils and connections will be described here.

Rheostat Arrangements. — The coils forming the rheostat (the variable resistance R in Fig. 2) may be arranged on the 1, 2, 3, 4 plan as shown in Fig. 3, on the 1, 2, 2, 5 plan, on the decade plan of Fig. 4, or on any other plan. (*See Resistors, Standard.*)

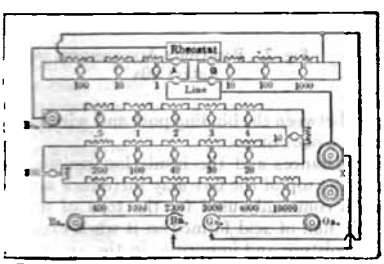

Fig. 3. Wheatstone Bridge (Post Office Type)

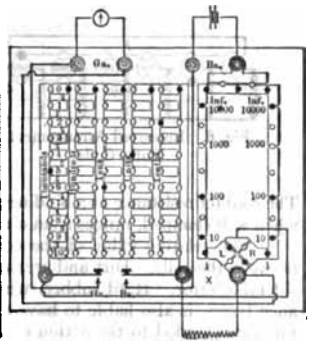

Fig. 4. Wheatstone Bridge (Anthony Type)

The advantage of the decade arrangement is that few plugs are required, and, therefore, there is less likelihood of error due to the contact resistance. A very good form of the decade type of rheostat is used in the Anthony type of Wheatstone bridge, shown in Fig. 4. In this bridge the coils may be joined in series or multiple or in any desired combination of series and multiple.

Plug and Dial Arrangements. — The resistances of the various arms of the bridge may be varied either by the insertion of plugs between the heavy metal terminals of the coils provided on the top of the box, or a dial arrangement similar to that employed on ordinary rheostats (but more carefully made to reduce the contact resistance) may be used.

Ratio Coils (Figs. 5 to 7). — The connections of the ratio arms in a common construction of dial bridge is shown in Fig. 5. The values of the coils are so chosen that the ratio of these coils is always that given by the stamping for various settings of the contact S. An advantage of this type of ratio coils is

that there is no error due to contact resistance in the ratio coils, as the contact is in series with the battery.

The arrangement of an improved form of ratio coils is shown diagrammatically in Fig. 6. This arrangement of ratio coils has the advantage over the old post-office arrangement shown in Fig. 7, in that there are but two plugs to operate and the coils can be checked by reversal.

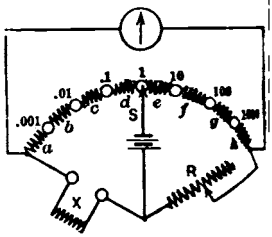

Fig. 5. Dial Type Ratio Coils

Precision of Measurements by Wheatstone Bridge. — The degree of accuracy with which a resistance can be measured by means of a Wheatstone bridge is determined by the following conditions:

1. The accuracy to which the resistances of the various coils is adjusted. The range of accuracy is from about 0.1 per cent for portable bridges to 0.02 per cent for precision bridges.

2. The relative value of the coil resistances and the contact resistances at plugs and terminals. A well-fitting, clean plug has a resistance of from 0.0001 to 0.00005 ohm; a poorly fitting or greasy plug a resistance of 0.01 ohm or higher.

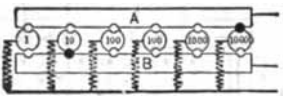

Fig. 6. Improved Arrangement of Ratio Coils

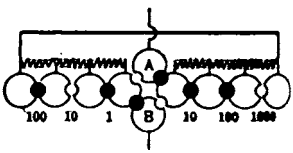

Fig. 7. Post-Office Arrangement of Ratio Coils

The contact resistance at a binding post between the binding post and wire, even when well clamped, ranges from 0.001 to 0.0001 ohm.

3. The relative value of the coil resistances and the insulation resistances between the coils. Dirt and grease on the top of the box may introduce a considerable error. Hard rubber, which is commonly used for the tops of resistance boxes, is also liable to have a thin film of acid formed on it when exposed for a long period to the action of the moisture and impurities in the air, which attack the sulphur in the rubber. Such a film will greatly reduce the insulation resistance between the lugs on top of the box.

4. The effect of changes of temperature in changing the resistances of the coils and in producing thermoelectric effects. The thermal e.m.f. in a copper-brass-copper circuit is about 2×10^{-6} volts per degree C. difference in temperature between the two junctions. Thermoelectric troubles can usually be avoided by reversing the connections of the battery to the bridge and taking the mean of the values of the resistances corresponding to the balance when the battery current flows through the bridge first in one direction and then in the other.

5. The maximum current that the coils will safely carry; this ranges from about 0.5 ampere for 1-ohm coils down to 0.005 ampere for a 5000-ohm coil.

6. The resistances of the galvanometer and battery, particularly the former. The battery resistance is usually small.

7. The relative resistances of the various arms of the bridge.

8. The sensitiveness of the galvanometer, i.e., the deflection per unit current.

Digitized by Google

Best Galvanometer Resistance. — Referring to Fig. 2, the best galvanometer resistance is

$$G = \frac{(A + X)(B + R)}{A + B + R + X},$$

where the letters designate the resistances of the various branches.

Best Location of Galvanometer. — Knowing the galvanometer and battery resistances (the galvanometer resistance is usually the larger), connect the one having the higher resistance so that it joins the junction of the two arms of the bridge having the highest resistances to the junction of the two arms having the lowest resistances.

Precautions in Making Measurements. — The following rules should be observed in using a Wheatstone bridge:

1. Do not employ a battery having an e.m.f. of over 5 volts; a lower value is desirable if sufficient sensitiveness can be obtained.
2. Always shunt the galvanometer during preliminary adjustments. The shunt circuit should be opened when the final balance is made.
3. See that all binding posts are screwed up tightly and all plugs firmly inserted. After withdrawing a plug those adjacent to it should be retightened.
4. For a preliminary balance use a 1 to 1 ratio.
5. In manipulating the keys be careful not to touch the metal work, as the heat and moisture of the hand is likely to set up appreciable electromotive forces.
6. Always close the battery switch first and then the galvanometer switch, to avoid momentary deflections of the galvanometer due to the transient e.m.f.'s set up while the currents are establishing themselves.
7. If the contact or lead resistances are appreciable relative to the resistances of the coils with which they are in series, these resistances should be separately determined.

Care of Bridge. — In order that a bridge or resistance box may remain in first-class condition, it must be carefully protected from dust and moisture by being covered when it is not in use. To insure high insulation the top must be kept clean, especially between the blocks. The plugs must be kept free from grit, grease or from contact with mercury. Grease may be removed by the use of a little benzol. Never use sand or emery paper for cleaning the plugs or holes, for the surfaces of the taper will be spoiled by this treatment. These materials work into the metal and cannot be removed, thus causing the plugs to "cut." If it becomes absolutely necessary to clean the plugs and sockets, a little of the very finest whiting may be employed. Extra holes of the proper taper bored in the brass blocks are convenient for holding the plugs when they are not in use, and also for attaching a movable terminal. Never apply undue force in inserting the plugs.

KELVIN BRIDGE. — The ordinary form of Wheatstone bridge is not suitable for measuring with accuracy a resistance of 0.1 ohm or less, due to the contact resistances introduced at the binding posts, this contact resistance being of the order of 0.0001 to 0.001 ohm. An arrangement of circuits to avoid these contact resistances devised by Lord Kelvin (*Wm. Thomson*) is shown in Fig. 8, and is known as the Kelvin or Thomson bridge. There will be no current in the galvanometer when

$$X = \frac{A}{B} \cdot R + \frac{bd}{a + b + d}\left(\frac{A}{B} - \frac{a}{b}\right).$$

If $\frac{a}{b}$ is made equal to $\frac{A}{B}$, then

$$X = \frac{A}{B} \cdot R.$$

Digitized by Google

It is also well to make the resistance of d extremely low in comparison with X or R, since the lower the resistance of d the less an error in $a/b = A/B$ will affect the accuracy of measurement.

In the above formulas X and R are the resistances between the arrowheads which represent the "potential terminals." Such terminals are always provided on low-resistance standards (*see Resistors, Standard.*)

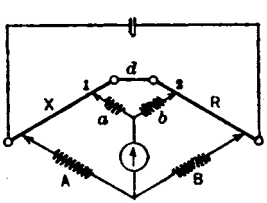

Fig. 8. Kelvin Bridge

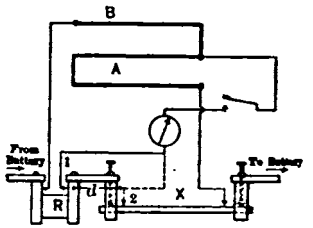

Fig. 9. Modification of the Kelvin Bridge

Simple Modification of the Kelvin Bridge. — When suitable resistances are not available for a and b, these resistances may be omitted and the galvanometer terminal be connected first at 1 and then at 2, and A adjusted for a balance in each case; let A_1 and A_2 be the corresponding values of A. Then

$$X = R\frac{A_1(B + A_2)}{B(B + A_1)}.$$

This method is very convenient for measuring the resistance X of a low-resistance shunt (*see Shunts*). The only standard resistances required are a low-resistance standard R and a resistance box with three terminals (or two separate resistance boxes). Fig. 9 shows such an arrangement.

HOOPES' CONDUCTIVITY BRIDGE. — This bridge is also a modification of the Kelvin bridge, designed for the rapid determination of the relative conductivity (*see Resistance and Conductance*) of samples of wire. It is extensively used in wire factories. A diagram of the connections is shown in Fig. 10.

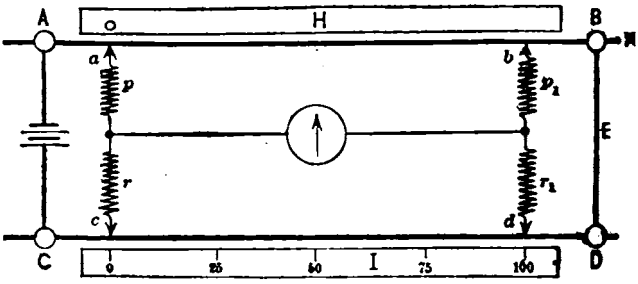

Fig. 10. Hoopes' Conductivity Bridge

The standard A–B and the unknown C–D are of the same metal; consequently if care be taken that they are at the same temperature, all corrections due to temperature are avoided. The arms p, r, p_1, r_1 are in the same case and are made of material of low temperature coefficient so that their relative values will not change. They are adjusted so that $p = r$ and $p_1 = r_1$; consequently at balance the resistance of c–d equals the resistance of a–b.

Digitized by Google

The sample *C–D* is placed alongside a scale *I* divided into 100 parts, so that the graduations represent percentages of the total length of the scale. Accompanying the standard wire *A–B* is a scale *H*, on which are laid off a number of points corresponding to the weights of the standard length (38 inches) of a range of sizes of sample wires.

To make a conductivity reading, the weight of the standard length of the sample *C–D* is found to within an accuracy of $\frac{1}{10}$ per cent. The contact *b* is set at the point on scale *H* corresponding to this weight, the contacts *a* and *c* being at the zero points of their respective scales. After the case has been closed a sufficient length of time to allow both the standard and sample to assume the same temperature, the contact *d* is moved until the galvanometer shows no deflection; this will occur when the resistance between *a* and *b* is equal to that between *c* and *d*. The scale reading corresponding to the position of *d* for a balance is equal to the per cent conductivity.

The Hoopes' bridge is so designed that the standard wire with its scale is removable from the bridge and so that a single standard covers a range of sizes equal to 3 numbers of B. & S. gauge. Any number of standards can be supplied with a bridge, so that it can cover an extensive range of sizes and can also be used for wires of different materials. In order to keep the standard wire and the test wire at the same temperature the bridge is mounted in a metal-lined case and the scale read through a glass window in the case, the window being closed by a metal screen when readings are not being taken.

Resistance of Electrolytes. — The resistance of an electrolyte can be measured by using the Wheatstone bridge principle with an a-c. source substituted for the battery and an a-c. detector in place of the a-c. galvanometer. Alternating current must be used on account of the polarizing action of a direct current. A convenient source of alternating current is an induction coil with the secondary winding in place of the battery, as in an ordinary set-up. A telephone receiver makes a very good detector when an induction coil is used. The current from an induction coil gives a very clear and sharp sound in the telephone, making accurate balancing of the bridge quite simple. If a sinusoidal alternating current is used, a vibration galvanometer may be used to better advantage than a telephone. To measure merely the resistance of an electrolyte it is only necessary to place the electrolyte in a vessel provided with two electrodes, preferably of gold or platinum, and connect this vessel into one arm of a Wheatstone bridge and balance for alternating current. The other arms of the bridge are resistances which must be strictly non-inductive.

To determine the resistivity it is necessary to place the electrolyte in a vessel whose length and cross-section can be accurately measured. Such a vessel may be made from a glass tube, whose internal diameter is known, and in the two ends of which metal plugs are inserted. These plugs may be any convenient distance (say 20 cm.) apart. There should be several small holes in the side of the tube. The tube is then immersed in a vessel containing the electrolyte and the bridge balanced as before. The resistivity is then the product of the cross-sectional area of the tube and the resistance, divided by the length of the tube.

COSTS (Pre-war prices). — A good slide-wire bridge costs about $20, a portable Wheatstone bridge from $50 to $125, depending upon the design, a laboratory Wheatstone bridge from $25 to $75 and a high-precision standard bridge from $700 to $400. A Hoopes' conductivity bridge with a single standard, covering 3 sizes of B. & S. gauge wire, costs about $500; additional standards cost about $50.

JS-BARS AND BUS-BAR STRUCTURES. — (*See also Circuit akers; Power Stations; Substations; Switches; Switchgear Equipment for wer Stations; Wires and Cables.*) Bus-bars, or "omnibus bars," as they were ginally called, are the common circuits into which the various generators de- r their output and from which the different feeders draw their supply of wer. In large-capacity, moderate-voltage a-c. plants the bus-bars are usually ced in structures and connected to the various generators, feeders, etc., by table wiring. The bus-bars and their connections, together with the bus-bar uctures, form one of the most important parts of large plants, as the entire rgy of the station is usually concentrated thereon.

BUS-BAR SYSTEMS. — Where there is only a single set of bus-bars ber in d-c. or a-c. stations the connections are said to be arranged on the ingle-throw" system; when the connections can be made to either of two ts of bus-bars the system is spoken of as "double-throw"; but if the connec- ns can be made to both sets of bus-bars instead of only to either set, the stem is spoken of as the "selector system." Occasionally three or more ts of bus-bars are used.

If there is only one set of bus-bars, but with switches provided for divid- g it into two or more sections, it is spoken of as a "sectioned bus." Where ere are two sets of these sectioned bus-bars connected together at the ds, the system forms a "ring bus." In many high-voltage plants having ep-up transformers each generator normally connects to the low-tension de of its own transformers, but switches are provided so that any transformer r generator can connect to a bus; such a bus is spoken of as a "relay bus." here a number of feeders connect to a bus which in turn connects to the ain bus through a switch or breaker, such a bus is spoken of as a "group us."

BUS-BAR MATERIAL. — Depending on the current and voltage, bus- ars may be made of wire, rod, tubing, cable or strap, either bare or insulated. olid wire is seldom used for more than 200 amperes, rod is used for less than 000 amperes, tubing for 300 to 600 amperes, cable up to 1000 amperes, while trap is used up to any capacity.

Strap for bus-bars, particularly for heavy current, possesses several advan- ages over other shapes, the chief one being the ease with which additional straps ay be added and the excellent radiating surface secured. Straps of different ections are in use, a typical one being 3 inches × ¼ inch. Where more than ne strap is required, a space is left between adjacent bars making the so-called aminated bus. The usual spacing left with 3 inches × ¼ inch bars is ½ inch. The connections from switches, circuit breakers, etc., to the bus are made of ne or more similar straps suitably interleaved and clamped together.

With this construction and due to the large surface exposed in comparison to he section of copper used comparatively high current density may be employed or a small number of straps without exceeding a safe temperature rise. The xact amount of current to be carried for a given rise depends somewhat on local onditions, ventilation, etc., and whether the bus is being used for direct current, 5-cycle, or 60-cycle service, and the temperature rise is not the same for differ- nt parts of the bar. A typical test under average conditions, 60-cycle service, 5° rise, indicated that one bar would carry 650 amperes, two bars 1150, three 1500, four 1800, five 2000, six 2160, showing that due to skin effect, lack of venti- lation, etc., the permissible current density falls off rather rapidly as the number of bars increases.

It is usually necessary to interleave the phases or to adopt special arrangements of the strap connections to balance the mutual induction, to secure proper cur-

Digitized by Google

rent distribution in the various straps for 60-cycle service to carry 3000 ampere or more without an excessive amount of copper.

Tubing for Small Currents and High Voltages. — For extremely high voltages with their correspondingly small currents, copper tubing for bus-bars and connections has many advantages over rods, cable or wire. These advantages are principally increased stiffness for the same amount of material, large and effective radiating surface, and the facility of making connections by flattening out the tubing at the point desired and bolting the tubing together at such points. On extremely high-voltage circuits tubing of approximately 1 inch outside diameter is not apt to be troubled by the brush discharge or corona effect that is sometimes noted with small wires or straps having sharp edges. In some plants iron piping is used for bus-bars and connections.

BUS-BAR STRUCTURES. — (*See also Power Stations; Substations; Switchgear.*) In large-capacity a-c. plants of 13,000 volts or less, with generators connected directly to the bus, the current that can be developed on a short circuit is something enormous, and every precaution has to be taken to prevent trouble from spreading if it ever starts. For this reason it has become customary to employ masonry compartments and cellular construction for the oil circuit breakers and bus-bars. In higher-voltage plants open wiring possesses several decided advantages. The vertical walls and septums of the circuit-breaker and bus-bar structures are usually built of brick or concrete, and the horizontal shelves between the bus-bars are ordinarily made of concrete, sandstone, soapstone, slate or marble. These substances are named in the order of their increasing cost. In some instances the bus-bar structures have been made of asbestos lumber, transite or similar material.

Low tension bus-bars when not too heavy can be supported by the wall bushing for the lead. For heavier work, or where bushings are not used, the bus-bars are supported on porcelain pillars, petticoat insulators, and similar devices resting on the bus-bar shelf, or attached to the wall.

In the larger generating stations due to the mechanical stress caused by the magnetic effects of the tremendous short-circuit current resulting from the size and number of turbo generators represented in present day station practice, close attention must be given to the adequacy of the bus-bar supports. Various curves and formulæ have been deduced for the purpose of calculating the mechanical strain on bus-bar supports at the instant of short-circuit. A typical formula is the following:

$$F = .27\ K.V.A.^2 \text{ divided by } A \times V^2 \times Z^2 \quad \text{where}$$

F = Maximum force exerted in pounds per foot of bus.
$K.V.A$ = Normal rating of the station including all synchronous apparatus.
A = Distance between buses in inches.
z = Impedance in per cent expressed in decimals to the point of short-circuit.
V = Line voltage.

In using this formula a typical example with 150,000 K.V.A. station capacity at 6600 volts, 8 per cent reactance, gives a maximum force on the bus-bars per foot of length, 735 pounds with 30 inch spacing between bars, 1470 pounds with 15 inch spacing between bars. With 4 feet between bus supports, each bus support would have to stand a strain of 2940 pounds if the buses are 30 inches on centers; 5880 pounds if the buses are 15 inches on centers. For heavy duty of this kind, multi-point supports are frequently used.

For supports for high tension bus-bars and connections it is customary to employ high-tension insulators of the pillar type, pin type, or suspension type, depending on the voltage.

Digitized by Google

he open system of wiring is preferable for any voltage higher than that for ch generators can be conveniently wound. This opinion is based on the wing reasons:

For the same kilovolt-ampere capacity back of an arc the current estab- ed is approximately inversely proportional to the voltage, and consequently violence of the arc and its destructive effects are less on a high-voltage n on a low-voltage system.

. The distance from wire to ground has to be greatly reduced from what ld be obtained with open wiring in the same space, as the conductivity of the proof barriers is sufficiently good to permit large currents to flow with high tages, in case an arc or a dead ground is established.

. A more expensive building and more costly construction are usually needed inclosed bus-bars and wiring than are required for open wiring.

. Inspection and repairs are more difficult when bus-bars, wiring, disconnect- switches and similar appliances are boxed in masonry compartments, and conductors are visible and accessible only by the removal of doors. Inspec- n will be more frequent and thorough and incipient trouble will be noticed sooner with open wiring than with inclosed, as the station attendant can everything in a walk of a few minutes, and will not have to remove many rs and visit two or three floors to examine the condition of the apparatus.

CONNECTIONS TO BUS-BARS. — Where the currents exceed 600 or 0 amperes, it is usual to employ laminated copper straps for connecting to s-bars; for smaller currents, cable, wire, rod or tubing is used. Cable and, a certain extent, bare wire are used for connections involving bends or long ns through conduits, but for straight runs or simple bends rod or tubing can used. Tubing, though more costly than rod or wire, is stiffer for the same tion, and can often be flattened out for making connections to studs, bars, :, without the necessity of additional terminals.

CALORIMETERS, FUEL. — (*See also Fuel.*) A fuel calorimeter is an instrument for determining the heating value of a fuel. Its essential features are a closed chamber in which a weighed sample of the fuel can be quickly and completely burned, a vessel of water surrounding this chamber, into which the heat generated by the combustion is transferred, a delicate thermometer for measuring the rise of temperature of the water, means for igniting the fuel, and provisions for preventing loss of heat from the apparatus by radiation or by the escape of the gases and vapors produced by the combustion. The most approved form of the instrument is Mahler's modification of Berthelot's calorimeter. The combustion chamber is a strong cylindrical steel vessel enameled on the inside, called a "bomb," into which about 1 gram of pulverized coal, contained in a small platinum dish, is placed. Oxygen under a pressure of 20 to 25 atmospheres is introduced, and the coal is ignited by an electric spark and burned explosively. The bomb is set in a water pail of thin brass, which is heavily felted and surrounded by a double-walled vessel filled with water of the temperature of the room. A stirring apparatus is used in the pail to circulate the water around the bomb. The thermometer is finely graduated. Readings of the temperature are made and recorded every minute until the maximum is reached, and a few minutes afterward to obtain a correction for radiation. The weight of the water, together with the water equivalent of the bomb and pail, multiplied by the rise in temperature, corrected for radiation and other minor errors, gives the number of heat units generated by the combustion of the coal.

The Junker calorimeter is commonly used to determine the heating value of fuel gas. A measured volume of gas is burned with air or oxygen in a vessel which is surrounded with water, and the calculations are made in the same way as those for the Mahler calorimeter.

ORIMETERS, STEAM. — (*See also Steam.*) For the purpose of
mining the percentage of moisture in the steam, in a boiler or engine test, a
calorimeter is used. Several forms of this instrument have been used
he most common is that of Professor Peabody, known as the throttling
meter. The action of this instrument depends upon the fact that the
of saturated steam is greater the greater the pressure, and consequently
pressure is reduced by throttling, the heat rendered available will convert
oisture into steam and in general produce more or less superheating.
½-inch pipe, closed at the end and perforated with several ⅛-inch holes in
alls, is inserted into the main steam pipe so that steam may enter these
. The other end of the calorimeter pipe is throttled by an orifice 1/16 inch
eter through which the steam escapes into a chamber which has an outlet
e atmosphere. The temperature and pressure of the steam on each side
e orifice are observed. The steam in the chamber is superheated more or
according to the amount of moisture contained in the sample drawn from
steam main.
he per cent of moisture in the steam is then

$$W = 100\,\frac{H - h - K\,(T - t)}{L},$$

re H = total heat and L = the latent heat of saturated steam at the pressure
he steam in the main pipe; h = total heat of saturated steam at the pressure
the discharge chamber of the calorimeter (= 1150.4, corresponding to a
sure of 14.7, when this chamber opens directly to the atmosphere); K =
ific heat of superheated steam (= 0.48 approximately); T = actual temper-
re in the discharge chamber; t = temperature of saturated steam at the
sure in the discharge chamber (= 212 when this chamber opens directly
he atmosphere). The above formula becomes

$$W = 100\,\frac{H - 1150.4 - 0.48\,(T - 212)}{L},$$

n the discharge chamber opens directly to the atmosphere, and when the
ospheric pressure is 14.7 pounds per square inch.
When the steam is very moist, so as to reduce the superheating on the dis-
rge side to 0°, the instrument fails, and a separating calorimeter, which is
ply a small steam separator (q.v.), must be used between the throttling calorim-
r and the steam pipe to collect the greater quantity of moisture. The
isture collected in the separator is then added to that determined by the
rimeter. The instrument must be thoroughly felted to reduce the error
to radiation. There is also usually a considerable error in obtaining steam
a average quality from the main pipe by the perforated tube.

CAMBRIC, VARNISHED. — (*See also Insulating Materials, Wires, Cables, Insulated.*) Varnished muslin, variously known as varnished cloth, varnished cambric is an insulating material for cables, which consists of tapes of cotton fabric coated with insulating varnish, wound helically around the conductor with a thin layer of plastic compound between turns. This compound prevents the absorption of moisture, precludes air spaces and permits the layers of fabric to slide upon each other when the cable is bent. It is also used for machine coils without the plastic compound.

The fabric is prepared by coating it with a mixture whose principal constituents are boiled linseed oil, resin, gilsonite, and benzine. This mixture dries and the oil is oxidized by contact with air, leaving a hard smooth surface. Three such coats are usually applied. The plastic material between layers is usually a mixture of petrolatum and resin.

The varnished fabric usually has a thickness between seven and thirteen mils, the thinner cambric being used on smaller cables. There are usually between 65 and 70 threads to an inch.

The tensile strength of the varnished tape should be not less than 2000 pounds per square inch.

After the varnished cambric has been placed in hot petrolatum having a temperature of 150° C., removed from petrolatum and allowed to cool, the film of varnish should not become soft or tacky.

Specific Resistance. — The value of K in the formula $M = K \log \frac{D}{d}$ (See article on rubber) ranges from $K = 300$ to $K = 1000$, the usual value being between 400 and 600.

The resistance of varnished cambric is more affected by temperature changes than that of rubber or impregnated paper. The amount of variation differs in different makes and in different batches of the same make, so that the accompanying table should be considered as an approximation only.

Temperature		Per cent of resistance at 60° C
C.°	F.°	
15.5	60	100
18.3	65	61
21.1	70	37
24.0	75	24
26.7	80	15
29.4	85	11
32.2	90	8
35.0	95	6
37.8	100	5

Dielectric Strength. — The dielectric strength of varnished cambric depends greatly upon the size and shape of electrodes used for testing. Using the equipment described below, the puncture voltage per mil at 25° C. is between 800 and 1000 volts. This decreases rapidly as the temperature rises, being between 300 and 600 volts per mil at 75° C.

Farmer, Kennelly and Wiseman have shown that the apparent dielectri

Digitized by Google

rength of 0.33 mm. varnished cambric decreased more than 50 per cent in anging from very small discs to discs exceeding 15 inches in diameter.

Tests are most readily made between the rounded edge of a strip of brass inch thick and 6 inches long, which constitutes the upper electrode, and a ip of brass about $\frac{1}{8}$ inch wide and 8 inches long, which is placed directly below e strip of varnished cambric to be tested, and forms the lower electrode. The ctrodes may be attached to a strip of wood about 16 inches long and 4 inches ide. Also the top electrode may be fastened to supports with revolving arms that it can be thrown out of the way when the test has been completed. In der to prevent flash-overs from one electrode to another, a wide strip of varshed cambric is placed underneath the lower electrode and petrolatum smeared er this strip of varnished cambric before the strip to be tested is placed over e lower electrode. The test strip of varnished cambric is pressed firmly against e lower strip so that the petrolatum makes a seal between the two strips thus eventing flash-overs from the top electrode to the bottom one.

Power Factor. — The power factor of varnished cambric insulation in cables much higher than that of impregnated paper. The following values are pical:

Temperature Deg. Cent.	Power factor, Per Cent
20	6.0
30	8.0
40	10.5
50	14.0
60	19.0
70	49.0
80	33.0
90	43.0
100	56.0

Bibliography 208

GENERAL RELATIONS AND DEFINITIONS. — Consider any number of conductors 0, 1, 2, 3, etc., either (1) at a great distance from all other conductors or (2) completely surrounded by a hollow conducting shell, the inside surface of which shell is to be considered as one of the conductors, say No. 0, of the system. The electrostatic condition of such a system of conductors is uninfluenced by any electrostatic effects produced outside the system; it may therefore be called an "electrostatically independent system."

Potential Coefficients (A). — Any conductor of an electrostatically independent system may be chosen as a conductor of reference; let this reference conductor be designated as conductor No. 0. Let v_{10}, v_{20}, v_{30}, etc., represent the potential drop from No. 1 to No. 0, from No. 2 to No. 0, from No. 3 to No. 0, etc., and let q_0, q_1, q_2, q_3, etc., represent the charges on No. 0, No. 1, No. 2, No. 3, etc. Then, if the relative positions of the various conductors and insulators in the field remain unaltered and the specific inductive capacities (*see Electricity and Magnetism, Principles of*) of the various insulating materials between the conductors are *constant* (not necessarily the same for each insulating material, however), the following relations hold for all values of the charges on and potential drops between conductors irrespective of how the conductors may be connected: *

$$\left.\begin{aligned} v_{10} &= A_{11}q_1 + A_{12}q_2 + A_{13}q_3 + \text{etc.},\\ v_{20} &= A_{12}q_1 + A_{22}q_2 + A_{23}q_3 + \text{etc.},\\ v_{30} &= A_{13}q_1 + A_{23}q_2 + A_{33}q_3 + \text{etc.},\\ q_0 &= -(q_1 + q_2 + q_3 + \text{etc.}), \end{aligned}\right\} \quad (1)$$

where the A's are all *constants* depending upon the distances apart of the con-

* By wires of small cross-section and length compared with the dimensions of the conductors.

Digitized by Google

luctors and the nature of the insulating medium between them. The coefficients A in these equations may be called the "potential coefficients" of he system of conductors. It should be noted particularly that *these coefficients are independent of how the conductors may be charged and of how they may be interconnected* (provided the connecting wires are small compared with urfaces of the conductors). In certain simple cases these coefficients A are eadily calculated; see below.

Electrostatic Induction Coefficients (B). — The above equations may lso be written

$$\left.\begin{aligned} q_1 &= B_{11}v_{10} + B_{12}v_{20} + B_{13}v_{30} + \text{etc.},\\ q_2 &= B_{12}v_{10} + B_{22}v_{20} + B_{23}v_{30} + \text{etc.},\\ q_3 &= B_{13}v_{10} + B_{23}v_{20} + B_{33}v_{30} + \text{etc.},\end{aligned}\right\} \qquad (1)$$

tc.

$$q_0 = -(q_1 + q_2 + q_3 + \text{etc.}),$$

here the B's are also constants and may be expressed directly in terms of the otential coefficients A by solving equations (1) for q_1, q_2, q_3, etc. The conants B are called the "electrostatic induction coefficients," and like the conants A are independent of how the conductors may be charged and of how ey may be interconnected. The B's may be expressed directly in terms of the normal and grounded capacities of the various conductors; see below.

Normal Capacity of Two Conductors (C). — By the normal capacity beeen any two conductors is meant the capacity of the condenser formed by ese two conductors when all the other conductors are connected to one anher and to the conductor of reference, the two conductors of course being sulated therefrom. The normal capacity between any two conductors of a stem, say Nos. 1 and 2, is, then, from equation (2),

$$C_{12} = \frac{B_{11}B_{22} - B_{12}^2}{B_{11} + B_{22} + 2B_{12}}. \qquad (2a)$$

When the arrangement of the conductors is perfectly symmetrical (as in a three-conductor cable), $B_{11} = B_{22}$ and the normal capacity between 1 and 2 is

$$C_{12} = \frac{1}{2}(B_{11} - B_{12}). \qquad (2b)$$

Grounded Capacity (C_g). — By the grounded capacity of any conductor of a system is meant the capacity of the condenser formed by this conductor as one "plate" and all the other conductors, including the conductor of reference, connected together as the other plate.* The grounded capacity of conductor No. 1, say, is then, from equation (2),

$$C_{1g} = B_{11}. \qquad (2c)$$

That is, the "electrostatic coefficient of self-induction" of any given conductor is the same as the grounded capacity of this conductor.

Capacity to Neutral (C_0). — In calculating the charging current, voltage drops, etc., in a single-phase or balanced three-phase transmission line it is sometimes convenient to consider the actual capacity between wires as made up of two capacities in series, each of twice the actual capacity between wires. This double capacity, viz.,

$$C_0 = 2C_{12}, \qquad (2d)$$

is called the capacity to neutral, since this capacity multiplied by the voltage to neutral, in either a single-phase or balanced three-phase line, gives the charge per wire, which charge is also in phase with the voltage to neutral. This prod-

* The term "grounded" arises from the fact that the conductor of reference is usually the ground.

Google

uct, however, does not give the charge per wire when the system is unbalanced the general equations (2) must then be used.

Charging Current and Capacity Susceptance. — The charging current taken by the various conductors of a system are found by differentiating equations (2) with respect to time; this gives the instantaneous values of the charging currents. In the case of sine-wave voltages all of frequency f, the effective values and phase relations of the charging currents in each conductor, in terms of the voltage drops to the conductor of reference, *all expressed in vector notation* (*see Alternating Currents*), are as follows:

$$\left.\begin{aligned} I_1 &= j\,2\pi f\,(B_{11}V_{10} + B_{12}V_{20} + B_{13}V_{30} + \dots\dots\dots\dots) \\ I_2 &= j\,2\pi f\,(B_{12}V_{10} + B_{22}V_{20} + B_{23}V_{30} + \dots\dots\dots\dots) \\ I_3 &= j\,2\pi f\,(B_{13}V_{10} + B_{23}V_{20} + B_{33}V_{30} + \dots\dots\dots\dots) \end{aligned}\right\}$$

etc.,

$$I_0 = -(I_1 + I_2 + I_3 + \dots\dots\dots\dots)$$

Note that the quantities in the brackets are to be added *vectorially*.

In the case of a system of but two conductors, i.e., a simple condenser, the relations reduce to

$$I = j\,2\pi fCV,$$

when V is the voltage drop through the condenser, I the current in the direction of this drop, and C the capacity of the condenser. That is, the charging current of a simple condenser leads the voltage drop by 90° and is equal numerically to the product of this voltage by $2\pi fC$. The factor

$$b = 2\pi fC$$

is called the capacity susceptance * of the condenser. Capacity susceptance is expressed in mhos or micromhos, being of the same dimensions as conductance. Numerically, the charging current of a simple condenser may be then expressed as

$$I = bV.$$

When V is in volts and b in mhos, the current I is in amperes. For either a single-phase or balanced three-phase line the charging current per wire may also be expressed as $I = b_0V_0$, where $b_0 = 2\pi fC_0 = 2b$, and may be called the "capacity susceptance to neutral." When b_0 is in micromhos (see tables below) and V_0 is in volts to neutral, the charging current per wire is

$$I = 10^{-6}b_0V_0.$$

In a single-phase line $V_0 = V/2$ and in a balanced three-phase line $V_0 = V/\sqrt{3}$ when V in each case is the voltage between wires.

FORMULAS FOR THE CAPACITY OF SIMPLE CONDENSERS — Let

K = specific inductive capacity of medium between conductors; medium assumed uniform; for air $K = 1$,

C = capacity of the condenser formed by the two conductors,

$C_0 = 2C$ = capacity to neutral.

Two Concentric Spheres. — Let r' = internal radius of outer sphere and r = external radius of inner sphere, both in centimeters, and R' and R the corresponding dimensions in inches.

$$C = \frac{Krr'}{r' - r} \qquad \text{statfarads,}$$

$$= 2.822 \times 10^{-4}\,\frac{KRR'}{R' - R} \qquad \text{microfarads.}$$

* The inductive susceptance of a condenser is $-2\pi fC$; see *Alternating Currents*.

Google

Two Parallel Plates. — Unless the plates are large compared with their distance apart no simple formula can be deduced, since the electrostatic field at the edge of the plates is not uniform. Let S = surface, in square inches, of contact between the metal plate and dielectric (the dielectric sheet is usually larger than the metal sheet, hence S is generally the surface, one side only, of the metal plate); D = thickness of dielectric in inches, K = specific inductive capacity, and let s and d be the dimensions in centimeters corresponding to S and D respectively. Then for D small compared with S, the capacity of two parallel plates is

$$C = \frac{Ks}{4\pi d} \quad \text{statfarads}$$

$$= 2.246 \times 10^{-7} \frac{KS}{D} \quad \text{microfarads.}$$

Stack of Plates. — Let N = the number of *metal* plates in the stack; there will then be $N-1$ effective dielectric sheets or $N-1$ parallel plate condensers in series. Using the same notation as above, the capacity of a stack of N metal plates, *connected in series*, is

$$C = \frac{Ks}{4\pi d\,(N-1)} \quad \text{statfarads}$$

$$= 2.246 \times 10^{-7} \frac{KS}{D\,(N-1)} \quad \text{microfarads.}$$

Round Wire in Concentric* Sheath. — Dimensions as in Fig. 1; since the *ratio* only is involved, it is immaterial what units are used for D and d provided *both* are expressed in the *same* unit. For a length of cable long compared with its diameter,

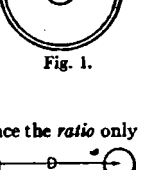

Fig. 1.

$$C = \frac{K}{2 \log_e \frac{D}{d}} \quad \text{statfarads per centimeter}$$

$$= \frac{7.354 \times 10^{-8} K}{\log_{10} \frac{D}{d}} \quad \text{microfarads per 1000 ft.}$$

Two Parallel Round† Wires. — Dimensions as in Fig. 2; since the *ratio* only is involved, it is immaterial what units are used for D and d provided *both* are expressed in the *same* unit. For length of line large compared with the distance apart of the wires, the exact formula‡ for the capacity *between wires* is

Fig. 2.

* When the wire is off center by a distance m (center of wire to center of sheath),

$$C = \frac{K}{2 \cosh^{-1}\alpha} \quad \text{statfarads per centimeter}$$

$$= \frac{16.93 \times 10^{-8} K}{\cosh^{-1}\alpha} \quad \text{microfarads per 1000 ft.,}$$

where

$$\alpha = \frac{D^2 + d^2 - 4m^2}{2Dd}.$$

† When the wires are far apart compared with the linear dimensions of their cross-section, the second group of formulas also applies approximately to wires of any shape of cross-section provided d is taken equal to the perimeter of the cross-section divided by π, i.e., equal to the "equivalent" diameter of the cross-section.

‡ Taking into account the non-uniform distribution of the charge on each wire; see Snider and Osborne, *Elec. World*, 1910, *Vol.* 56, *p.* 667.

Digitized by Google

$$C = \frac{K}{4 \cosh^{-1} \frac{D}{d}} \quad \text{statfarads per centimeter}$$

$$= \frac{8.467 \times 10^{-3} K}{\cosh^{-1} \frac{D}{d}} \quad \text{microfarads per 1000 feet.}$$

When D is greater than 10 d the following formulas for the capacity of *wires* may be used instead of the above with an error of less than 0.1 per cent:

$$C = \frac{K}{4 \log_e \frac{2D}{d}} \quad \text{statfarads per centimeter}$$

$$= \frac{3.677 \times 10^{-3} K}{\log_{10} \frac{2D}{d}} \quad \text{microfarads per 1000 feet}$$

$$= \frac{19.41 \times 10^{-3} K}{\log_{10} \frac{2D}{d}} \quad \text{microfarads per mile.}$$

The *capacity to neutral* in all cases is $C_0 = 2C$. Tables of capacity to neut for various sizes of wires and various spacings, when separated by air ($K =$ are given in the tables below. Note that these tables and the above formu are strictly applicable to ordinary overhead lines only when the distance b the wires to other conductors, particularly the earth, is large compared wi their distance apart. However, the effect of the earth is usually small in m practical cases (see below), and the formulas and tables give a very fair a proximation to the actual capacities.

The capacities of standard strands given in the following tables are calcula by the same formula as for smooth round wires using for the diameter d t diameter of the strand; see *Wires and Cables, Bare*. The values as thus c culated are therefore not exact, but the error is probably less than 3 per c for all practical cases.

Single Round* Wire Parallel to the Ground. — Dimensions as in Fig. 3. The dotted circle represents the "image" of the wire in the plane. The capacity of the actual condenser formed by the wire and the earth (assumed equivalent to an infinite conducting plane parallel to the wire) is the same as the capacity to neutral of the fictitious condenser formed by the wire and its image, the distance between the two wires of this fictitious condenser being $D = 2H$. Hence using the approximate expressions, since the wire is practically always more than 10 times its diameter above the other, the capacity *between the wire and the earth* is

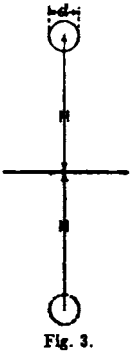

Fig. 3.

$$C = \frac{K}{2\log_e \frac{4H}{d}} \quad \text{statfarads per centimeter}$$

$$= \frac{7.354 \times 10^{-4} K}{\log_{10} \frac{4H}{d}} \quad \text{microfarads per 1000 feet}$$

$$= \frac{38.83 \times 10^{-3} K}{\log_{10} \frac{4H}{d}} \quad \text{microfarads per mile.}$$

SYSTEMS OF THREE CONDUCTORS. — Three practical examples of an electrostatically independent system consisting of three conductors only are: (1) three parallel overhead wires at a distance above the earth large compared to their distances apart, (2) two wires in a lead sheath and (3) two overhead wires and the earth. In the first case any one of the three wires may be considered as the conductor of reference; in the second case it is convenient to choose the sheath of the cable as the conductor of reference, whether grounded or not, and in the third case to choose the earth as the conductor of reference. The general equations (1) and (2) are applicable to either case. Designating the reference conductor as No. 3 instead of No. 0, and the other two conductors as No. 1 and No. 2 respectively, the general equations may be written

$$\left.\begin{aligned} v_{13} &= A_{11}q_1 + A_{12}q_2, \quad & q_1 &= B_{11}v_{13} + B_{12}v_{23}, \\ v_{23} &= A_{12}q_1 + A_{22}q_2, \quad & q_2 &= B_{12}v_{13} + B_{22}v_{23}, \\ & & q_3 &= -(q_1 + q_2). \end{aligned}\right\} \qquad (5)$$

v_{13} and v_{23} indicate the potential drop from 1 to 3 and from 2 to 3 respectively. Solving the first set of equations for q_1 and q_2 gives

$$B_{11} = \frac{A_{22}}{A_{11}A_{22} - A_{12}^2}, \quad B_{22} = \frac{A_{11}}{A_{11}A_{22} - A_{12}^2}, \quad B_{12} = \frac{-A_{12}}{A_{11}A_{22} - A_{12}^2}. \qquad (5a)$$

Possible Combinations of Three Conductors which may be used as a Condenser — "Part Capacities." — The following combinations are possible:

No. 1 against † No. 2 with No. 3 insulated,
No. 2 against No. 3 with No. 1 insulated,
No. 3 against No. 1 with No. 2 insulated,
No. 1 against No. 2 and No. 3 connected together,
No. 2 against No. 3 and No. 1 connected together,
No. 3 against No. 1 and No. 2 connected together.

* When the wire is at a height large compared with the linear dimensions of its cross-section these formulas also apply approximately to wires of any shape of cross-section provided d is taken equal to the perimeter of the cross-section divided by π.

† By "against" is here meant that the source of e.m.f. is connected between the two conductors designated, e.g., in the fourth case No. 1 is charged positively say, and an equal and opposite charge divides between 2 and 3.

Digitized by Google

The capacities corresponding to these various combinations may be called "part capacities," and may be designated by subscripts thus: C_{12} = capacity of No. 1 against No. 2 with No. 3 insulated (= normal capacity between 1 and 2), $C_{1(3)}$ = capacity of No. 1 against No. 2 and No. 3 connected together (= grounded capacity of No. 1), and so on for the others. The values of these part capacities can be deduced directly from equations (5), viz.,

$$\left.\begin{aligned} C_{12} &= \frac{1}{A_{11} + A_{22} - 2A_{12}}, & C_{1(23)} &= B_{11} \\ C_{23} &= \frac{1}{A_{22}}, & C_{2(31)} &= B_{22} \\ C_{31} &= \frac{1}{A_{11}}, & C_{3(12)} &= -(B_{11} + B_{22} + 2B_{12}) \end{aligned}\right\} \quad (6)$$

Three Overhead Parallel Wires, Effect of Earth Neglected. — Arrangement of wires and dimensions as in Fig. 4; distance apart of wires and diameters both in the *same* unit of length, but this unit may be either centimeters or inches. From equation (20c) in the article on *Electricity and Magnetism, Principles of*, the following closely approximate values of the A's (accurate to within less than 0.1 per cent when the distance apart of the wires is greater than 10 diameters) may be deduced, taking K as unity, since the dielectric in the case under consideration is air:

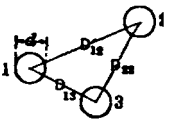

Fig. 4.

$$A_{11} = 2\log_e \frac{4D_{12}^2}{d_1 d_2}, \quad A_{22} = 2\log_e \frac{4D_{23}^2}{d_2 d_3}, \quad A_{12} = 2\log_e \frac{2D_{12}D_{23}}{d_2 D_{13}}, \quad (7)$$

all in c.g.s. electrostatic units for a length of one centimeter.*

From these relations the values of the coefficients B may be calculated for any arrangement of three parallel wires.

Equilateral Triangle Arrangement. — A common arrangement of the three wires of a three-phase transmission line is to place them so that their centers form the three vertices of an equilateral triangle. In this case $D_{12} = D_{23} = D_{13} = D$, say; and if all three wires are of the same diameter $d_1 = d_2 = d_3 = d$, say, then $A_{11} = A_{22} = 4\log_e \frac{2D}{d}$ and $A_{12} = 2\log_e \frac{2D}{d}$ in c.g.s. electrostatic units, and therefore, from equation (6) the normal capacity between any two of the wires with the third wire insulated is

$$C_{12} = \frac{1}{4\log_e \frac{2D}{d}} \quad \text{statfarads per centimeter,}$$

$$= \frac{3.677 \times 10^{-8}}{\log_{10} \frac{2D}{d}} \quad \text{microfarads per 1000 ft.,}$$

which is the same as the capacity between two parallel wires by themselves see above.

Equilateral Triangle Arrangement with Balanced Three-phase Voltages. — For sine-wave voltages between the wires equal in effective value to V and differing in phase by 120 degrees, the above equations for the charges and

* To find the values of the B's in microfarads per 1000 feet change 2 $\log_e$ in these formulas to 1.36 $\log_{10}$ and apply equations (5a).

Digitized by Google

charging currents give the following relations between the *effective* values of the voltages, charges and charging currents, for each of the three wires:

$$Q = C_0 V_0, \qquad I = 2\pi f C_0 V_0,$$

where

$$V_0 = \frac{V}{\sqrt{3}} = \text{voltage to neutral},$$

$$C_0 = 2\,C_{12} = \text{capacity to neutral}.$$

When the C's are in microfarads the charge Q is in microcoulombs and the charging current in micro-amperes.

The charge on any particular wire is in phase with the voltage between that wire and the neutral (*see Alternating Currents*) and the charging current for that wire is 90 degrees ahead of the voltage drop from that wire to the neutral. For the same voltage V between wires in a single-phase system as in a three-phase balanced system, the charging current per wire in the three-phase system with the equilateral triangle arrangement of wires is $\frac{2}{\sqrt{3}} = 1.155$ times the charging current per wire in the single-phase system.

For any other arrangement of wires and for an unbalanced three-phase system, the general equations (5) and the general formulas for A_{11}, A_{22} and A_{12} given above must be used.

Two-conductor Cable. — Arrangement of wires and dimensions as shown in Fig. 5. The sheath forms the conductor of reference and when designated as conductor No. 3, general equations (5), (5a) and (6) apply directly to this case also. For the symmetrical arrangement of the wires shown in the figure, $A_{11} = A_{22}$ whence, dropping the first subscript,

$$B_1 = \frac{A_1}{A_1^2 - A_2^2}, \qquad B_2 = \frac{-A_2}{A_1^2 - A_2^2}.$$

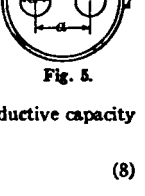

Fig. 5.

Russell (*Alternating Currents, Vol. 1*) gives the following values of A_1 and A_2, assuming a dielectric filling the space between the wires and the sheath to have the *same** specific inductive capacity throughout:

$$A_1 = \frac{2}{K}\log_e \frac{D^2 - a^2}{Dd}, \qquad A_2 = \frac{2}{K}\log_e \frac{D^2 + a^2}{2Da}, \tag{8}$$

both in c.g.s. electrostatic units for a length of one centimeter. To reduce to practical units for a length of 1000 ft. change $2\log_e$ to $1.36\log_{10}$.

Normal Capacity of a Two-conductor Cable. — Substituting Russell's values for A_1 and A_2 in equation (6) gives

$$C_{12} = \frac{K}{4\log_e\left(\frac{2a}{d}\cdot\frac{D^2 - a^2}{D^2 + a^2}\right)} \quad \text{statfarads per centimeter}$$

$$= \frac{3.677 \times 10^{-1} K}{\log_{10}\left(\frac{2a}{d}\cdot\frac{D^2 - a^2}{D^2 + a^2}\right)} \quad \text{microfarads per 1000 ft.}$$

Grounded Capacity of a Two-conductor Cable. — The capacity in this case, from equations (6), is

$$C_{1(2)} = B_{11} = \frac{A_1}{A_1^2 - A_2^2}.$$

*This is seldom realized in practice, since the dielectric is made up of insulation, fillers and braids having different specific inductive capacities; see *Wires and Cables, Insulated.*

By substituting Russell's values of the A's an approximate value for this capacity may be obtained; it will be greater than the normal capacity C_{12}.

Effect of the Earth on the Capacity of Two Overhead Wires. — As a fair approximation the earth may be considered as a conducting plane of infinite extent and the wires as parallel to this plane. Such a combination is electrostatically equivalent to two wires and their two "images" at a distance below the earth equal to the distance of the actual wires above the earth, see Fig. 6. Let q_1 and q_2 represent the charges on the actual wires and q_3 the actual charge on the earth, and V_{12} and V_{32} the potential differences between the two wires and the earth respectively (the p.d. between the two wires $v_{12} = v_{13} - v_{23}$); equations (5), (5a) and (6) then apply to this case also. The values of the A's in this case are (putting $K = 1$, since the dielectric is air)

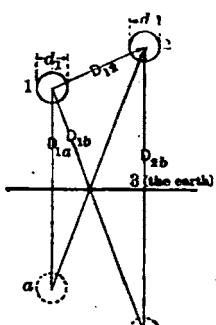

Fig. 6.

$$A_{11} = 2\log_e \frac{2D_{1a}}{d_1},\ A_{22} = 2\log_e \frac{2D_{2b}}{d_2},\ A_{12} = 2\log_e \frac{D_{1b}}{D_{12}}, \tag{9}$$

all in c.g.s. electrostatic units per centimeter length. To find the values of the B's directly in microfarads for a length of 1000 feet change 2 $\log_e$ to 136 $\log_{10}$.

Consider the special case where both wires are at the same height H, say, and both of the same diameter d; then from equation (9), putting D for the distance between their centers,

$$A_{11} = A_{22} = 2\log_e \frac{4H}{d},\quad A_{12} = 2\log_e \frac{2H}{D'}, \tag{9a}$$

where

$$D' = \frac{D}{\sqrt{1+\left(\frac{D}{2H}\right)^2}} = \text{"equivalent" distance apart.}$$

Then from equations (6)

$$C_{12} = \frac{1}{4\log_e \frac{2D'}{d}} \quad \text{statfarads per centimeter.} \tag{10}$$

Comparing the formula for C_{12} with that for two wires by themselves, equation (4), it is evident that the effect of the earth in this case is to increase the capacity by an amount equal to the increase in capacity which would result from decreasing the distance between the wires from the actual distance D to the "equivalent" distance D'. For D small compared with the height H, which is usually the case, the equivalent distance D' is practically equal to D and the effect of the earth is therefore negligible.

Effect of the Earth When One Wire is Grounded. — Let No. 2 be grounded. Consider the same case as in the preceding paragraph, i.e., both wires at the same height H and of the same diameter d. From equation (5a)

$$B_{11} = B_{22} = 2C_{12}\left(\frac{A_{11}}{A_{11}+A_{12}}\right),\qquad B_{12} = -2C_{12}\left(\frac{A_{12}}{A_{11}+A_{12}}\right),$$

where C_{12} has the value given by equation (10) and the A's the values given by (9a). The charge taken by conductor No. 1 is then $B_{11}v$, the charge taken

Digitized by Google

y conductor No. 2 is $B_{12}v$, and the charge taken by the earth $(B_{11} + B_{12})v$, here v is the drop of potential from No. 1 to No. 2.

Effect of the Earth When Middle or Neutral Point of the System s Grounded. — In this case $v_{23} = -v_{13} = v_0$, where v_0 = voltage to neutral. rom equation (5) it is then evident that grounding the middle point of the ystem has no effect upon the charging current.

SYSTEMS OF FOUR OR MORE CONDUCTORS. — The method of lculating the capacities for a three-conductor system, described in detail bove, may be readily extended to a system of any number of circuits, inde-endent or otherwise, made up of any number of conductors.

Relations Between the *A*'s and *B*'s for a Four-conductor System. — or a four-conductor system the relations are as follows: put

$$M = A_{11}A_{22}A_{33} + 2A_{12}A_{13}A_{23} - (A_{11}A_{23}^2 + A_{22}A_{13}^2 + A_{33}A_{12}^2),$$

hen

$$\left.\begin{aligned} B_{11} &= \frac{A_{22}A_{33} - A_{23}^2}{M}, & B_{12} &= -\frac{A_{12}A_{33} - A_{13}A_{23}}{M}, \\ B_{22} &= \frac{A_{11}A_{33} - A_{13}^2}{M}, & B_{23} &= -\frac{A_{22}A_{11} - A_{12}A_{13}}{M}, \\ B_{33} &= \frac{A_{11}A_{22} - A_{12}^2}{M}, & B_{13} &= -\frac{A_{12}A_{23} - A_{13}A_{22}}{M}, \end{aligned}\right\} \quad (11)$$

here are 32 part capacities in the general case of a four-conductor system ut in cases of symmetry they reduce to a lesser number.

Three-conductor Cable. — Arrangement and dimensions as shown in Fig. 7. The sheath forms the conductor of reference; let it be designated as nductor No. 0. From symmetry $A_{11} = A_{22} = A_{33} = A_1$, say, nd $A_{12} = A_{23} = A_{13} = A_2$, say. Equations (11) then reduce to

$$B_{11} = B_{22} = B_{33} = \frac{A_1 + A_2}{(A_1 - A_2)(A_1 + 2A_2)} = B_1, \text{ say},$$

$$B_{12} = B_{23} = B_{13} = \frac{-A_2}{(A_1 - A_2)(A_1 + 2A_2)} = B_2, \text{ say},$$

nd the capacity between any pair of wires is

$$C_{12} = \tfrac{1}{2}(B_1 - B_2).$$

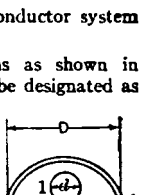

Fig. 7.

For sine-wave voltages equal in effective value and differing in phase by 120 egrees, the effective value of the charging current per wire is then, from quation (3),

$$I = 2\pi f (B_1 - B_2) V_0 = 2(2\pi f C_{12}) V_0,$$

here $V_0 = \frac{V}{\sqrt{3}}$, the voltage V being the p.d. between wires. This current ads the voltage drop to neutral, V_0, by 90 degrees.

Calculated Value C_{12} for a Three-conductor Cable. — Russel (*Alternating Currents, Vol. 1*) gives the following approximate values for A_1 and A_2, ssuming the insulation fillers and braids to have the same specific inductive apacity (which is not usually the case),

$$A_1 = \frac{0.1360 \times 10^9}{K} \log_{10}\left(\frac{D^2 - 1.33\,d^2}{Dd}\right) \text{ and } A_2 = \frac{0.0680 \times 10^9}{K} \log_{10}\left(\frac{0.75\,D^4 - 1.78\,d^4}{d^2D^2(3D^2 - 4d^2)}\right)$$

in practical units for a length of 1000 feet. Using these values the normal capacity between wires is

$$C_{12} = \frac{3.677 \times 10^{-8} K}{\log_{10} \frac{2a\rho}{d}} \quad \text{microfarads per 1000 feet,}$$

where

$$\rho = \sqrt{\frac{(3D^2 - 4a^2)^2}{(3D^2)^2 - (4a^2)^2}}.$$

That is, the capacity is the same as that of two parallel wires by themselves but at a distance ρa between centers instead of the actual distance a.

Effect of the Earth on the Capacity of Three Overhead Wires. — For any kind of arrangement, as shown in Fig. 8 (the dotted circles are the "images" of the actual wires), the general expressions for the A's in c.g.s. electrostatic units* for a length of one centimeter are as follows:

$$A_{11} = 2 \log_e \frac{2 D_{1a}}{d_1}, \quad A_{22} = 2 \log_e \frac{2 D_{2b}}{d_2}, \quad A_{33} = 2 \log_e \frac{2 D_{3c}}{d_3},$$

$$A_{12} = 2 \log_e \frac{D_{1b}}{D_{12}}, \quad A_{13} = 2 \log_e \frac{D_{1c}}{D_{13}}, \quad A_{23} = 2 \log_e \frac{D_{2c}}{D_{23}}.$$

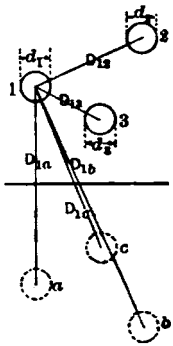

Fig. 8.

The values of the B's may then be calculated from equation (11) and the charging currents from equation (3). For any numerical case the calculations are tedious, but not difficult. Ordinarily the formulas given above neglecting the effect of the earth are sufficiently accurate for all practical purposes; compare with the effect of the earth on a two-wire line.

Electrostatic Induction From One Circuit to Another. — The general equations (1), (2) and (3) together with the method of calculation of the A's given in the last paragraph make it possible to calculate the induced voltages from one line to another, e.g., the voltages induced from a high-tension line to a telephone line. The method is straightforward, but tedious. The discussion given above indicates how such a problem may be attacked; space is not available for a detailed discussion here.

MEASUREMENT OF CAPACITY. — See the article on *Condensers, Electric.*

BIBLIOGRAPHY. — Russell, Alex., *Alternating Currents;* Ferguson, *Elements of Electrical Transmission;* Deutsch., W., *Graphical Method of Calculating the Capacity of Cylindrical Combinations,* Archiv f. Elektrotechnik, 2, p. 435, 1914, gives a method for calculating the capacity of parallel conductors of any form of cross-section whatever.

CAR BARNS AND INSPECTION SHEDS. — (*See also Cars, Electric; Locomotives, Electric; Railways.*) In every electric railway system it is necessary to provide car barns and inspection sheds where the cars may be taken regularly for a systematic inspection. In some cases these barns are used for the storage of cars and in special cases are equipped as regular repair shops. Provision for inspection is necessary, provision for storage is optional, although it is customary to provide storage at least for those cars which are idle during the daytime. The expense of providing for the storage under cover of all the cars that are idle between midnight and 6 a.m. is of doubtful value, for the deterioration of the cars left in the open is likely to be less than the fixed charges on the increased capacity of the sheds.

Location. — The location of the car barn may be determined by several considerations. It may be located in the city on account of the convenience of the employees, the possibility of placing the general offices in the same building, and on account of the fact that the city service is an important part of the whole system. It may be located in the suburbs where real estate is cheap and ample space available. It may be located at a convenient point such as the center of gravity of the system, so that the dead mileage of the cars will be a minimum. Finally, it may be located adjacent to the power station, so that the repair shops of the two departments may be combined and thus become more efficient.

Construction. — Preparatory to designing a car house it is necessary to become acquainted with municipal and underwriters' regulations and conforming with these, to provide space for car storage, inspection, administration offices, line department, road department, car employees' lobby, car sign storage, sand drying and storage, salt storage, oil storage, wash-room and toilets.

The standard construction consists of a concrete foundation and brick walls, but many of the smaller railroads have mill frame buildings with 2-inch cement curtain walls. The floors are made of concrete with cement finish and sloped for drainage.

Illumination. — The illumination of a car barn should be both general and local. The general illumination should consist of incandescent lights, suspended from overhead between the tracks and spaced about a car length apart. These may be run five in series on the trolley circuit, although an ungrounded system is better. The intensity of illumination on the floor should be from 1 to 1.5 foot-candles or lumens per square foot. Frequent sockets for drop lights must also be provided for many portions of the car equipment are in dark corners.

Inspection Pits. — Inspection pits between the rails are usually 4 ft. 6 in. deep below the top of rails. It is important to have these pits thoroughly drained and well illuminated.

Tracks. — Tracks should be spaced not less than 11 feet between centers where there are no posts between tracks and not less than 13 feet where there are posts. The tracks at the entrance to the car house should be designed to permit the rapid movement of cars with the least interruption to traffic.

Fire Risks. — Attention should be given to the prevention of fire by the adoption of the following precautions:

1. Use of automatic sprinklers.
2. Provision of two sources of water supply such as mains and tank.
3. Division of building by fire-proof walls. The underwriters stipulate that no section shall contain cars to the value of over $200,000.
4. Avoiding proximity to inflammable buildings.

Digitized by Google

5. Having ample provision of water pails, sand pails, chemical extinguishers and short hoses, the last being usually 2 ½ inches in diameter and provided with 1¼ inch nozzles.
6. Locating car house near a fire station.
7. Building tracks on a grade so that cars may be easily pushed out by hand.
8. Having numerous auxiliary fire alarms.
9. Consulting underwriters when planning.

Repair Shops. — It is usual to provide about 200 sq. ft. of repair shop floor per car owned. This area is usually divided about equally between departments, with, and those without car tracks. Where tracks are installed the usual spacing is from 15 to 16 feet between centers. Cars and car parts are usually lifted by travelling cranes, but in the smallest shops it is common practice to use jacks, hydraulic lifts, screw hoists and chain hoists. Transfer tables are preferred to ladder tracks for moving cars between departments.

Shop buildings should be surrounded with sufficient ground for storage of trucks, lumber, scrap material, etc.

CARS, ELECTRIC. — (*See also Control Systems for Railway Motors; Collectors, Current; Locomotives, Electric.*) The cars used on electric railways may be divided into two classes, viz., single-truck and double-truck. Each of these classes may be subdivided into types according as the cars are open or closed.

SINGLE-TRUCK CARS have a seating capacity as high as 32 passengers. Their characteristics are given in the accompanying table.

Item	Dimension
Over-all length	28 to 31 ft.
Rigid wheel base	5 to 7 ft.
Weight loaded and equipped	12 to 20 tons
Maximum speed	25 m.p.h
Maximum motor capacity, total	80 h.p.
Number of motors	2

They are only used in city service with frequent stops and usually have a cylinder-type controller at each end with hand brakes, although there are cases where these cars have been fitted with remote control and air brakes.

Considerable attention is being given at present to the subject of equipping these cars so that during the hours of heavy traffic they may be run in trains of two, controlled by one motorman. This causes less congestion in the streets for a given service and obviates the waste of operating throughout the day cars of large capacity designed to meet rush-hour conditions.

DOUBLE-TRUCK CARS.— The double-truck type of car has an over-all length of from 30 to 70 feet, a seating capacity of from 32 to 70 passengers and a maximum speed of from 40 to 70 m.p.h. One of these cars consists of a body mounted on two, four-wheel trucks. The car body under-frame is supported on a cross piece in the truck known as the bolster and is kept in position by a king-pin fitted into a king-pin center plate on the car body. The truck may swivel around this king-pin through quite an angle, guided by curved plates on each member.

Construction of Trucks. — The truck consists of axles, carried in journal boxes in side frames, transoms which connect the side frames, and the bolster which is carried by the transoms by means of springs (either spiral or elliptical) and a spring plate swung from the transoms. Coil springs are inserted between the journals and the side frames. The bolster may be of the "rigid," "floating" or "swinging" type depending upon the amount of play in the bolster. The rigid bolster is employed in locomotives only. The swinging bolster is most generally used for passenger cars, particularly in high-speed service, as it makes a much more easy riding construction. The three-axle truck is common in high-speed steam railroad practice, but the two-axle truck is generally used in electric railway practice as it allows more room for the motors. Four-wheel trucks are sometimes called "bogie" trucks or "swiveling" trucks to distinguish them from the "pony" or "radial" trucks having two wheels, which are used on steam locomotives.

Motor-car trucks have wheels of from 33 to 36 inches in diameter, and usually weigh from 10,000 to 15,000 pounds depending upon the size of the motors and body they are intended to carry. The rigid wheel base is from 6 to 8 feet. The problem of making a motor-driven truck guide properly is considerably more difficult than guiding the trucks of a car that is hauled, as there is a tendency for the motor-driven truck to get out of line and become cramped between the

rails. On this account and on account of the weight of the motors, trucks for a motor car must be stronger and heavier than for a trailer car.

Suspension of Motors. — The motors are usually hung between the axles on a single-truck car and between each axle and the transom on a double-truck car. In the "nose" suspension a lug is cast on the side of the motor frame away from the axle and this is attached to the transom with or without springs. The other side of the motor is carried by arms containing bearings which encircle the car axles. Thus about one-half of the weight of the motor is carried as a dead weight on the car axle, and the rest by the truck framing. In the "cradle" suspension both motors of a truck are carried by a cradle which is suspended from the car axles by springs. By this arrangement the entire weight of the motors is spring supported and carried by the axles, thus relieving the transom and side frames of the weight of the motors.

Maximum Traction Truck. — This is a special form of bogie truck with two axles having wheels of different diameters. The equalizing arrangements in this truck are such that about three-quarters of the total weight comes on the main axle which has the larger wheels and carries the motor, and the balance comes on the other axle which has small wheels. This arrangement gives a double-truck car with only two motors and yet provides that about three-quarters of the total weight shall be on driving axles, thus yielding "maximum traction." This type of truck is used on cars which are too long and heavy to use the two-axle rigid truck but which have such slow speed that only two motors are required. It is not adapted to high-speed work.

CAR BODIES may be classified as closed, convertible, semi-convertible and open.

Closed Cars.— The small closed type for city service is always of wood and has longitudinal seats. The general dimensions are given in the table below. Large closed cars with double trucks for interurban or rapid-transit service have both transverse and longitudinal seats, the proportion depending upon the proportion of long-haul traffic. The longitudinal seats give an arrangement permitting convenience of movement into and out of the car and allow more room for standing, but are not comfortable for long trips. Transverse seats are more comfortable for a long trip and for a service employing a high rate of acceleration.

Convertible Cars are constructed so that all the side panels of the body may be folded either up into the roof, or down to the floor leaving only the upright posts carrying the weight of the roof, thus converting a closed car into an open car at will.

Semi-convertible Cars. — A semi-convertible car, as its name implies, is arranged so that it may be partly opened in the summer time. It makes a very good car for high-speed interurban service because it is not advisable to operate open cars in high-speed service.

Open Cars usually have the transverse seats extending clear across the car. Access is obtained by steps running the length of the car on each side. They may be of the single- or double-truck type. They provide the maximum seating capacity for a given weight.

Cars for Rapid Handling of Traffic. — In large cities where the service is congested special means must be provided to aid and direct the rapid loading and unloading of cars. In a rapid transit service having stations this is accomplished by placing doors in the sides of the cars at the center and at or near the ends, and requiring all passengers to enter by the end doors and leave by the center doors. Both center and end doors are operated by compressed air and controlled by a guard at one end of the car. For street service the pre-payment or "pay as you enter" car is employed. This is built with extra long platforms

at each end. The passengers are required to deposit their fare in a box as they enter the car from the rear platform, where the conductor stands, and to leave by the front door and platform. The rear platform is made roomy to take care of congestion while the conductor is making change. Cars of this type recently installed in Chicago and Philadelphia are arranged for both entrance and exit of passengers at the front end, the conductor's station also being at this end.

The "One Man Safety Car" was introduced in 1914 to give more frequent service with decreased expense and in 1919, more cars of this type were built than of all other types combined. The principal data on a typical car are: Seats 32, single truck, length overall 28 feet, two 25 h.p. motors, wheel base 8 feet, wheels 24 inches, total weight equipped 7 tons, maximum speed 18 to 20 m.p.h., energy consumption 0.75 kw.-hr. per car mile. The car is equipped with air brakes, control system automatically interlocked with brakes and car doors and other special safety devices making it possible for one man to operate it with minimum possible chance of mistakes.

Construction of Car Bodies. — Most of the car bodies used on electric railways are constructed of wood, but for underground roads or for roads operating a high-class suburban service of multiple-unit trains the cars are preferably constructed of steel to reduce the dangers from collision and fire. This construction is demanded by consideration of safety, but it is directly contrary to the general tendency of the present day to reduce the weight of cars as much as possible. The proportion of weight of car to weight of load is very high and it entails a considerable waste of energy to propel this dead weight. The weight of car per passenger or seat capacity is a figure that should receive careful consideration and it should be kept at the minimum value compatible with strength and safety.

DIMENSIONS AND WEIGHTS OF TYPICAL EQUIPMENTS. — There are indicated in the following table the principle data for electric cars which are being operated in various typical services.

Service	City	City	City	City P. A. Y. E.	Suburban	Interurban	Subway	N. Y. C. R.R.	W. S. R.R.
Seating capacity	14	24	32	32	38	40	52	64	52
Number of trucks	1	1	1	2	2	2	2	2	2
Length over-all, ft.	22	30	32	41	38	40	50	60	49
Length of body, ft.	16	20	21	28	28	29	41	50	38
Number of motors	2	2	2	2	2	4	2	2	4
H.p. of each motor	40	40	40	70	70	50	200	200	75
Weight of body, lb.	6,000	9,530	7,500	15,800	15,670	19,200	34,300	55,000	35,110
Weight of trucks, lb.	4,600	4,800	4,500	10,400	10,600	16,000	22,500	14,940	23,000
Weight of electric equipment, lb.	5,990	6,962	7,062	9,500	8,350	16,542	21,510	25,460	21,680
Weight, total, lb.	16,590	21,292	19,062	35,700	34,620	51,742	78,310	95,400	79,790
Weight per passenger, lb.	1,185	887	594	1,118	911	1,293	1,506	1,490	1,534
Weight of load, lb.	2,240	3,640	4,760	4,760	5,600	5,889	7,560	9,240	7,560

CASTINGS, IRON AND STEEL. — These are made by pouring the molten material into sand or iron molds of the desired shape and allowing it to cool. Sand molds are generally used, and are made by packing molding sand about a wooden pattern having the shape of the desired casting and somewhat larger dimensions to allow for the contraction of the metal in cooling. The removal of the pattern leaves a hollow in the sand of the shape of the object to be cast. In order to have sufficient consistency the sand should either contain some clay and be somewhat moist, giving a "green sand" mold, or it should be mixed with a binding material giving a "dry sand mold."

Simple patterns may be made in one piece, but if the pattern be at all complicated it must be made in two or more pieces to permit withdrawal from the sand without disturbing the latter.

Steel castings are more difficult to make than iron castings, as they are more porous; thin steel sections should be avoided for such castings, as the steel cools too rapidly when thin.

In all castings sudden changes in the thickness of the metal should be avoided, as the unequal cooling of sections of different thicknesses causes temperature stresses and may crack the metal. This is particularly true in steel castings.

Care should be exercised in designing castings to make them such that the patterns can be readily removed from the sand molds.

Process of Making a Mold. — A wooden or iron box called a flask, consisting of sides only, is used in making the molds. This is divided into a bottom portion called the drag, and an upper portion called the cope; see Fig. 1. Intermediate portions, called checks, are used for complicated patterns.

A hole is made through the cope to convey the metal to the mold. Molds made of "dry sand" should be baked in an oven before pouring. The surface of the mold is frequently coated with "blacking."

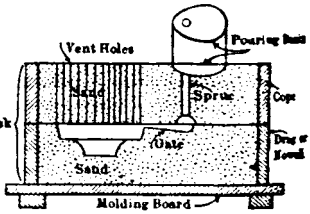

Fig. 1.

If holes are to be made in the casting they are formed by cores of hard-baked sand inserted after the pattern is removed and are held in place by studs of metal, called "chaplets," and by impressions in the mold made by projections on the pattern called "prints."

Cost of Iron and Steel Castings (Pre-war prices). — The cost of an iron casting, exclusive of the pattern, depends somewhat upon the intricacy of the pattern; representative costs in 1914 were for simple patterns of moderate size, 3 to 5 cents per pound; for large engine and dynamo castings 3 to 4.25 cents per pound; for small intricate castings 6 to 10 cents per pound. Malleable iron and steel castings about 50 to 100 per cent more.

CELLS, STANDARD. — (*See also Batteries, Primary; Electrochemistry, Principles of; Potentiometers.*) The need of a standard of electromotive force was recognized in the early days of the electrical industry, and the Daniell cell (*see Batteries, Primary*) was largely used for this purpose. This cell is readily prepared from ordinary chemicals, and is still used to some extent as a rough and ready standard. Such a cell, however, deteriorates quite rapidly, and has therefore been supplanted, for all accurate measurements, by other cells which possess to a greater degree the necessary characteristics of permanence and reproducibility. There are at present two types of standard cells in general use, the Clark and the Weston cells. The latter is the more generally used at the present time.

Pure Chemicals Required. — In order that the e.m.f. of any form of primary standard cell may accord with the stated value, great care must be exercised in the preparation of the materials, the processes for which have been carefully worked out by Kahle and later by Wolff and Waters (*Bull. Bureau of Standards, 1907, Vol. 4, p. 1*).

CLARK CELL. — In Fig. 1 is shown the Kahle's H-form of the Clark cell, which is one of the most satisfactory of the several forms in which the Clark cell is made. The container is of glass, which is mounted in a metal case with insulated binding posts connected to the two platinum terminals. The saturated solution of zinc sulphate forms the electrolyte, the paste of mercurous sulphate and zinc sulphate acts as a depolarizer, the mercury forms the positive pole and the zinc the negative pole. Detail directions for the preparation of the cell are given in the Bulletin of the Bureau of Standards, 1907, Vol. 4, p. 1.

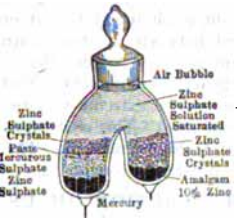

Fig. 1. Kahle's H-form of Clark Cell

Electromotive Force of Clark Cell. — The e.m.f. of the Clark cell, as determined at the time of the adoption of the international units (*see Units, Practical Electrical*), was given as 1.434 volts at 15° C. Subsequent investigations have shown that its true value is 1.4328 international volts at 15° C. At any other temperature $t°$ C. its e.m.f. is

$$E_t = 1.4328\,[1 - 0.00077\,(t - 15)].$$

The chief objections to the Clark cell are its relatively high temperature coefficient and the length of time required for the e.m.f. to attain a constant value after a change in the temperature of the cell.

Carhart-Clark Cell. — To reduce the temperature coefficient and time lag of the saturated or "normal" Clark cell, Carhart devised a form of Clark cell in which the zinc sulphate solution was just saturated at 0° C. with no excess of crystals. The e.m.f. of this type of cell is approximately

$$E = 1.440\,[1 - 0.00039\,(t - 15)].$$

For accurate work, however, such cells must be calibrated, as the e.m.f. of individual cells may differ appreciably.

WESTON OR CADMIUM CELL. — In Fig. 2 is shown the construction of the "normal" Weston or cadmium cell. The container is of glass suitably mounted in a case provided with binding posts to which the platinum wires are attached. This cell differs from the Clark cell chiefly in the use of cadmium amalgam and cadmium sulphate in place of the zinc amalgam and zinc sulphate

for the negative pole and electrolyte respectively. The particular advantag in the use of cadmium instead of zinc arises from the low temperature coefficien and small temperature lag thus obtainable. It also has a longer life and polarizes less rapidly than the Clark cell.

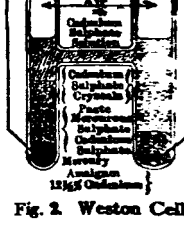

Fig. 2. Weston Cell

Electromotive Force of Weston Normal Cell. — The e.m.f. at 20° C. of the Weston normal cell (the word normal designating that the cadmium sulphate solution is saturated) is 1.01830 international volts. At any other temperature $t°$ C. its e.m.f. is

$$E_t = 1.01830 - 10^{-6}[40.6\ (t - 20) + 0.95\ (t - 20)^2 + 0.001\ (t - 20)^3].$$

(*See Bulletin Bureau of Standards, 1909, Vol. 5, p. 309.*) The e.m.f.'s of normal cadmium cells as set up by various observers following the same specifications differ among each other by less than 1 part in 10,000.

Portable Cadmium Cell. — A portable form of cadmium cell is made, which differs from the normal cadmium cell chiefly in that the cadmium sulphate solution is just saturated at 4° C., and therefore does not contain an excess of cadmium sulphate crystals at ordinary temperatures. This type of cell is to be used between the temperatures of 4° and 40° C. The temperature coefficient is much smaller than that of the normal cell and is negligible for any ordinary measurements; each cell is accompanied by a certificate stating its e.m.f. The extreme variation among 145 cells of this type was found to be 0.0009 volt. This is at present the best form of secondary standard cell, being remarkably permanent. The e.m.f. is approximately 1.0186 international volts; the resistance, roughly, 200 ohms.

PRECAUTION IN USING STANDARD CELLS. — No appreciable current can be taken from a standard cell without alteration of its e.m.f., due to polarization. It is found that the change is not permanent, for the cell gradually recovers its original e.m.f.; of course the cell is unreliable until the recovery is complete. Consequently standard cells should be used only where their e.m.f. is opposed to an equal p.d., as in connection with potentiometers. They should always be protected by a key, which is closed only momentarily, and for preliminary adjustments a high resistance, several thousand ohms at least, should be in series with the cell. When an approximate balance has been obtained this resistance should be cut out and the final balance then made.

COSTS (Pre-war prices). — A normal Clark cell costs about $12, a normal cadmium cell $15, a portable Weston cell $15.

CEMENT. — (*See also Concrete.*) The cements used in engineering construction are Portland, natural and Puzzolan (or slag) cements. Of these Portland cement is the most reliable and should always be used in reinforced concrete construction. The processes of manufacture and general characteristics of these cements are given in the following paragraphs, the descriptions being copied from the report of the Joint Committee as published in *Trans. Am. Soc. C. E.*, 1917.

PORTLAND CEMENT. — This is the finely pulverized product resulting from the calcination to incipient fusion of an intimate mixture of properly proportioned argillaceous and calcerous materials. Portland cement should be used in reinforced concrete construction and in any other construction that will be subject to shocks or vibrations or stresses other than direct compression.

Specifications. — The following specifications are taken by permission from the *Am. Soc. Test. Mat. Standards*, 1918.

The following limits shall not be exceeded:

Chemical Limits. — Loss on ignition, 4 per cent; insoluble residue, 0.35 per cent; sulfuric anhydride (SO_3), 2 per cent; magnesia (MgO), 5 per cent.

Specific Gravity. — The specific gravity of cement shall be not less than 10 (3.07 for white Portland cement). Should the test of cement as received fall below this requirement a second test may be made upon an ignited sample. The specific gravity test will not be made unless specifically ordered.

Fineness. — The residue on a standard No. 200 sieve shall not exceed 22 per cent by weight.

Soundness. — A pat of neat cement shall remain firm and hard, and show no signs of distortion, cracking, checking or disintegration in the steam test for soundness.

Time of Setting. — The cement shall not develop initial set in less than 45 minutes when the Vicat needle is used or 60 minutes when the Gillmore needle is used. Final set shall be attained within ten hours.

Tensile Strength. — The average tensile strength in pounds per square inch of not less than three standard mortar briquettes composed of one part cement and three parts standard sand, by *weight*, shall be equal to or higher than the following:

Age at test, days	Storage of briquetts	Tensile strength pound per sq. in.
7	1 day in moist air, 6 days in water....	200
28	1 day in moist air, 27 days in water...	300

The average tensile strength at standard mortar at 28 days shall be higher than the strength at seven days.

NATURAL CEMENT. — This is the finely pulverized product resulting from the calcination of an argillaceous limestone at a temperautre only sufficient to drive off the carbonic acid gas. Natural cement does not develop its strength as quickly, nor is it as uniform in composition, as Portland cement. Natural cement may be used in massive masonry where weight rather than strength is the essential feature. Where economy is the governing factor, a comparison

Digitized by Google

may be made between the use of natural cement and a leaner mixture of Portland cement that will develop the same strength.

Specifications. — The following specifications are taken from the *Am. Soc. Test. Mat. Standards*, 1918 by permission.

Fineness. — The residue on a standard No. 100 sieve shall not exceed [illegible] per cent and on a standard No. 200 sieve shall not exceed 30 per cent by weight.

Soundness. — Pats of neat cement about 3 inches in diameter, ½ inch thick at center, tapering to a thin edge, shall be kept in moist air for a period of 24 hours.

(*a*) A pat shall then be kept in air at normal temperature.

(*b*) Another pat shall be kept in water maintained as near 70° F. as practicable.

These pats shall be observed at intervals for at least 28 days, and, to satisfactorily pass the tests, shall remain firm and hard and show no signs of distortion, checking, cracking, or disintegrating.

Time of Setting. — The cement shall not develop initial set in less than ten minutes, using the Vicat needle. Final set shall be attained in not less than 30 minutes nor more than 3 hours, using the Vicat needle.

Tensile Strength. — The minimum requirements for tensile strength for briquettes 1 sq. in. in cross-section shall be as follows; and the cement shall show no retrogression in strength within the periods specified:

Neat cement	Strength
24 hours in moist air	75 lb.
7 days (1 day in moist air, 6 days in water)	150 lb.
28 days (1 day in moist air, 27 days in water)	250 lb.
One part cement, three parts standard Ottawa sand	
7 days (1 day in moist air, 6 days in water)	50 lb.
28 days (1 day in moist air, 27 days in water)	125 lb.

PUZZOLAN OR SLAG CEMENT. — This is the finely pulverized product resulting from grinding a mechanical mixture of granulated basic blast-furnace slag and hydrated lime. Puzzolan cement is not nearly as strong, uniform or reliable as Portland or natural cement, is not used extensively and never in important work; it should be used only for foundation work underground where it is not exposed to air or running water.

COST OF CEMENT. — As the cost of transportation is an important item in the cost of cement, the market price depends largely upon the place of sale. Quotations are given in the first number each month of *Engineering News-Record*.

CHAINS AND CHAIN DRIVE. — Chains for hoisting and similar purposes may be made with straight open links, twisted links or with links with transverse studs to prevent the links from collapsing under heavy loads. These types of chains are known as straight-link chains, twisted chains and stud chains, respectively. The twisted chain is usually employed when the chain has to be wrapped around a smooth drum. Crane chains are straight-link chains carefully made to fit the corrugations of the winding drum.

Chains for transmitting power are of various forms. The more common types are block chains, roller chains and various makes of "silent" chains. In all these chains the links are made of several pieces of metal, the longitudinal pieces being riveted, bolted or screwed to the end pieces or studs. In the block chain, an example of which is the ordinary bicycle chain, the end pieces are solid blocks of metal; in the roller chain the end pieces form studs which carry small rollers. With block or roller chains the power is transmitted from or to the sprocket directly by the studs or rollers, whereas in the various types of "silent" chains, e.g., the Morse and Renold chains, the longitudinal pieces of the links are provided with lugs or fingers which mesh with the teeth of the sprocket wheel and thus pull it around.

Link belts are essentially power transmitting chains made by mounting a number of single chains side by side, so that they all move as a unit. Link belts are used both for power transmission and for belt conveyors.

DATA ON ORDINARY CHAINS (Penn. R.R. Specifications, 1920)

Description	Diam. of wire, inches	Width of links, inches	Length of 100 links, inches	Weight per foot, pounds	Breaking load, pounds	Safe working load, pounds
Twisted iron	5/32	....	....	....	1,250	315
Twisted iron	3/16	....	....	....	1,800	450
Straight-link	1/4	1	100	0.70	3,400	850
Straight-link	5/16	1 3/16	114	1.05	5,300	1,325
Straight-link	3/8	1 3/8	125	1.55	7,700	1,925
Straight-link	7/16	1 5/8	137	2.00	10,500	2,625

Elongation of all sizes 12 per cent. Proof test one-half of breaking load.

SIZE, PITCH, STRENGTH AND WEIGHT OF CHAINS. — The s of an ordinary chain in which the links are made of wire or rods is specified the diameter of the wire or rod. The pitch of a chain is the distance betwe the centers of successive links, usually expressed in inches. The proof te of a chain is the specified load it must carry without deformation, and is usua taken as one-half the breaking load. The ordinary safe load is usually taken about two-thirds of the proof test, or one-third the breaking load.

The safe working load is dependent on the amount of rivet-bearing surface, speed, size of sprockets, etc., and ranges from 1/8 to 1/40 of the tensile strength.

STRENGTH OF ROLLER AND BLOCK "DIAMOND" CHAINS

Pitch, inches	Tensile strength, pou	
	Roller	Block
½	1,200	.....
5/8	1,200	.....
¾	4,000	.....
1	6,000	1200-2500
1¼	9,000	.....
1½	12,000	5000
1¾	19,000	.....
2	25,000	.....

CHAIN DRIVE. — The advantages of chain drive are positive speed ratio, capability of transmitting large amounts of power at low speeds, not seriously affected by moisture, oil or grease, no stretch, and for short transmissions greater efficiency than leather, rubber or fiber belting. Roller chains should not as a rule be run at speeds of over 1000 feet per minute, and block chains not over 700 feet per minute.

Wherever possible, the distance between centers of shafts should permit of adjustment in order to regulate th sag of the chain. A chain should be adjusted, in proportion to its length, t show slack when running, care being taken to have it neither too tight nor to loose, as either condition is destructive.

The principal cause of trouble within the chain itself is elongation. It r the result of stretch of material or natural wear. Sudden jars or jolts beyon the limit of elasticity of the material will quickly render the chain useless. I for any reason a link elongates unduly it should be replaced at once, as an elongated link will eventually ruin the entire chain.

To minimize wear, chains should be kept well greased and protected fro mud and grit, cleaned often, and when replaced put back so that they run i the same direction and same side up. A new chain should never be applie to a much-worn sprocket.

Sprockets. — Properly proportioned and machined sprockets are essentia to successful chain gearing. For block chain these are obtained as follows:

Sprockets should be gauged to discover thick teeth and inaccurate diameters A poor chain may operate on a good sprocket, but a bad sprocket will ruin good chain. Sprockets of 12 to 60 teeth give best results. Fewer may b used, but cause undue elongation in the chain, wear the sprockets and consum too much power. Eight-tooth sprockets ruin almost every roller chain applie to them, and ten and eleven teeth are fitted only for medium and slow speed with other conditions unusually favorable.

IMNEYS. — (*See also Draft, Mechanical.*) A chimney serves as a means establishing a sufficient draft through a furnace to produce the combustion the fuel. The amount of air *required* per hour depends upon the quantity fuel burned per hour and the quality of fuel. The amount actually used pends also on the manner of firing, or the judgment and skill of the fireman. he *force required* to produce this draft in turn depends upon the quality of the el, the method of firing, the thickness of the fuel bed, the design of the furnace, e length and cross section of the gas passages, the height and cross section of e chimney, the location of the chimney with respect to neighboring buildings d hills, and the direction and velocity of the wind which may be blowing. he *force available* for producing the draft depends upon the height and cross ction of the chimney and the difference in temperature of the hot gases in the imney and the cold air outside. On account of the number of these variables d their great range of variation from time to time, it is practically impossible deduce a rational formula for the size of the chimney required for the combustion of fuel at a given rate. The following approximate method for determining the height and cross section of a chimney, however, has been found tisfactory in practice. The formula connecting the height, cross section and te of fuel consumption is an empirical one, deduced by the author from merous actual cases, and first published in 1884. It has been extensively ployed with satisfactory results by numerous engineers since that time.

INTENSITY OF DRAFT AND HEIGHT. — The difference in weight tween the hot gases inside the chimney and the weight of an equal column of he external air is the cause of the draft produced by the chimney. The pressure due to this difference is called the "intensity" of the draft and is usually measured in inches of water column required to balance it. The measurement is made by a draft gauge, usually a U-tube partly filled with water, one leg connected by a pipe to the interior of the flue between the boiler and chimney and the other open to the external air. For finer and more accurate readings some form of multiplying gauge is used.

Let t_1 be the average temperature of the chimney gases, t_2 the temperature of the external air, both in degrees Fahrenheit, and let H be the height of the chimney in feet. Then the total intensity of draft produced by the chimney, expressed in inches of water column for normal atmospheric pressure, is

$$F = H\left(\frac{7.64}{460+t_2} - \frac{8.00}{460+t_1}\right).$$

For an atmospheric pressure of P inches of mercury, multiply the left-hand side by $\frac{P}{30}$.

The intensity of the draft and consequently the velocity and the volume of the hot gases will of course be greater the greater the temperature of the hot gases, but as the temperature increases the volume of a given weight increases, that is, their density decreases. When the temperature of the gases exceeds a certain value the increase in the velocity due to a further increase of temperature will be more than offset by the decrease in density. According to Rankine the temperature corresponding to the maximum value of the product of volume and density, that is the maximum weight of gases discharged, is, under ordinary conditions, 600° F., when the external temperature is 60°. Hence the total intensity of draft F_0 corresponding to maximum weight of discharged gases may be found approximately by substituting 600 in the above formula for t_1, and 60 for t_2. The formula then reduces to $F_0 = 0.007\ H$.

The actual intensity of the draft is usually less than that calculated from the

Google

temperature taken at the bottom of the chimney, on account of the coolin of the gases as they ascend the chimney and from other causes. Taking th reduction at 20 per cent the formula expressing the relation of intensity of draf to height of chimney becomes $F_n = 0.0057\,H$ on the assumption of a temper ture of 600° at the bottom of the chimney.

MINIMUM HEIGHT. — Hence when the intensity of the draft necessar to produce the necessary current of air through the breeching, boiler and furnac is known, the minimum height of chimney which will produce this draft is

$$H = 175\,F_n \text{ feet},$$

where F_n is the net intensity of draft in inches of water required. The followin table gives the intensity of draft required under ordinary conditions.

DRAFT PRESSURE REQUIRED FOR COMBUSTION OF DIFFEREN FUELS

Kind of fuel	Total draft in inches of water	Kind of fuel	Total draft in inches of water
Straw	0.20	Slack, very small	0.7-1.1
Wood	0.30	Coal dust	0.8-1.1
Sawdust	0.35	Semi-anthracite coal	0.9 1.2
Peat, light	0.4	Mixture of breeze and slack	1.0-1.3
Peat, heavy	0.5	Anthracite, round	1.2-1.4
Sawdust mixed with small opal	0.6	Mixture of breeze and coal dust	1.2-1.5
Bituminous, run of mine	0.4-0.7	Anthracite slack	1.3-1.8

Thurston gives the following formulas for the intensity of draft and height chimney in terms of the fuel consumption per square foot of grate per hour.

Let C = pounds of coal burnt per hour per square foot of grate. Then

for anthracite coal

$$F_n = 0.001875\,(C-1)^2 \quad \text{and} \quad H = \frac{(C-1)^2}{4};$$

for best Penn. or Welsh

$$F_n = 0.00148C^2 \quad \text{and} \quad H = \frac{C^2}{5};$$

for Pittsburgh or Illinois

$$F_n = 0.000833C^2 \quad \text{and} \quad H = \frac{C^2}{9}.$$

In any particular case the required draft may differ considerably from the figur given above. The design of a chimney should be left to an engineer of experien in this kind of work.

According to C. L. Hubbard (*Am. Elec., Mar., 1904*), the following heigh have been found to give good results in plants of moderate size (500 horse-pow or less), with sufficient draft to force the boilers 20 to 30 per cent above the rating:

Digitized by Google

With free-burning bituminous	75 feet
With anthracite of medium and large size	100 feet
With slow-burning bituminous	120 feet
With anthracite pea	130 feet
Witb anthracite buckwheat	150 feet
With anthracite slack	175 feet

For plants of 700 or 800 horse-power or over, the chimney should not be less than 150 feet high regardless of the kind of coal used. It is evident that the figures in the above table are subject to wide variations with different qualities of coal as regards caking and non-caking, clinkering and non-clinkering, etc., with different proportions of grate to heating surface and with different kinds of grates and furnaces.

On account of the elimination of the grate in oil-burning boilers and the injection of oil under pressure the height of a chimney for an oil-burning boiler is less than for a coal-burning boiler of the same capacity. According to Gebhardt a height of from 80 to 90 feet is sufficient to force oil-burning boilers to 50 per cent above their rating. In large oil-burning plants, however, the chimney is usually designed on the coal-burning basis, in order to permit the use of coal should this subsequently prove desirable.

CROSS-SECTION OF CHIMNEY. — All chimney formulas are based on the hypothesis that the capacity or theoretical coal consumption of a chimney varies directly as the area (effective area) and the square root of the height

Let C = coal consumption in pounds per hour.
A = area of actual cross-section of chimney in square feet.
H = height above the grates in feet.

Then the typical formula may be written:

$$C = KA\sqrt{H}$$

where K = a constant. Kent uses the formula

$$C = K'A'\sqrt{H}$$

where A' is the "effective" area, taken equal to $(A - 0.6\sqrt{A})$, and K' is a constant.

The value of the constant K, as given by different authorities, varies greatly, Toldt gives $K = 5$; Prechtl, $K = 6.4$; Molesworth, $K = 9$; Ser, $K = 9.3$; Hutton, $K = 10$ to 16; Seaton and Rounthwaite, $K = 12$; Henthorn, $K = 16.6$; Brinckerhoff (average), $K = 18.1$. Kent gives for K' the value 16.65. Toldt and Prechtl refer mainly to German metallurgical practice, Ser to general French practice, Molesworth and Hutton to English practice, Seaton and Rounthwaite to marine practice, Henthorn to American mill practice.

An average of 30 stacks of various sizes now doing good work gives $K = 9.4$. An average of three notoriously overworked stacks gives $K = 17.9$.

Ser's figure $K = 9.3$, was obtained theoretically by allowing for twice the amount of air necessary for perfect combustion. By allowing an excess of one-half the amount necessary for perfect combustion, which result can readily be obtained by the use of automatic stokers, the constant $K = 12$ will be obtained. For preliminary calculations the above formula with $K = 12$, gives practical results, but the chimney should be checked by comparison with known stacks of similar diameter and height for the final calculations.

The value of $K = 12$ applies only to brick-lined stacks. In case an unlined iron or steel stack is being considered, the value of K may be increased to 14 or 15 and for small stacks 16 may be used.

Digitized by Google

STABILITY — THICKNESS OF WALLS. — All chimneys of any considerable size should consist of an outer stack of sufficient strength to give stability to the structure, and an inner stack or core, independent of the outer one, to protect the latter from the high temperature of the hot gases. The core sometimes extends up to a height of but 50 or 60 feet above the base of the chimney, but better practice is to extend it the full height or to 100 to 120 feet in chimneys over 120 feet high. The core is usually constructed of fire brick; the outer stack may be built of common brick, or radial brick (the Custodis chimney is an example of the latter) or of steel or of reinforced concrete. To determine whether a chimney is stable, treat it as a cantilever loaded throughout its length with a load equal to the total pressure (*see Elasticity and Strength; Wind Pressure*); at no section of the chimney should the stress in the walls exceed the safe working stress for the material of which it is constructed.

Brick Chimneys. — The base of a brick stack should rarely be less than one-tenth of the height. The allowable batter according to different authorities varies from 1 in 192 to 1 in 20 on each side, but the best practice lies between 1 in 30 and 1 in 40 for ordinary brick, with 1 in 60 to 1 in 80 for the Custodis hollow-tile method of construction.

In brick chimneys practice varies as to the thickness of the walls. The linings are not exposed to wind pressure, and consequently can be much thinner than the outside wall. The usual practice is to make the steps about 50 feet high and 4½ inches thick at the top up to a height of 150 feet.

For higher chimneys the lining should be 8 inches thick at the top. The outside walls for chimneys up to 150 feet high may be 8 inches thick at the top, with the steps about 50 feet high or the upper steps may be as high as 60 feet with 50 feet for the lower steps. For stacks built on the Custodis principle the two courses are from 8 to 13 inches thick, depending on the height. The thickness of the moulded brick is increased 2 inches every 5 meters, or about every 16 feet.

All brick stacks should be topped with a waterproof cap, usually of cast iron, although in many cases it is made of stone or monolithic concrete.

Reinforced Concrete Chimneys began to come into extensive use in this country in 1901 and several hundred of them are now in use. Reinforced concrete chimneys built by the Weber Co., of Chicago consist of two parts: the lower double shell and the single shell above. The inside shell is usually 4 inches thick, while the thickness of the outside shell depends upon the height and varies from 6 to 12 inches. The single shell is from 4 to 10 inches thick. The height of the double shell depends upon the height of the chimney, nature and temperature of the gases, etc. The bending forces caused by wind pressure are taken up by vertical steel reinforcement; the resistance of the concrete itself against tension is not considered in calculation.

Steel Chimneys are largely used, especially for tall chimneys of iron-works, from 150 to 300 feet in height. The advantages claimed are: greater strength and safety; smaller space required; smaller cost, by 30 to 50 per cent, as compared with brick chimneys; avoidance of infiltration of air and consequent checking of the draft, common in brick chimneys. The best constructions for steel stacks include a number of vertical stiffeners riveted to the shell which support horizontal cast-iron or steel rings on which the linings are built. The vertical stiffeners are usually spaced about 5 feet apart, and the horizontal rings about 20 feet apart. By this method any section of the lining may be replaced without disturbing the other sections. The thickness of the metal at the top of the stack in such cases is usually ¼ inch, increasing ⅛ inch

Digitized by Google

ry 50 feet. Stacks in which the linings are not supported may be ¼ inch k at the top increasing 5/16 inch every 30 feet. They are usually made adrical in shape, with a wide-curved flare for 10 to 25 feet at the bottom. eavy cast-iron base-plate is provided, to which the chimney is riveted, and plate is secured to a massive foundation by holding-down bolts. No guys used.

Sheet Iron Smokestacks. — Guyed stacks of light sheet iron are frequently d for single boilers and even for quite large plants especially where the ected life of the plant is short. The smaller stacks are made up in lengths about 20 feet of ⅛ inch steel connected by angle rings on the outside or the ke stack may be riveted in one piece on the ground and erected with a gin e.

For these stacks the value of K in the general formula may be as high as 20 as y are usually connected directly to the boiler uptake and are exposed to high peratures.

uch stacks deteriorate very rapidly and cannot be considered a desirable truction, but occasionally circumstances will require their use. Galvanized aded wire cables form the best guys and the anchors may be concrete blocks the larger sizes. For the smaller sizes the guys usually lead to the steel build-structure.

...ne Stacks. — During the last few years a type of stack has been developed ...urope which offers marked advantages both as to cost and ease with which draft may be controlled. The stack action is based on the injector principle, the theory has not been well worked out as yet. The stack resembles a ...turi meter set up on end, the upper cone or diffuser enclosing an angle of 7°. ...e stacks are rarely over 60 or 70 feet in height and are usually applied to ...e boilers or batteries, in order that the control may be perfect. It is usually ...ble to attain an evaporation of about 2 lb. of water per square foot of boiler ...ce with the stack alone. For the higher ratings air is injected just below ...enturi throat, thereby inducing a higher rate of suction than the height of ...ack would make. It is possible so to proportion the stack and blower ...ities that a suction draft of 3 or 4 inches of water may be obtained, but this ...ally unnecessary, as drafts of from 1 inch to 1½ inch will fulfill most of the ...rements.

FOUNDATIONS. — Chimney foundations are as a rule constructed of c crete except where the nature of the soil necessitates the use of piles or a gril of timber or steel. (For the bearing power of various soils see section on *Fou tions* in article on *Power Stations*.) For masonry chimneys the foundatio designed to give the necessary support for the shaft without particular refere to its weight and shape. In steel and reinforced concrete chimneys the wei and shape of the foundation are important factors in securing the proper stabil of the chimney, since the shaft is usually securely fastened to the foundati and the two form practically one mass.

SIZES OF FOUNDATIONS FOR HALF-LINED STEEL CHIMNEYS
(Selected from circular of Phila. Engineering Works.)

Diameter, clear, feet	3	4	5	6	7	9	1

Least depth foundation, feet	.....	7	10	10	12	12	

BREECHING. — The area of the flue or breeching leading from the b to the stack is usually made 20 per cent greater than that of the stack. W several boilers discharge into the same flue its section may be tapered proportioned to the number of boilers. When two flues enter the stac opposite sides at the same level a diaphragm is inserted between the openings.

COSTS (Pre-war figures). — The following table gives the cost of l chimneys:

COST OF BRICK CHIMNEYS

Approximate horse-power	Height, feet	Diameter flue, inches	Cost, erected
85	80	25	$598
135	90	30	786
200	100	35	1226
300	110	43	1492
400	120	51	1785
750	130	61	2528
1000	140	74	3060
1650	150	88	3750
2500	160	110	5095

The following approximate cost of radial brick chimneys (adapted Gebhardt, *Steam Power Plant Engineering*) will serve to indicate the variati cost with height and diameter:

Digitized by Google

COST OF RADIAL BRICK CHIMNEYS

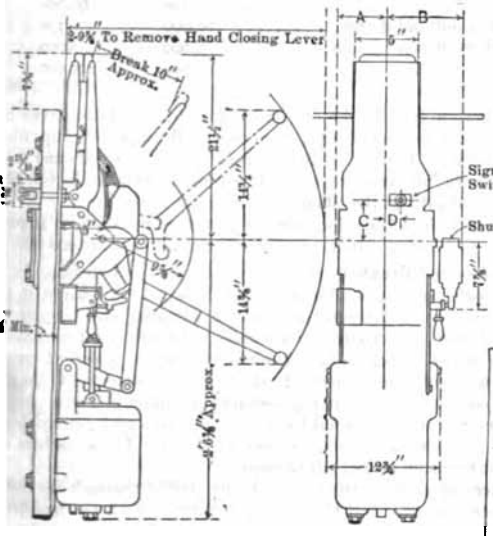
CIRCUIT BREAKERS. — (*See also Bus-Bars; Switchboards; Switch*
Switchgear Equipment for Power Stations.) A circuit breaker is a device to ope
an electric circuit which is normally held closed by the action of a latch, togg
or similar mechanism. This tendency to open is the feature that usually di
tinguishes a circuit breaker from a switch, as the latter, although used to ope
electric circuits, is without any latch or similar device and hence will remai
in the closed position. This distinction between switches and circuit breake
is not always followed, as circuit breakers which open in oil are frequentl
spoken of as "oil switches."

TYPES OF CIRCUIT BREAKERS. — When a circuit breaker acts
matically opens the circuit as the result of certain abnormal conditions, such
overload, the circuit breaker is said to be "automatic," but if the breaker do
not open unless tripped by the attendant it is spoken of as "non-automatic.
An automatic breaker usually can be released by hand also. A breaker design
to be closed directly by the operator is spoken of as "direct controlled," wh
a breaker mounted at a distance is "remote controlled." The latter can
"manually operated" if worked through a system of bell cranks, levers or simi
devices; "electrically operated" if worked by motor or solenoid; or "pne
matically operated" if controlled by compressed air.

Small circuit breakers, particularly of low voltage, are usually direct controll
and large-capacity high-voltage breakers are usually remote controlled, su
auxiliary source of power being employed. For such distant-controlled breake
automatic operation is secured through relays (*see Relays*). Relays are a
frequently used with direct-controlled breakers.

Underload, Over-voltage, Under-voltage and Reverse Curr
Breakers. — The principal demand for circuit breakers is to have them op
the circuit when the current reaches a certain predetermined value,
breakers are designed with this end in view. They are also built for und
load conditions to open on minimum current, for over-voltage to open wh
the voltage exceeds a certain amount, for under-voltage to open when the v
age falls below a certain minimum value, for reversal when the current fl
in the opposite direction through the breaker from that which was intended
is, of course, possible to combine these various features of overload, underlo
reversal, etc., in one and the same breaker. (*See Relays.*)



PRINCIPLE OF OPERATION. — The opening of a circuit breake
usually secured by the releasing of a latch or the upsetting of a toggle joint
keeps the breaker closed. Various schemes have been adopted to secure
adjustment or "calibration" of the overload tripping device, so that it may
made to operate within reasonably wide limits, usually 80 to 160 per cent of
normal rating.

Breakers Opening in Air. — Fig. 1 shows the general arrangement of
magnetic circuit of a typical carbon-break circuit breaker, arranged for han
solenoid operation, as used on heavy-capacity d-c. and low-voltage a-c. circ
The current passes in at one stud across the contact brush and back through
other stud, thus forming a loop or turn in the electric circuit. A U-shaped
frame is placed around the lower stud and the movable armature completes
magnetic circuit.

The current passing through the breaker magnetizes the iron circuit and
to lift the movable armature. At a certain predetermined current the attra
overcomes the force of gravity, and the raising of the moving arm opens
latch or upsets the toggle which holds the breaker closed.

Two methods of securing the necessary range or calibration can be emplo
one by varying the air gap between the stationary and moving iron, and

other by giving the electromagnet more work to do by increasing the weight to be lifted. This latter method can employ either additional weights at a fixed

	Amperes

D	1 9/16	2 1/16

Fig. 1. Carbon-break Circuit Breaker

istance from the fulcrum, or a fixed weight at a variable distance from the ulcrum.

For small currents the electrical circuit is carried more than once around the on circuit, which results in a solenoid design with a movable plunger. With is scheme the tripping range is secured by adding weights to the solenoid or arying the air gap.

Oil Circuit Breakers (Figs. 2 to 6). — With high-voltage oil circuit breakers e tripping coil is usually a solenoid of a fairly large number of turns, which is nnected in series with the main circuit or serves as the secondary of a current ansformer whose primary is connected in the high-tension circuit. For poly- ase circuits two or more tripping coils are used.

DESIGN. — For different classes of service various types of circuit breakers e used, and the functions of these types overlap more or less. The following ble gives the approximate values of the maximum normal current and voltage which these various types are used at present.

In connection with the carbon-break circuit breaker 24,000 amperes is the rgest size in actual service, but larger breakers could be built if desired. The ximum d-c. voltage at present used for railway service in America, is 5000 t; but carbon breakers can be built for higher d-c. voltages if desired; they e been used up to 22,000 volts for a-c. service.

The fuse type has not been built for more than 100 amperes or 66,000 volts, could be made for higher voltages if desired.

Digitized by Google

Type	Max. Current Amperes	Max. Volts
Carbon Break	24,000	5,000
Fuse Type	100	66,000
Magnetic Blowout, old design	10,000	750
Magnetic Blowout, new design	3,000	3,000
Oil Break	6,000	220,000

The magnetic blowout type in the old design for street railway service has been built up to 10.000 amperes but it has been practically superseded by carbon breakers for this service. For d-c. railway service above 750 volts and up to 3000 volts the magnetic blowout breaker has been used owing to the very high speed that can be obtained and the efficient blowing out of the arc.

The oil break type is in service for current capacities up to 6000 amperes and for voltages up to 150,000. It has recently been built for 220,000 volts.

Air-break Carbon-type Breakers are made in a variety of designs; Fig. 1 shows a typical single-pole carbon-break circuit breaker. As shown in the figure, the circuit-breaker mechanism consists of a swinging arm carrying the main and the arcing contacts actuated by a handle and toggle-joint mechanism. The main contacts are of copper and are laminated to insure a perfect contact with the copper blocks which are fastened to the base and connected to the line. Above the copper contacts are the arcing contacts of carbon. These contacts consist of one or more carbons carried by a swinging arm and pressed firmly against stationary contacts when the breaker is closed. These carbons are mounted on a pivot to insure proper adjustment.

When the breaker opens the current is gradually shifted through the copper shunts to the carbon contacts, and thus no arc is formed until the final break takes place between the carbon contacts at the top. This arrangement, combined with the natural tendency of an arc to rise, prevents any injury to the breaker by the arc.

For large capacities strap connections are almost invariably used and to facilitate the employment of these strap connections the studs of large breakers are made of laminated construction.

Heavy capacity carbon-break circuit breakers are also made solenoid or motor-operated. With the solenoid design there is a definite end to the movement of the core that prevents damage to the mechanism from overtravel. The motor mechanism has a device that disconnects the worm gear and shuts down the motor when the breaker has closed and the toggle or latch has locked. This device is also so arranged that if an overload or short-circuit exists when the breaker is closed, the breaker will immediately trip out even though the control switch is held in the "close" position. This feature of being "nonclosable on overload" is one that is embodied in a large number of breakers of all kinds, and is a very valuable and useful one.

Switch and Breaker for Rotary Converters. — A combination motor operated switch and circuit breaker has been supplied for various rotary converters and 600-volt feeder circuits supplying current for third-rail electrifications. One motor is provided for each combined circuit breaker and switch and it has suitable clutches, shafts, operating rods and mechanism, so that in the act of closing the circuit breaker is first thrown in and the closing device is then disconnected before the switch is thrown in, so that in case of trouble the breaker can immediately trip out and open the circuit.

Air-break Fuse-type Breaker. — This type is a modification of the carbon break type and is intended for moderate capacity circuits for voltages of 6000 to 60,000. This breaker consists essentially of a stationary and a movable arm

mounted on suitable insulators supporting the line connections. These arms are hinged together at one end. The free ends are held together against gravity and a strong spring by a piece of aluminum fuse wire that passes through a blow-out tube. When the current exceeds a certain amount, the fuse wire melts and the free end of the movable arm swings away from the stationary arm, the arc being ruptured in a blow-out tube.

Magnetic Blow-out Type Breaker. — This type of breaker is provided with auxiliary contacts that open in a strong magnetic field which blows out the arc formed at these auxiliary contacts. The main contacts are solid copper blocks bridged by a laminated copper brush. These open first when the breaker operates, leaving the final arc to be broken on the auxiliary contacts, which are protected by the magnetic blow-out device and which can be readily renewed at comparatively small expense. Although breakers of this type have been installed on the switchboards of power plants, they have been practically superseded by carbon breakers for this work. For such service as the protection of the circuits on a railway car, requiring a few hundred amperes at 600 volts, the magnetic blow-out principle is used to advantage, as the discharge vent from the blow-out compartment can be so set that the vapors from the arc will do no damage.

Since the advent of the high voltage d-c. railways operating at voltages of 1200-1500 or 2400–3000 the magnetic blowout effect has been utilized to great advantage in connection with the high speed breakers developed for that class of service.

Oil **Circuit Breaker** (Figs. 2 to 6). — The essential feature of this type of breaker is the opening of the circuit under oil and the smothering of the arc in a restricted space. These breakers are used almost to the exclusion of all other designs on d-c circuits of large capacity and high voltage. Oscillograph tests show that the circuit is interrupted at the time of zero point of the alternating-current wave, and, therefore, there is little tendency to set up surges in the circuit. The rapid interruption of a direct current, however, is apt to set up surges, and therefore the oil-break design is not commonly used with d-c. service.

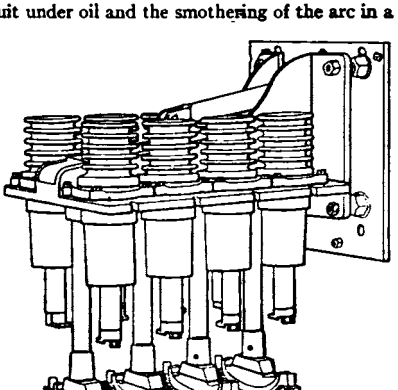

Fig. 2. 300-ampere, 15,000-volt, 4-pole Circuit Breaker

Oil-break circuit breakers are designed to meet various conditions of current, voltage and amount of power that may might be called upon to handle in case of a short-circuit. For moderate amounts of power where the size and cost of the breaker is to be kept to a minimum it is often possible to locate all the poles in one oil tank. For slightly larger amounts of power each pole is in a separate oil tank but all the poles are mounted on the same frame. For still greater amounts of power at moderate voltages each pole is in a separate tank and each tank in a separate compartment. For very high-voltage work each pole is in a

separate steel tank of such substantial construction as to be proof against any explosion due to the effects of a short-circuit.

Fig. 2 shows a 300-ampere, 15,000 volt, 4-pole breaker of a type that is built on various frames for various sizes up to 2000 amperes at 7500 volts, and 600 amperes at 25,000 volts. In this type of breaker each pole with its pair of contacts is in a separate tank with an insulating lining and all poles on the same frame. This breaker is readily arranged for manual operation or electrical operation by a solenoid and it can be mounted on a wall, framework, switchboard panel or on suitable supports of pipe or structural iron for open construction or for masonry compartments.

Fig. 3 shows a solenoid operated breaker of a type built on various frames for wall mounting, pipe mounting, or structure mounting, in capacities up to 2000 amperes at 15,000 volts and 1200 amperes at 25,000 volts. Each pole of this breaker is in a separate tank mounted on an independent frame and arranged

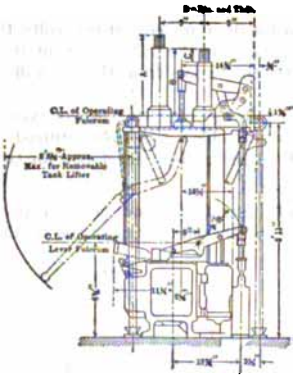

Fig. 3. 2000-ampere, 15,000-volt Solenoid Operated, Oil Circuit Breaker

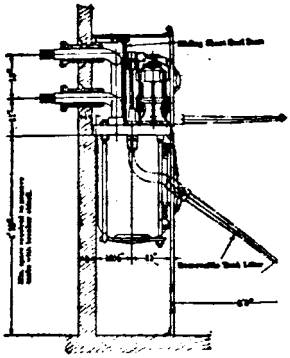

Fig. 4. Solenoid Operated, 15,000-volt, Oil Circuit Breaker

so that it can readily be located in a masonry compartment or on a framewor Two, three, or four pole units are made by connecting the mechanisms of tw three, or four poles to the same soleonid operating device. The mechanism a terminal insulators are mounted on the steel top of the breaker and a simp system of toggles operated by a powerful solenoid is used for closing the break A second solenoid is used to disengage a trigger on the operating mechanism trip the breaker. A two pole, double throw switch is mounted on the breal and operated by the motion of the levers in opening or closing the breaker; t switch being used to control the signals on the switchboard.

Fig. 4 shows a solenoid operated back connected heavy capacity breaker b in capacities of 600 to 3000 amperes at 15,000 volts, guaranteed capable rupturing 23,000 amperes per phase at 15,000 volts. Both terminals of e pole are in a single circular tank pressed out of ¾ inch sheet steel, forming a sea less tank of great strength. An insulated lining is provided and each tank a gauge glass for observing the height and condition of the oil. These breal in service are placed in masonry structures and their design is based on secur the maximum rupturing capacity in a given space. A heavy steel casting car the powerful operating mechanism as well as the contact rods. tanks e

aking the breaker a self-contained unit. A modification of this breaker has he three poles independent, each pole being located in a separate masonry ompartment.

Fig. 5 shows a 400 ampere o,ooo volt indoor frame ounted 3 pole solenoid oper- ted oil circuit breaker. Each ole of the breaker is located i a welded steel tank with icarta lining. All of the perating mechanism is ounted in the tank top and rovision is made for readily ropping any tanks to obtain ress to the mechanism.

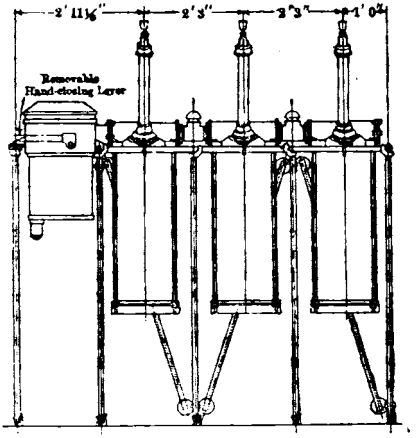

Fig. 5

This type of breaker is built oth for indoor and for out- oor service, frame mounted, nd floor mounted, for voltages om 25,000 to 73,000 frame ounted, and from 37,500 up o 155,000 volts for floor ounting. Designs are avail- ble up to 220,000 volts.

A three pole breaker is made p of three elements entirely dependent of each other, except that they are connected by a single operating d. The spacing of the poles, particularly on the floor mounting breaker, n readily be made to suit the station wiring. For manual operation the perating solenoid is replaced ; a bell crank device. The ndenser bushing leads that m the stationary terminals n readily be unclamped and moved through the cover. he series transformers for the eration of ammeters and re- s are usually arranged to be mped directly around the ndenser bushing leads which m the single turn primary. his permits the use of a sim- , compact and cheap form series transformer.

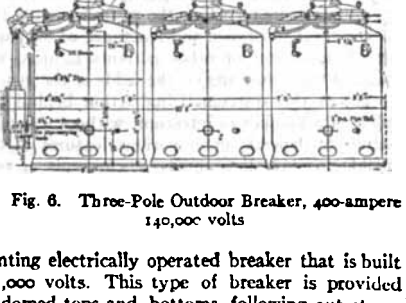

Fig. 6. Three-Pole Outdoor Breaker, 400-ampere 140,000 volts

Fig. 6 shows a 400 ampere, ,000 volt outdoor floor mounting electrically operated breaker that is built izes from 50,000 up to 155,000 volts. This type of breaker is provided h cylindrical tanks having domed tops and bottoms, following out steam ler practice and utilizing tanks that withstand pressures as high as 150 unds per square inch. Designs are available up to 220,000 volts.

The breaker shown on Fig. 6 has main features corresponding closely with se of Fig. 5 previously described.

For outdoor service the condenser bushing leads of the breaker are covered with ries of porcelain insulators, and the space between the bushing and the insula- n is filled with a moisture proof compound.

Digitized by Google

The operating mechanism is covered by a metallic hood and the pull rods connecting the poles of the breaker pass through pipes. The various joints are made thoroughly water proof. Access to the interior of the tank is secured by the removal of the mechanism cap or manhole cover which exposes the lever system and presents a sufficiently large opening to withdraw any necessary parts. The mechanism is so disposed that a terminal bushing complete with its contact details can be withdrawn without disturbing any other details, and the moving contact elements can be withdrawn through the mechanism cover.

Where circuit breakers are exposed to temperatures of 0° C. or below, ordinary oil becomes sufficiently viscous to seriously impair the efficiency of the circuit breaker. This is caused by the slowing up of the opening action due to the heavy oil and also to the sluggish action of the oil itself in flowing in and suppressing the arc. Special grade oil having low freezing characteristics is available to overcome this difficulty, but for very large units heating elements may be installed in the tanks and put in service during the continuance of dangerously low temperatures. These heating elements can easily be placed so as not to interfere with the action of the mechanism in any way. The cost of these heating elements and the amount of power consumed by them is less on very large units than the difference in cost between the low freezing oil and the ordinary oil.

High voltage breakers of the outdoor type have been in service for a number of years in various parts of the United States, and have also been supplied to Japan, France, Spain and Italy.

RATING — (*See below for Table of Sizes.*) The rating of a circuit breaker is usually given as the normal current which it will carry continuously with a temperature rise not exceeding 30° C. for carbon breakers and 50° C. for oil breakers, above the surrounding air. This rating has no direct relation to the maximum short-circuit current which the breaker will safely interrupt. (*See below under Ultimate Capacity.*) The tripping range of the breaker is usually from 80 to 160 per cent of this normal rating. The cross-section of the conductors and the area of contact surfaces depend so much upon the character of design, the cooling effect of bodies of oil and masses of metal, that no definite current density can be given as an average value for the various types of breakers.

Ultimate Breaking Capacity. — (*See table below.*) When a short circuit or ground occurs on a line, the rush of current thereby produced depends upon (1) the total resistance and reactance of all parts of the circuit through which flows this current or other currents induced thereby, (2) the demagnetizing action of these currents on the fields of the generators producing them, and (3) the lag of this demagnetizing action behind the current producing it. The ability of a breaker to interrupt, without damage to itself, a current of a given magnitude depends upon various features of design, and it is evidently impossible to state how much synchronous or transforming apparatus may be safely connected directly to a breaker of a given rating, unless the conditions of operation are also fully specified.

In the table below the ultimate capacity of various breakers is given in terms of the amperes that they will actually rupture at the arc at their maximum rated voltage. They will rupture this current twice with a two minute interval between short circuits, and will be in condition to carry their full rated current, but may not be in condition to open up under short circuit without further attention.

For voltages less than the rated voltages the rupturing capacity in amperes can be increased usually more rapidly than the decrease in voltage, but a limit is reached when the short-circuit current amounts to approximately fifty times the normal current rating of the breaker.

Curves were published in the February 1918 Proceedings of the A.I.E.E. giving the short-circuit currents of typical American generators with various percentage

Digitized by Google

of reactance after the expiration of various lengths of time and these can be used to advantage in determining the short circuit to be expected in any system.

In determining the short-circuit characteristics of any particular system, the reactance of the generators and other devices has to be considered. On the basis of an average reactance of 8 per cent the momentary short-circuit current is roughly 12½ times normal and this usually dies down to about one-half this amount or 6¼ times normal by the time that any automatic breaker can open. At the expiration of a certain time that may be taken roughly as two seconds, the output of the system will be down to the continuous short-circuit basis of possibly two or three times normal rating.

The larger rupturing capacity breakers for 15,000 volts or less are almost invariably mounted in masonry compartments, usually with each pole in a separate cell and the leads carefully isolated from each other. The very high voltage breakers do not utilize the cellular construction and are very frequently arranged for outdoor installation.

DIMENSIONS, WEIGHTS AND COSTS. — Although the dimensions, weights costs etc. of breakers of various manufacturers naturally differ and are subject to change with the progress of designs, and while the same manufacturer frequently builds various grades for the same capacity the data that follows will give an idea of the range covered by the breakers of a single manufacturer.

CIRCUIT BREAKER DATA

Item	Amperes	Volts	Rupture, Amperes	Height, inches	Width, inches	Depth, ins.	Weight	Prices
1	400	750	.....	24	4¾	14¼	130	$140

23	400	135,000	5,350	170	272	84¾	26,400	17,660

The information in the above table is based on apparatus manufactured by one of the largest American builders of switchgear and is practically correct at the date of its preparation (October, 1920). Changes are made from time to time in the design of equipment that may slightly modify this information.

The dimensions, height, breadth, and depth for carbon circuit breakers, items 1, 2, 3, and 4, refer to single pole switchboard mounting breakers; and the depth is given from the front of the panel, that is, the length of the studs projecting through the panel is neglected. For the switchboard mounting oil circuit breakers the dimensions are given from the back of the panel, that is, the length of the handle sticking through the board is neglected. All of the oil breakers are three pole, items 5, 6, and 7, being hand operated, the remainder being electrically operated. For the electrically operated breakers the dimensions include the operating solenoids. For cell mounting breakers the dimensions include the cells but the weight and prices are exclusive of cells, oil, current and potential transformers. For the high voltage breakers the dimensions are over the terminals and the width is based on the minimum spacing recommended for any particular voltage. The dimensions are in every case the maximum overall dimensions except as mentioned. The costs given are the approximate selling prices under date of October 1920, and are sufficiently accurate for the preparation of preliminary estimates, but for accurate work should be checked by actual quotations from a reliable builder.

Items 1 to 4 are single pole hand operated carbon circuit breakers, similar to Fig. 1.

Items 5 and 7 are hand operated oil circuit breakers with all contacts in the same tank and barriers between contacts.

Item 6 is an oil breaker with each pole in separate tanks but all tanks on the same frame.

Item 8 is an electrically operated breaker with each pole in a separate tank on a separate frame, and arranged for cell mounting, wall mounting or pipe mounting.

Item 9 is a three pole breaker with all poles in separate tanks, all tanks on a common frame arranged for wall mounting, pipe mounting, or cell mounting.

Items 10 and 11 are essentially cell mounting breakers with each pole in a separate cell, and items 12 and 13 are cell mounting breakers with circular tanks with each pole in a separate tank, all three tanks on the same frame.

Items 14, 15, and 16, are frame mounted solenoid operated indoor breakers.

Items 17 and 18 are solenoid operated floor mounting indoor breakers.

Item 19 is a solenoid operated frame mounting outdoor breaker.

Items 20 and 21 are solenoid operated floor mounting outdoor breakers with oval tanks.

Items 22 and 23 are solenoid operated outdoor breakers with cylindrical tanks.

LLECTORS, CURRENT. — (*See also Cars, Electric; Locomotives, Elec-; Third-Rail Systems; Trolley Systems, Overhead; Trolley Systems, Under-und.*) Current collectors for electric cars or locomotives are divided into ee classes in accordance with the form of the working conductor from ich they collect current, as follows:

a) Overhead Trolley, which may be of the wheel, scraping bow or roller e.

b) Third-Rail Shoes, which may be of the over-running or under-running e.

c) Underground Conduit Plow.

WHEEL TROLLEY. — The wheel trolley consists of a grooved brass or cop- wheel held in bearings in a prong called a "harp" at the end of a steel pole ich is pressed upward by a system of springs and levers. The trolley wire from 18 to 22 feet above the rails. The pole ses the wheel upward against the wire with a ssure of from 20 to 40 pounds, the higher pres- e being used for the higher speeds. The current ich a wheel trolley can collect is limited at the ious speeds as indicated in the accompanying le. If greater currents are required, resort must ad to the third rail. The trolley wheel is not ry satisfactory on cars in trains as each trolley le requires the attention of a conductor to replace it curves and switches, and moreover, it is difficult to manipulate the trolley e from a platform between two cars.

Miles per hour	Amperes
5	1200
15	600
40	350
60	200

BOW TROLLEY. — This type of trolley is used to collect current from a h-voltage conductor because it is self-adjusting and needs no attention while cars are running. At high voltages its current capacity is sufficient to supply ver for a train of considerable size but it would not have sufficient capacity supply power for heavy trains at 600 volts. In America, bows are usually de of mild steel. In Europe aluminum is preferred but it has been found re that aluminum containing 6 per cent of copper, gives the best results. e bow may be held up either by simple springs in the same manner as the ley pole or it may be mounted upon a pantagraph mechanism which is held by springs and folded down by a compressed-air cylinder. The St. Paul 0 volt locomotives have pantographs with two pans pressing upward with ressure of about 50 pounds per pan and have successfully collected currents 000 amperes at low speeds. The pans are hinged to the pantograph proper order to make better contact with the trolley wire. A special form of overhead struction must be used for the bow trolley as the bow would strike the down- rdly projecting cars and the guy wires of the ordinary trolley construction. e roller trolley may be used in place of the bow on the same form of mech- ism. The roller has a greater current capacity and causes less wear on the rking conductor than the bow. The rollers used by the Butte, Anaconda and ific Ry., are steel tubes 5 inches in diameter and 2 feet long. They are each ured to collect 750 amperes at 2400 volts.

THIRD-RAIL SHOES. — A third-rail shoe will collect currents as high as 0 amperes at low speeds and 600 amperes at 60 miles per hour. As they are l-adjusting two or three may be placed on a locomotive or car just as well one, so that there is practically no limit to the current that can be collected this way. In fact it is always customary to put two on each side of each motive or car in order to prevent a cessation of current when passing

Digitized by Google

over breaks in the third rail due to switches or crossings. (See article on *Third Rails*.)

Over-running vs. Under-running Types. — The third rail for top contact or for over-running shoe is cheaper to install, to protect and to maintain and most generally used. The under-contact rail is less liable to trouble from sleet, snow and ice and is therefore warranted where climatic conditions are bad.

UNDERGROUND CONDUIT PLOW. — The underground plow consists of an insulated steel plate hung from a movable structure on the car. On the two sides of this plate and thoroughly insulated from it are two shoes pressed outward from the plate by springs. These shoes press against the two working conductors which are usually steel Tees separated from each other by about 8 inches and supported on some form of ceramic insulator. The current is led from the shoes to the car body by flexible insulated conductors.

OMPLEX QUANTITIES. — (*See also Vectors.*) The square root of a gative quantity is called an "imaginary" quantity, or a pure imaginary. quantity consisting of the sum or difference of a real quantity and an imagiry quantity is called a "complex" quantity. For example, $\sqrt{-3}$ is a pure aginary, and $2+\sqrt{-3}$ is a complex quantity. All the rules of ordinary ebra apply to pure imaginaries and complex quantities. For example, $\sqrt{-3}$ y be written $\sqrt{-1}\sqrt{3}$, and in general $\sqrt{-a}$, where a is a positive quany, may be written $\sqrt{-1}\sqrt{a}$. The square root of minus one is called the aginary unit and is usually represented by the symbol j (writers on pure thematics use the symbol i), that is,

$$j=\sqrt{-1}.$$

y complex quantity may then be written

$$a+jb,$$

ere a and b are both real quantities.

Geometrical Representation of a Complex Quantity. — A positive real antity may be represented by a line drawn in a given direction; a negative real antity may be represented by a line drawn in the opposite direction. Multiying a quantity by -1 then reverses its direction. Also, since multiplying a al quantity by $\sqrt{-1}$ twice is equivalent to multiplying it by -1, the operaon of multiplying once by $\sqrt{-1}$ may be represented by turning the line repreting the quantity through 90° in the positive direction rotation. The positive direction of rotation is taken as e opposite direction to that in which the hands of a ck move. Hence, a complex quantity $a+jb$ may be presented by the line OP in the figure, where $OA=a$ d $AP=b$. The complex quantity $a+jb$ is then comtely specified by a line of length $\sqrt{a^2+b^2}$ making an gle θ, with the axis of reference OX where $\tan\theta=\frac{b}{a}$.

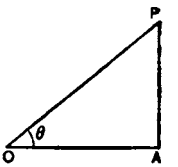

Fig. 1

e length $M=\sqrt{a^2+b^2}$ is called the magnitude of the complex quantity d the angle $\theta=\tan^{-1}\frac{b}{a}$ is called its angle. From the figure it is evident at the complex quantity $a+jb$ may also be written

$$a+jb=M(\cos\theta+j\sin\theta).$$

xpanding $\cos\theta$ and $\sin\theta$ into series (*see Series*) and adding, the resultant ies obtained is the series for $e^{j\theta}$; hence

$$a+jb=Me^{j\theta}. \qquad (1)$$

From the above definitions and equation (1) it is evident that complex numrs possess the following properties:

Addition of Two Complex Quantities. —

$$(a+jb)+(a_1+jb_1)=(a+a_1)+j(b+b_1).$$

Subtraction of Two Complex Quantities. —

$$(a+jb)-(a_1+jb_1)=(a-a_1)+j(b-b_1).$$

Digitized by Google

Multiplication of a Complex Quantity by a Complex Number. —

$$(a+jb)(a_1+jb_1) = aa_1 - bb_1 + j(ab_1 + a_1b)$$

or, putting $a+jb = Me^{j\theta}$ and $a_1+jb_1 = M_1e^{j\theta_1}$

where $M = \sqrt{a^2+b^2}$, $M_1 = \sqrt{a_1^2+b_1^2}$,

$$\tan\theta = \frac{b}{a},$$

and

$$\tan\theta_1 = \frac{b_1}{a_1}$$

we have $(a+jb)(a_1+jb_1) = Me^{j\theta}M_1e^{j\theta_1} = MM_1e^{j(\theta+\theta_1)}$.

Hence the product of two complex quantities is in general a complex quant which has a magnitude equal to the product of the magnitudes of the two qu tities and an angle equal to the sum of the angles of the two quantities.

Division of a Complex Quantity by a Complex Number. —

$$\frac{a+jb}{a_1+jb_1} = \frac{(a+jb)(a_1-jb_1)}{(a_1+jb_1)(a_1-jb_1)} = \frac{aa_1+bb_1-j(ab_1-a_1b)}{a_1^2+b_1^2}$$

or

$$\frac{a+jb}{a_1+jb_1} = \frac{Me^{j\theta}}{M_1e^{j\theta_1}} = \frac{M}{M_1}e^{j(\theta-\theta_1)}.$$

Hence the quotient of two complex quantities is in general a complex quant which has a magnitude equal to the quotient of the magnitudes of the t quantities and an angle equal to the difference of the angles of the two qu tities.

Example. — Suppose

$$I = \frac{10+j15}{3+j1};$$

then by the rule for division

$$I = 4.5+j3.5,$$

that is, I contains a real part 4.5 and an imaginary part j 3.5.

Equations Containing Complex Quantities. — Since a real quantity c not be equal to an imaginary quantity it follows that any equation of the fo

$$A+jB = A_1+jB_1,$$

where A, B, A_1 and B_1 are all real quantities (which may, however, consist any number of terms), is equivalent to the two equations

$$A = A_1$$

and

$$B = B_1.$$

Also, if one member of an equation reduces to the form $A+jB$, then the ot member of this equation must likewise contain an equal real and an equal aginary part.

CONCRETE. — (*See also Cement, Concrete, Reinforced.*) Concrete as used by engineers in construction is generally formed of an artificial mixture of Portland cement (*see Cement*) and an aggregate consisting of sand and gravel or broken stone. These ingredients are mixed with water either by hand or by machine mixers.

Light-weight Concrete. — During the Great War a light-weight concrete was developed for building concrete ships in the U. S. In this concrete the aggregate instead of being ordinary stone is made from calcined clay specially treated. This light-weight concrete weighs about 110 pounds per cubic foot and has a crushing strength of about 4000 pounds per square inch after 28 days ageing. It has to be made richer in cement than ordinary concrete and is consequently more costly. (*W. L. Scott, Engineering, 108*, p. 33, *July, 1919.*)

SPECIFICATIONS. — The quality of the materials can be determined only by careful tests, but for construction of minor importance and magnitude the following simple specifications should give good results.

Cement. — The cement shall be first-class American Portland cement of standard brand, guaranteed to conform to the Standard Specifications of the American Society for Testing Materials. (*See Cement.*) Such cement may be delivered either in bags or barrels but must be kept dry during storage.

Sand. — The sand shall be clean and coarse and free from dust, vegetable, loam or other organic matter, and other impurities, and should pass, when dry, a screen with holes $\frac{1}{4}$ of an inch in diameter.

Gravel. — The gravel shall consist of clean pebbles, and contain no foreign matter. It shall be screened over a ¼-inch mesh; the sand passing through the screen may be remixed in definite proportions with the gravel. If dirty or heavy, the gravel should be washed by a hose before mixing.

Broken Stone. — The broken stone shall consist of hard and durable stone such as trap, granite and limestone. Unless otherwise specified, all stone shall pass through a 2½-inch screen.

Water. — The water used for mixing shall be free from oil, acid and other injurious substances.

PROPORTION OF INGREDIENTS. — The amount of each ingredient is usually measured by volume. The concrete is designated by the proportion by volume of each of the ingredients in the following order: Cement, Sand, Stone or Gravel. For example, a 1 : 2 : 4 mixture is one consisting of one barrel of cement, two barrels of coarse sand, and four barrels of loose gravel or broken stone (standard cement barrels contain 3.8 cu. ft; four bags of packed cement may be considered as equal to one barrel).

The following proportions are somewhat generally adopted for different classes of work.

1 : 1 : 2 or 1 : 1½ : 3 for water tanks and standpipes carrying considerable pressure and required to be water-tight.

1 : 2 : 4 for arches, reinforced floors, beams, columns, engine foundations subject to vibration, sewers, and in general for structures subjected to bending stresses of some magnitude. A mixture as rich as this is also desirable where concrete is to be deposited under water since in such a case some of the cement may be washed away from the mixture.

1 : 2½ : 5 for bridge abutments and piers when laid in air, retaining walls and ordinary machine foundations.

1 : 3 : 6 for heavy walls, ordinary foundations, backing for stone masonry, etc.

Digitized by Google

Quantity of Ingredients.— The following rule devised by Wm. B. Fuller may be used for approximate determination of the quantity of the various ingredients.

Let c = number of parts of cement,
s = number of parts of sand,
g = number of parts of gravel or broken stone. Then

$\frac{10.5}{c+s+g} = N$ = number of barrels of Portland cement required per cu. yd. of concrete,

$\frac{1.55}{c+s+g}s$ = number of cu. yd. of sand required for one cu. yd. of concrete,

$\frac{1.55}{c+s+g}g$ = number of cu. yd. of stone or gravel required for one cu. yd. of concrete.

For tables giving more accurate values see Taylor and Thompson, *Concrete, Plain and Reinforced.*

MIXING. — The ingredients consisting of sand and aggregate should be thoroughly mixed while dry until the mass is uniform in color and homogeneous. Mixing should preferably be done by machine. When necessary to mix by hand, the mixing should be done on a water-tight platform and the ingredients should be turned not less than six times. Enough water should be used to produce a mixture which will flow readily into its place in forms or elsewhere.

Concrete Mixing in Freezing Weather. — Reinforced concrete should not be mixed or deposited in freezing weather unless special precautions are taken to keep the materials free from ice, and to protect the concrete from freezing until it has been thoroughly hardened. To accomplish these results the aggregates may be heated, salt water used in mixing, and the concrete carefully covered after it has been deposited. Portland cement concrete which is to be deposited in large masses may be laid in freezing weather provided the surface appearance is not important, and provided that hardened surfaces be thoroughly cleaned from frost as well as dirt before a new surface is laid. Natural cement concrete should never be laid in freezing weather.

Concrete Shrinkage and Temperature Changes. — Cracks in cement may be caused by contraction in setting, or by temperature changes, as well as by excessive stress. To preserve a good appearance it is common to establish artificial cracks in long walls, sidewalks, etc. For spacing of such cracks see reference in *Bibliography*. The insertion of steel reinforcing bars even when not needed to carry stresses due to applied loads is an expedient often adopted to prevent the occurrence of such cracks. The amount of reinforcement to be used for this purpose should generally be not less than one-third of one per cent.

Effect of Sea Water and of Acids on Concrete. — The data available relating to the effect of sea water upon concrete indicate that there may be some chemical action resulting in a softening and disintegration of the surface. To offset this action as far as possible, concrete laid in sea water should be carefully proportioned and well mixed. There is also great danger from disintegration due to frost in cold climates in concrete lying between high water and low water. To protect against this the concrete may be protected by a surface of stone in the zone exposed to such action.

Thoroughly hardened concrete of good quality may be considered as resisting the action of acids and mineral oils as well as other building materials. Oils containing fatty acids may produce injurious effects by combining with the lime in the concrete, resulting in a disintegration of the latter.

Waterproofing Concrete. — Concrete may be made reasonably impervious to water under moderate pressures by using a rich mixture and by careful pl

Digitized by Google

portioning and mixing. In the case of building foundations and other structures where leakage is not permissible it is usually advisable to protect the concrete by a separate coating applied either on the outside or inside of the wall or floor. The usual method of waterproofing the exterior is to construct a so-called membranous coating consisting of alternate layers of pitch and tarred felt. The inner surface of concrete basement walls and floors of many of the important buildings in New York City and other large American cities have been waterproofed by the use of a patented compound called "Hydrolithic Cement." Many so-called waterproofing powders, pastes, etc., are manufactured which are claimed to make concrete entirely water-tight if incorporated with it during mixing, but their value is problematical.

COMPRESSIVE STRENGTH AND WORKING STRESSES. — In the Joint Committee Report (*Trans. Am. Soc. C.E.*, 1917) the following table of compressive strength of thoroughly set concrete is given:

COMPRESSIVE STRENGTHS OF DIPPERENT MIXTURES OF CONCRETE

Tested in cylinders 8 inches in diameter and 16 inches long

Set 28 days under favorable conditions

In Pounds per Square Inch

Aggregate	1 : 3	1 : 4½	1 : 6	1 : 9	1 : 7½
Granite, trap rock	3300	2800	2200	1800	1400
Gravel, hard limestone and hard sandstone	3000	2500	2000	1600	1300
Soft limestone and sandstone	2200	1800	1500	1200	1000
Cinders	800	700	600	500	400

The following recommendations are also made:

When compression is applied to a surface of concrete of at least twice the loaded area, a stress of 35 per cent of the compressive strength may be allowed in the area actually under load.

For concentric compression on a plain concrete pier, the length of which does not exceed four diameters, or on a column reinforced with longitudinal bars only, the length of which does not exceed twleve diameters, 22.5 per cent of the compressive strength may be allowed.

The extreme fiber stress of a beam, calculated on the assumption of a constant modulus of elasticity for concrete under working stresses may be allowed to reach 32.5 per cent of the compressive strength.

For reinforced structures see the full report of the Committee in the *Trans. A.S.C.E.*, 1917.

Modulus of Elasticity. — The value of the modulus of elasticity of concrete has a wide range, depending on the materials used, the age, the range of stresses between which it is considered, as well as other conditions. It is recommended that in computations for the position of the neutral axis and for the resisting moment of reinforced concrete beams and for the compression of concrete in columns it be assumed as:

(a) One-fifteenth of that of steel, when the strength of the concrete is taken at 2200 lb. per sq. in. or less.

(*b*) One-twelfth of that of steel, when the strength of the concrete is taken at eater than 2200 lb. per sq. in., or less than 2900 lb. per sq. in., and
(*c*) One-tenth of that of steel, when the strength of the concrete is taken at eater than 2900 lb. per sq. in.

COST OF CONCRETE (Pre-war prices). — The following table * gives pproximate costs of concrete in place not including excavation forms, steel or iscellaneous items. The values include superintendence, overhead charges id general expense but not office expense nor profit.

Item	Cost per cubic yard	
	Range	Average
Mass concrete as in dams, piers, foundations, etc.:		
Labor only	$0.75 to $2.50	$1.25
Material and labor	3.00 to 9.00	5.50
Concrete in tunnels and conduits:		
Labor only	1.00 to 3.00	2.00
Material and labor	4.50 to 8.00	6.25
Concrete reservoirs and standpipes:		
Labor only	0.75 to 3.00	1.50
Material and labor	3.50 to 13.00	7.00
Concrete buildings:		
Labor only	0.75 to 4.00	1.50
Material and labor	4.50 to 9.00	6.50
Concrete bridges:		
Labor only	0.50 to 2.50	1.50
Material and labor	4.00 to 8.00	6.00
Concrete sewers:		
Labor only	0.75 to 1.75	1.50
Material and labor	3.50 to 8.00	6.00
Granolithic sidewalks:		
Labor only	1.00 to 3.00	1.75
Material and labor	6.25 to 9.00	7.00
Granolithic sidewalks:		
Labor only	2¢ to 4¢ per sq. ft.	2¾¢ per sq. ft.
Material and labor	5¢ to 14¢ per sq. ft.	10½¢ per sq. ft.

NCRETE, REINFORCED. — (*See also Cement; Concrete; Structures, ple.*) Reinforced concrete beams, girders and slabs are made of Portland ent concrete with the addition of steel bars or steel mesh to resist tensile ses. They are usually fixed at the ends by being built into columns, walls, ther girders and are continuous over intermediate supports; they are, there- subject to negative bending moments at the ends and at intermediate orts and positive bending moments between supports. It is common to bottom reinforcement throughout the length and top reinforcement across

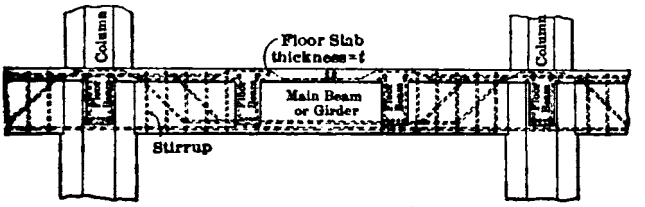

Fig. 1.

supports. Vertical or inclined reinforcement is also usually necessary to ry the diagonal tensile stresses occurring in the web. Fig. 1 shows the general aracter of a reinforced concrete beam and shows methods of making con- ctions to column and floor beams.

Character of Reinforcement. — The steel reinforcement may consist of nd or square bars of which the diameter or side seldom exceeds 1½ inches. The are rods are sometimes twisted when cold, this pe of bar being known as the Ransome bar. There also various forms of corrugated or otherwise formed bars on the market, some of which are wn in Fig. 2. Steel mesh is seldom used for ordi- ry beams, but is frequently employed in floor slabs. e steel reinforcement should preferably be of the me quality as that used for ordinary steel structures, hough the use of a slightly less ductile material may warranted in some cases where the steel is unlikely be subjected to injurious shocks.

Fig. 2.

Proportions of Concrete; Forms. — The propor- ns of concrete for beams and other reinforced con- te structures subjected to flexure is commonly 1:2:4 r *Concrete*). The forms or molds in which reinforced ncrete beams are constructed are usually of wood bolted together, although el forms are sometimes employed. In general, the size of the beam should uch that the forms can be manufactured from standard size boards. Forms uld be watertight, and should be left in place until concrete has set sufficiently carry the load to which it may be subjected at time of removal of forms.

Fireproofing. — In order to make reinforced concrete beams and columns proof the steel reinforcement must be protected by a reasonable amount of ncrete. A common provision is that the metal in girder and columns be pro- ted by a minimum of 2 inches of concrete; that the metal in beams be pro- ted by a minimum of 1½ inches of concrete; and that the metal in floor slabs protected by a minimum of 1 inch of concrete. It is also advisable that all ners shall be beveled or rounded.

Digitized by Google

Spacing of Reinforcement. — Lateral spacing should not be less than th diameters center to center, with a clear spacing of not less than one inch. T distance from the side of the beam to the center of the nearest bar should be t less than two diameters. More than two layers should not be used unl securely tied together by metal connections particularly at or near points wh bars are bent.

Electrolysis and Corrosion in Reinforced Concrete. — The best expe mental data available indicate that no danger from electrolysis need be antic pated to the steel reinforcement in carefully mixed and proportioned Portlan cement concrete free from salt or calcium chloride. Portland cement concre may be considered to thoroughly protect embedded steel from corrosion provid the concrete is properly proportioned and mixed. If the concrete is porou corrosion may be expected. See also article on *Electrolysis of Ground Structures*.

Reinforced Concrete Beams. — The table on the following page gives t safe uniformly distributed loads per lineal foot for a series of reinforced co crete beams one (1) inch in width. The constants upon which the table based are as follows: 1:2:4 concrete with ultimate compressive strength 2000 pounds at 28 days. Allowable stress in concrete = 650 and in steel 16,000 lb. per sq. in. Modulus of elasticity of steel 15 times that of concre Area of steel = 0.77 per cent area of beam above center of reinforcement.

FORMULAS FOR REINFORCED CONCRETE STRUCTURES. Detail formulas for design cannot be given here; see references in Bi *ography*.

Reinforced Concrete Slabs. — These resemble beams, are much used f floors of buildings, and usually form an integral part of the floor beams and gi ers as indicated in Fig. 1. They may be computed in the same manner as re forced concrete beams (*see above*) provided the shears and moments due to t outer forces are known. For slabs supported on four sides the distribution of t load may be determined by the application of the following formula recommend by the Joint Committee (*see Concrete*).

$$r = \frac{l}{b} - 0.5,$$

in which r = proportion of load carried by the transverse reinforcement, l length, and b = breadth of slab.

Using values above specified, each set of reinforcements is to be calculated the same manner as slabs having supports on two sides only, but the total amo of reinforcement thus determined may be reduced 25 per cent, by gradu increasing the rod spacing from the third point to the edge of the slab.

If length of the slab exceeds one and five-tenths its width the entire load sho be assumed as carried by transverse reinforcement.

Girderless floors or flat slabs are much used for factories and warehou In this type of construction the flat slab is supported directly on the colu which are constructed with capital of considerable size. For information rega ing the methods of design, reference should be made to the Joint Commit Report, the Building Codes of Chicago and Boston, and the standard text-bo

Columns of Reinforced Concrete. — For such columns it is customary limit to 15 the ratio of unsupported length to least width, and to consider effective area as that within the protective coating (*see section on Fireproof above*), or for hooped columns or columns reinforced with structural shapes the area within the hooping or structural shapes. The reinforcement may c

Digitized by Google

t either of longitudinal bars or of longitudinal bars connected by bands, hoops, spirals, or of rigid structural forms. The following formulas may be used design. Let A_c = cross-section of concrete, A_s = cross-section of steel, $A = A_c + A_s$ = total cross-section, n = ratio between modulus of elasticity of steel d concrete, usually 15, P = total safe load, f_c = allowable unit stress in concrete, f_s = allowable unit stress in steel, $p = A_s/A$. Then

$$P = f_c(A_c + n A_s) = f_c A[1 + (n-1)p],$$

$$f_c = \frac{P}{A[1 + (n-1)p]},$$

$$f_s = nf_c.$$

LOWABLE LOAD (POUNDS) ON REINFORCED CONCRETE BEAMS

lowable uniformly distributed load in pounds per lineal foot, in excess of weight f beam, for end-supported rectangular reinforced concrete beams. *Tabular ulues to be multiplied by width of beam in inches to get safe applied load (dead + ive + impact).*

CONDENSERS, ELECTRIC. — (*See also Capacity and Charging Current.*) Any two conductors separated from each other by a dielectric form an electric condenser. The capacity C of such a condenser is the quotient of the numerical value of charge Q on either conductor by the difference of potential V between the two conductors *when equal and opposite charges are given the two conductors*, i.e., $C = Q/V$. The usual way of giving the conductors equal and opposite charges is to connect them respectively to the two terminals of a battery or other source of electromotive force. Unless the conductors are close to each other relative to the linear dimensions of their surfaces the capacity is small. Large capacities are usually obtained by using flat plates separated from each other by a thin sheet of dielectric. Unless the two conductors are close to each other relative to their distances from other conductors their capacity is influenced by the presence of the other conductors.

Formulas for Capacity. — See the article on *Capacity and Charging Current*.

Condensers in Series and in Multiple. — See *Electricity and Magnetism, Principles of*.

Energy Stored in a Condenser. — See *Electricity and Magnetism, Principles of*.

Electric Absorption and Dielectric Hysteresis in Condensers. — When an ordinary condenser is charged by connecting it to the terminals of a source of constant e.m.f. the amount of charge which it takes depends upon the time during which the e.m.f. is applied, i.e., there is an apparent absorption of charge by the dielectric. Time is also required for the dielectric to give up this charge when the plates are short-circuited. Absorption is particularly pronounced in such heterogeneous substances as glass, paper, ordinary mica, etc. On account of this absorption both the capacity and apparent resistance of a condenser in general depend upon the time of application of the e.m.f., i.e., upon the time of electrification.

Dielectrics, when submitted to an alternating electric field, absorb a certain amount of energy over and above that corresponding to the direct current "ohmic" loss. This loss is made up of two elements, one due to the conversion of displacement current into the leakage current at the boundaries of electrically dissimilar elements of the insulation, and the other due to a property similar to magnetic hysteresis. The former depends upon the frequency but is not proportional thereto; the latter is directly proportional to the frequency.

TYPES OF CONDENSERS AND THEIR APPLICATION. — Condensers may be classified according to the nature of the dielectric used as (1) air condensers; (2) mica condensers; (3) glass condensers; (4) paper condensers; and (5) electrolytic condensers.

Air Condensers. — Due to the low specific inductive capacity and relatively low dielectric strength of air, air condensers have very low capacity and are therefore seldom used except for standards of small capacity. For the latter purpose they are well suited, since their capacity is not appreciably affected by temperature, time of electrification, or frequency.

Mica Condensers. — These are built of alternate sheets of mica and metal foil, impregnated with paraffine. They are much used for standards of capacity and for telephone, radio and other work requiring condensers which have a small power factor, high insulation resistance and which remain constant. A good working thickness of mica is from [illegible] to [illegible] inch. A single sheet of this

Digitized by Google

ph (product of megohms by microfarads not less than 1000) and the absorption
, only sheets of the finest clear "ruby" mica should be used.

Fig. 1 shows the plan view and connection
a subdivided mica condenser. Since this ar-
gement permits of series, parallel, or series-
allel connection of the condensers a very
ge number of values of capacity may be ob-
ned.

Fig. 1. Subdivided Standard Condenser

The power factor of well-made standard mica
ndensers ranges from about 0.1 per cent to
out 1.75 per cent; see Grover, F. W., *Bulletin of the Bureau of Standards*,
l. 3, No. 3.

Glass Condensers. — On account of its high dielectric strength and specific
luctive capacity glass is particularly well suited for high-tension condensers,
ch as required for wireless telegraphy and the like. The Leyden jar is a
mmon form of glass condenser. Moscicki's modification of the Leyden jar,
wn in Fig. 2, consists of specially formed glass tubes closed at one end and
ted inside with silver deposited chemically, the outer coating being sometimes
plied in the same way and sometimes dispensed with altо-
her, the outer electrode in the latter case consisting of
ixture of glycerine and water in which the tubes are
mersed.

Fig. 2. Moscicki Condenser

Mordey (*Jour. Inst. Elec. Eng., 1909, Vol. 43, p. 621*) re-
rts a test on a Moscicki condenser consisting of 8 tubes
ving a total capacity of 0.03 microfarad, designed for 10,000-
lt a-c. working. Each tube is 2 inches in diameter and 2 feet
inches long, or with connections 3 feet 2 inches long. The
wer factor of this condenser was approximately constant
d equal to 1.0 per cent for frequencies from 40 to 60 cycles
r second and for voltages from 5000 to 10,000 volts.

Condensers of this type are used to a considerable extent in Europe as a
otective device on high-tension overhead transmission lines, as well as for
reless telegraphy. It has also been suggested by Mordey that they could be
ed economically for improving the power factor of highly-inductive loads,
ch as induction motors.

Paper Condensers. — Paper condensers for telephone and telegraph work are
de either (1) by building up a stack of alternate sheets of tinfoil (0.0003
h thick) and tissue paper, two sheets to the layer, each sheet about 0.001 inch
ck, or (2) by rolling up alternate strips of foil or "foiled" paper and tissue
per, the roll after being dried and impregnated with paraffin or other wax
ing pressed into a cubical shape, and suitably mounted in airtight metal boxes.
e "foiled" paper is made by depositing very fine flakes of tin on suitable tissue
per which is then run through a press which forces the flakes into contact with
ch other, resulting in a paper resembling the so-called silver paper used for
apping tea but having a fairly high conductivity. According to G. F. Mans-
dge (*see reference below*) this paper possesses two decided advantages over the
inary metal foil, (1) it is much lighter, and (2) when punctured it is self-
aling, the spark vaporizing the tin in the immediate vicinity of the puncture
thout destroying the paper itself. For a complete description of the method
making the paper and the condensers see Mansbridge, G. F., *Jour. Inst.*
r. *Eng.*, 1908, Vol. 41, p. 535.

Paper condensers for telephone and telegraph work are usually built to with-
nd about 400 volts. The following weights and dimensions are taken from
British Post Office specifications for metal-cased telephone condensers

One-microfarad paper condensers designed for a working pressure of 1000 and having the dimensions 8¾ by 6¼ by ½ inches and weighing 8 ounces are made by the Western Electric Co.

DIMENSIONS AND WEIGHT OF PAPER CONDENSERS

British Post Office Specifications

Capacity, microfarads	Length, inches	Width, inches	Thickness, inches	Weight, ounces
0.5	4¾	2⅝	5/16	4
1.0	4¾	4¾	5/16	8
2.0	4¾	4¾	9/16	12
4.0	4¾	4¾	1⅛	20
10.0	4¾	4¾	2 1/16	46

The power factor of well-made paper condensers ranges from about 0.5 to 2 per cent, but unless care is taken in their manufacture the power factor may be considerably larger; values as high as 30 per cent have been obtained.

Paper condensers similar in construction to those used for telephone work are also used for power factor correction on distribution circuits up to 2300 volts. These condensers are usually made up of a number of units in parallel, each unit having a capacity of 5 kv-a. at 60 cycles. See *G. E. Bulletin, No. 4071A, Feb, 1920.* Up to about 300 kv-a. the cost of a static condenser is less than that of a synchronous condenser (*see Motors, Synchronous*).

Electrolytic Condensers. — Electrolytic cells of the three following types have been used to a limited extent in Germany as condensers for telephone work: (1) acid cells, consisting of two small electrodes of platinum dipping in an acid solution, (2) sodium cells, in which the electrolyte is a solution of common salt, and (3) aluminum cells, in which the electrodes consist of aluminum and the electrolyte is some kind of basic solution. The capacity action of these cells arises from the formation of an extremely thin insulating layer at the anode of the cell which apparently has an enormously high specific inductive capacity. The anode and electrolyte therefore form two plates of a condenser having this thin layer of dielectric between them, forming a condenser of exceptionally large capacity per unit volume. The power factor of this condenser, however, is very high, due to the leakage current from anode to electrolyte, and consequently these cells are little used strictly as condensers, either in telephone or in power work. However, the aluminum cell is very extensively used as a lightning arrester, on power circuits, its capacity action combined with the self-healing property of the film making it an excellent device for this purpose (*see Lightning Protectors*).

TESTING OF CONDENSERS. — The three important properties of a condenser are its capacity, its insulation resistance and its power factor. The insulation resistance is determined by the use of direct current (*see Resistance and Conductance*). The power factor is measured by employing a source of alternating e.m.f. and a Wheatstone bridge and may be looked upon as a measure of the effective a-c. resistance. The power factor of a good mica condenser is practically constant over a wide range of frequency.

A great many arrangements of circuits have been devised for measuring the capacity of condensers, cables, etc. Only one or two of the simple methods

l in engineering practice can be described here. For a description and com-son of the various methods which have been used see Grover, F. W. *Bulletin* e *Bureau of Standards*, Vol. 3, No. 3.

-C. Versus A-C. Capacity Tests. — Due to the effect of electric absorp- above described, the charge taken by a condenser depends upon the time lectrification; the discharge also depends on the time. Consequently, when capacity is measured by any direct-current scheme a standard time of elec-ication and a standard method of determining the discharge must be chosen. British Post Office call for the capacity to be measured by taking the instan-eous discharge (by ballistic galvanometer) after the condenser has been rged for a period of 10 seconds. As a rule the capacity measured by a-c. thods is less than that measured by d-c. methods, since the charge does not e time to soak in; for the same reason the a-c. capacity also decreases htly with increase of frequency. Hence a-c. tests should be made at a stand-frequency, preferably that of the circuit on which the condenser or cable is e used. It is also desirable, when possible, to make the capacity test at the e voltage, both in value and wave form, as is to be used on the condenser.

Voltmeter-ammeter Test of Capacity. — Connect the condenser in series h an a-c. ammeter and impress on this circuit the selected a-c. voltage. asure the voltage drop across the condenser by means of a high-resistance voltmeter. Let the current read by the ammeter (voltmeter circuit open) d, the voltmeter reading V, the frequency f, then the capacity is

$$C = \frac{I}{2\pi f V},$$

ided the voltage is a pure sine wave and the power factor of the condenser ligible. As neither of these conditions are usually fulfilled, such a test rule gives only a rough approximation to the true capacity.

Ballistic Galvanometer Method. — Fig. 3 shows the arrangement of cir-ts for testing the capacity of a cable. B is a battery ing the desired constant e.m.f., K a highly insulated , G a ballistic galvanometer properly shunted (*see Gal-nometers and Shunts*). The sheath of the cable is ally earthed. It is best to charge the core of the le positively as shown. If a condenser is to be tested rial of a cable, the plate corresponding to the sheath y or may not be earthed, as desired. Care should be re that there is no leakage of current directly from the battery into the lvanometer or into the cable.

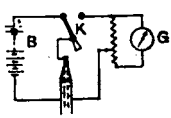

Fig. 3.

The procedure is as follows: Throw the key to the left for the desired length of e, note the position of the galvanometer needle (or spot of light), then throw key to the right and note the first swing or maximum deflection of the spot ght. Call this D_x. Next, keeping the same battery, substitute for the cable ndard condenser of known capacity C and make a similar observation. Let deflection in this case be D. Then the unknown capacity is

$$C_x = \frac{D_x}{D} C,$$

ided the damping of the galvanometer is the same in both cases.

While this method is satisfactory when applied to perfect condensers, it fails a greater or less extent when applied to cables, especially if they are very long, to any condenser having high absorption. With such condensers the dis-rge consists of two portions: a sudden rush when the key is first closed,

followed by a current gradually diminishing toward zero, due to the re of the "absorbed" charge. Both portions of the discharge are active in ducing the deflection, hence the apparent capacity depends to a certain e on the period of the galvanometer employed, as well as upon the ti electrification.

Wheatstone Bridge Method. — The following method gives a mea measuring both the capacity and power factor of a condenser, provided the available a standard condenser whose capacity and power factor is known. The bridge is arranged as shown in Fig. 4. C is the standard condenser and C_x the condenser to be tested. All resistances must be non-inductive and adjustable. A is a source of alternating e.m.f. of pure sine-wave form and of frequency f. T is the detector; it may be either a telephone or, if the frequency be kept perfectly constant, a vibration galvanometer. For ordinary tests the telephone is the more convenient instrument; for good work with it the frequency should be high.

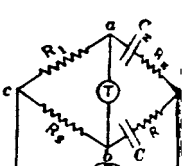

Fig. 4.

The balancing is effected as follows: with R_x and R both zero, adjust R_1 R_2 until a minimum of sound is obtained; then adjust either R_x or R as t case may require, until the minimum is the best possible; then readjust R_1 R_2, and so on, thus obtaining the perfect balance by successive adjustments.

$$C_x = \frac{R_2}{R_1} C,$$

$$\tan \phi_x = \tan \phi + 2\pi f (RC - R_x C_x),$$

where f is the frequency, ϕ_x is the angle whose *sine* is equal to the power fact of the condenser under test and ϕ is the angle whose *sine* is equal to the pow factor of the standard condenser. The effective alternating-current conductan of the condenser under test is then

$$G_e = 2\pi f C_x \tan \phi_x,$$

which as a rule is many times the reciprocal of its insulation resistance as measu by direct-current methods (*see Resistance and Conductance*).

The value of the power factor for the standard is best determined at t Bureau of Standards in Washington; it is done by indirect reference to an condenser.

Sources of Error. — The sources of error when the most refined measu ments are to be made are the inductance or capacity of the various resistanc error in the ratio of R_1 and R_2, and electrostatic induction between the brid and its surroundings. These sources of error are fully discussed by Grov above referred to.

COSTS OF CONDENSERS (Pre-war prices). — A good standard mi condenser of ½ microfarad, guaranteed to stand 300 volts maximum across terminals costs about $25. An adjustable mica condenser, such as shown in F 1, having a maximum capacity of 1 microfarad and suitable for voltages up 300 volts costs about $60. Paper condensers, such as used on telephone circu cost about 70 cents per microfarad. A standard 1000 volt, 1 microfarad pap condenser can be had for about $3.75.

CONDENSERS, STEAM.— (*See also Cooling Systems for Power Stations; Power Stations; Pumps; Steam Engines; Turbines, Steam.*) The primary object of a condenser is to reduce the back pressure in the exhaust of a steam-engine or steam turbine, although in cases where the supply of suitable feed-water is limited the recovery of the condensed steam is of equal importance. Theoretically the gain in the output of a given engine for the same steam-output is proportional to the reduction in back pressure, but practically the gain is usually much less than this, depending upon the type of engine and conditions of operation.

CLASSIFICATION OF CONDENSERS. — Condensers are of two general types, jet condensers and surface condensers.

Jet Condensers. — In a jet condenser cooling water and the exhaust steam mingle together in a closed chamber, the water condensing the steam by direct contact. The cooling or injection water on entering the condenser is broken up into a fine spray or is spread out into a thin sheet. Jet condensers may be classified as follows:

Standard or Ordinary Jet Condensers, in which the cooling water, condensed steam and air are exhausted by a pump.

Barometric Condensers (Siphon Condensers), in which the cooling water and condensed steam are exhausted by a barometric column, the air being exhausted with the water and condensed steam or by means of pump. In certain types of barometric condensers the condensing water is forced into the condenser by atmospheric pressure (if the lift of the condensing water is not over 15 feet), and the condenser is then called a "siphon" condenser.

Ejector Condensers, in which the condensed steam and air are exhausted directly to the atmosphere by the momentum acquired by the cooling water and condensed steam as they pass through the condenser.

Rotary Condenser. — The best known form of this type of condenser is the Leblanc Condenser (made by the Westinghouse Machine Co.), which accomplishes the separate removal of water and air by means of a pair of relatively small turbine-type rotors on a common shaft in a single casing, which is integral with or attached directly to the lower portion of the condensing chamber. The condensing chamber itself is but little more than an enlargement of the exhaust pipe. The injection water is projected downwards through a spray nozzle, and the combined injection water and condensed steam flow downward to a centrifugal discharge pump under a head of 2 or 3 feet, which insures the filling of the pump. The space above the water level in the condensing chamber is occupied by water vapor plus the air which entered with the injection water and with the exhaust steam. This space communicates with the air-pump through a relatively small pipe.

The air-pump differs from pumps of the ejector type in that the vanes in traversing the discharge nozzle at high speed constitute a series of pistons, each one of which forces ahead of it a small pocket of air, the high velocity of which effectually prevents its return to the condenser. A small quantity of water is supplied to the suction side of the air-pump to assist in the performance of its functions. The power required for the pumps is said to approximate 2 to 3 per cent of the power generated by the main engine.

Surface Condensers. — Ordinary surface condensers consist of nests of small brass or copper tubes usually ⅝ inch or 1 inch in diameter through which cooling water is forced and which are surrounded by an air-tight shell to which the exhaust steam is admitted. There may be one, two or more sets of tubes through which the steam passes in succession, the condenser being referred to

Digitized by Google

"single-flow," "double-flow" or "multi-flow" respectively. Steam is
tted at the top of the shell and the condensed steam drawn off at the bottom.
r enters the lower tubes and is discharged at the top, securing thus the
ntages of the counter-flow principle. The rate of heat transmission depends
y upon the state of the tubes. Transmission is much retarded by a water
ating the exterior of the tubes and by interior coatings of scale, dirt or
sion. In the so-called "dry-tube" type baffles are arranged to catch the
from each set of pipes, drain it off at the side and so prevent it from falling
e pipes below.

Evaporative and Air-cooled Surface Condensers are sometimes
oyed when condensing water is scarce. Brief descriptions and references
e found in Gebhardt's *Steam Power Plant Engineering*.

LASSIFICATION OF CONDENSER PUMPS. — (*See also Pumps Pumping Engines.*) The following names are usually applied to the pumps in connection with a condenser.

njection or Circulating Pump, the pump used for injecting the cooling r into a condenser.

Vet-air Pump, the pump used for exhausting the air, condensed steam hot water from a condenser when these are all exhausted together.

Dry-air Pump, the pump used for exhausting the air and water vapor ly. A dry-air pump must be used when high vacua are required.

Hot-well Pump. — This name is applied to the wet-air pump when this mp exhausts to a hot-well. The hot-well is a well provided to hold the con-nsed steam, which is approximately at the same temperature as that of the aust steam in the condenser. If this hot water is to be used over again for ler feed it is pumped from the hot-well to the boiler by the boiler feed pump (*Boilers, Steam*).

CHOICE OF TYPE OF CONDENSER. — The chief advantage of the face condenser over the jet condenser is that the condensed steam does t mingle with the cooling water and therefore the condensed steam may be ed over again for boiler feed water, provided any oil which may be carried the exhaust steam from the cylinders is eliminated before the steam reaches t condenser (*see Separators, Steam*). When there is plenty of cooling water ldily handled a higher vacuum is usually obtained by means of a surface ndenser than by means of a jet condenser. To offset these advantages, how-r, the surface condenser is much more expensive than a jet condenser, and quires as a rule a greater amount of cooling water.

Consequently the use of a surface condenser is in general justified only when e cost of obtaining suitable feed water is relatively high (*see also Feed-water aters and Purifiers*), and cooling water, unsuitable for feed water however, lively cheap (*see also Cooling Towers, Ponds, etc*). Before finally selecting her type of condenser an estimate of the total annual cost, including interest, preciation, maintenance and all operating charges should be made for each e.

According to Prof. Wickenden the following vacua, based on a 30-inch barom-r, have been found most economical in general practice.

Piston engines	26 to 26.5 inches
Turbines at 20 per cent load-factor or less	27 to 27.5 inches
Reaction turbines at high load-factors	28 to 29.5 inches
Impulse turbines at high load-factors	28.5 to 29 inches

summer months warm cooling water often renders these vacua impracticable. hen cooling towers are required to conserve the water supply the economic

limits of vacuum are lower, due to the extra investment and the relati warm state of the water. Jet condensers are cheaper to install and ope for vacua up to 27 inches. They require less water and give somewhat h hot-well temperatures if closely regulated. For higher vacua the load o dry-air pump becomes excessive, due to the air entrained with the co water. Surface condensers are then preferable and for extreme vacua they indispensable.

DEGREE OF VACUUM AND BACK PRESSURE. — Let

V = degree of vacuum, i.e., the reading of vacuum gauge, in inches of mer column,

B = reading of barometer.

Then the back pressure in pounds is

$$p = 0.491\,(B - V).$$

The degree of vacuum is usually referred to a barometric pressure of 30 inch Calling V_0 the vacuum in inches of mercury corresponding to a barom pressure of 30 inches, and B and V the observed barometric pressure and ga reading respectively, then

$$V_0 = V + (30 - B).$$

(If V_0 is the vacuum in inches referred to 760 millimeters or 29.91 inches mercury, substitute for 30 the number 29.91.)

Vacua from 20 to 29 inches are used in practice, corresponding to back pr sures of from 4.5 to 0.5 pounds. The higher the vacuum the more cooling w required and the greater the cost of the air and circulating pumps.

CONDENSING WATER REQUIRED. — Let

T = temperature, in ° F., of dry saturated steam at the pressure corresponding to the desired degree of vacuum,

T_i = temperature, in ° F., of the injection water,

T_s = temperature, in ° F., of the condensed steam at bottom of condenser,

T_w = temperature, in ° F., of the discharge water (for a jet condenser $T_w = T_s$),

H = total heat (above 32° F.) of the exhaust steam, in B.t.u. per pound.

Then the weight of condensing water required per pound of steam is

$$W = \frac{H - T_s + 32}{T_w - T_i}.$$

In applying this formula the values of T_s and T_w must be determined and an allowance must be made for the regulation of the supply of condensing water

	Jet condensers		Surface condensers	
	Parallel-current	Counter-current	Single and double flow	Multi-flow*
	Deg. F.	Deg. F.	Deg. F.	Deg. F.
T_s less than T by.....	10 to 15	5 to 10	5 to 10	0 to 5
T_w less than T by.....	10 to 15	5 to 10	10 to 20	0 to 10

* Cases have been reported where T_s and T_w are both *higher* than T by a few degrees. (*Proc. Inst. Nav. Arch., March., 1906.*) [Probably due to errors of gauges.]

Digitized by Google

ituse of T_s and T_w. — Air is always present in exhaust steam and in the of jet condensers a certain amount of air also enters the condenser with ooling water. The effect of the air is to reduce the temperature of the n (T_s) below that corresponding to saturated dry steam (T) at the same ure. The amount of air present depends upon the type of condenser and upon the amount of air in the cooling water in the case of a jet conden-

he relations between T_s, T_w and T, as shown in the table on page 256, found to hold in practice.

lowance for Regulation of Injection Water. — It is usual to take for the above formula the value corresponding to dry saturated steam at the n pressure in the condenser (*see tables in article on Steam*), and then to ease the value of W so obtained by from 5 to 15 per cent to allow for im-ect regulation of the injection water and for the more or less unknown state he steam as it enters the condenser.

ample. — A vacuum of 25.85 inches, referred to 29.92-inch barometer, be maintained in a surface condenser, with injection water at 60° F. The e of T from the steam tables is 126° F. and H = 1115 B.t.u. Take T_s = °, T_w = 115°, T_i = 70°; then

$$W = \frac{H - T_s + 32}{T_w - T_i} = \frac{1115 - 120 + 32}{115 - 70} = 22.8.$$

IMENSIONS OF CONDENSERS. — There is so great a difference he design of the various forms of jet condensers that it is impossible to give average dimensions. See the catalogues of the makers; representative es of the various types are listed above.

n the case of surface condensers the tube surface exposed to the steam varies ectly as the coefficient of heat transfer (i.e., the number of B.t.u. per hour ° F. difference in temperature between the steam and water per square foot ooling surface) and directly as the mean temperature difference between the ter and the steam. Let

T_i = temperature, in ° F., of the injection water,
T_s = temperature, in ° F., of the exhaust steam at condenser pressure,
T_w = temperature, in ° F., of the discharge water,
Q = pounds of cooling water required per hour,
U = coefficient of heat transfer.

en, according to Josse (*Power, Feb. 2, 1909*), the required cooling surface square feet is

$$S = \frac{2.3\,Q}{U} \log_{10} \frac{T_s - T_i}{T_s - T_w}.$$

e value of U depends upon the metal used for the tubes, the condition of the ernal surface of the tubes and especially upon the condition of the internal face of the tubes (scale and corrosion decreasing the value of U very markedly), d upon the velocity of the water, being greater the higher this velocity. may be taken as 250 for water velocities of from 25 to 50 feet per minute d 375 for velocities of from 50 to 75 feet per minute. There is, however, siderable difference of opinion regarding the proper formula for S and proper value to assign to U. (*See Hoefer, K., A.S.M.E., J. 41, p 962, 1919*).

In reciprocating engine plants an allowance of 2 square feet of tube sur-e per indicated horse-power is customary. In early steam-turbine instal-ons an area of from 2 to 4 square feet per kilowatt was commonly ployed, but subsequent improvements in condensers and the water rates turbines have tended to reduce these areas. In the most modern plants

of large capacity condenser surfaces range from 1.2 to 2.5 square feet kilowatt.

From the relations implied in the above formulas it is seen that the surf may be reduced by forcing large quantities of water at high velocities to pass tubes; or, with a given surface, the vacuum may be heightened by increas the flow of cooling water. However, the gain may be more than offset by t cost of pumping this water.

SIZE OF CONDENSER PUMPS. — (*See also articles on Blowers a Compressors; Pumps and Pumping Engines.*) The size of the injection or c culating pump required can be calculated directly from the quantity of injecti water to be handled and the head against which it is to be pumped, includ of course the friction head. Separate injection pumps for jet condensers a not usually required, as the head does not as a rule exceed that correspondi to the difference between atmospheric and condenser pressure. In the case surface condensers the intake and discharge tunnels are usually at about t same level, and consequently the head is largely friction head. The fricti head of a condenser is not readily calculated, but may be obtained from t manufacturer.

Wet-air Pumps. — The predetermination of the size of wet-air pumps difficult, owing to the uncertainty in estimating the quantity of water vapor air which they must handle. In the case of jet condensers the total weight water (including the vapor) and air is equal to the combined weight of exhaust steam and cooling water, whereas for a surface condenser only the t densed steam and air in it is handled by the wet-air pump. Hence the wet- pump for a surface condenser is usually much smaller than for a jet conden

Formulas, partly analytical and partly empirical, for calculating the pis displacement of wet-air pumps will be found in Gebhardt's *Steam Power Pl Engineering*. For average practice the volume capacity or piston displacem is equal to the volume of *cooling water* multiplied by the following factors.

For jet condensers, single-acting pump	3
For jet condensers, double-acting pump	3.5

Piston speeds are usually about 50 feet per minute at full load.

For surface condensers the volume capacity is equal to the volume of *condensed steam* multiplied by the following factors.

For reciprocating engines	10
For steam turbines	20

These figures are based on a study of some 200 installations (Gebhardt, 1910 e

Dry-air Pump. — The required volume capacity is found in practice be equal to the volume of the *condensed steam* multiplied by the follow factors:

For vacua under 27 inches	20 to 30
For vacua 28 inches or over	50

In both cases the barometer is assumed as 30 inches. These figures are gi by Gebhardt and are based on an investigation of some 50 installations.

POWER REQUIRED FOR CONDENSER PUMPS. — The power quired for the circulating pump is calculated in the ordinary way from weight of the water delivered and the head, including the friction head *article on Pumps and Pumping Engines*).

The power required for the wet-air and dry-air pumps can be accura determined only when the proportion of air in the exhaust steam and als the cooling water, in the case of a surface condenser, is known. Surface w under atmospheric pressure contains from 2 to 12 per cent, by volume, of To allow for leakage, a liberal factor of 20 per cent may be taken.

ower Required to Exhaust the Air.—Let
p_a = atmospheric pressure, pounds per square inch,
p_c = pressure in condenser, pounds per square inch,
T_i = initial temperature of injection water, in ° F.,
T_f = initial temperature of feed water, in ° F.,
T_c = temperature in condenser in ° F. (approximately the temperature of the exhaust steam),
W_w = weight of cooling water in pounds per *minute*,
W_s = weight of condensed steam in pounds per *minute*.
n for a jet condenser the volume of air in cubic feet per minute at condenser sure to be handled by the pump is

$$V_1 = \frac{(W_w + W_s)\, p_a\, (T_c + 460)}{310\, p_c\, (T_i + 460)},$$

for a surface condenser

$$V_1 = \frac{W_s p_a\, (T_c + 460)}{310\, p_c\, (T_f + 460)},$$

suming in both cases that there is 20 per cent air by volume in the water at nospheric pressure. This percentage is probably high when the feed water aken from a hot-well, since the heating of the water drives out the air. Also, e temperature T_c for a counter-current jet condenser and separate air pump ower nearly the temperature of the injection water than that of the steam. The horse-power required to exhaust the air is then

$$P_a = \frac{p_c V_1}{66.2\, e} \left\{ \left(\frac{p_a}{p_c} \right)^{0.29} - 1 \right\},$$

re e is the mechanical efficiency of the pump, which may range from 30 to er cent. (*See article on Blowers and Compressors.*)

ower Required to Exhaust the Condensed Steam and Water.—The er required to exhaust the water and condensed steam from a jet condenser r be calculated in the same manner as for an ordinary pump (*see article on ps and Pumping Engines*), using the proper value of the head under which pump operates. This will depend upon the arrangement of the condenser, tion of the pumps and hot-well, etc.
f a wet-air pump only is used, then the total horse-power of this pump will $P_a + P_w$, where P_w is the horse-power required to remove the condensed m and water. If a dry-air pump is used in connection with the wet-air p (which then exhausts the water only) the horse-power of the dry-air p is P_a, and the horse-power of the wet-air pump P_w.

er Cent of Total Available Energy Used by Condenser Pumps.—n steam-driven pumps are employed and the exhaust from these pumps t utilized the steam consumption of the pumps is properly taken as a measure he energy required for their operation: this may range from 5 to 20 per cent he total steam generated by the plant. When the exhaust from the steam aders of the pumps is utilized for heating the feed water (*see Feed-water ters*), the *heat consumption* of the pumps is properly taken as a measure of energy required for their operation; this may range from about 1 to 5 per . of the total B.t.u. utilized by the main engines, for a large part of the : in the steam used in the pumps is returned to the boiler via the feed water. n electrically-driven pumps are employed, the kilowatt-hour input to the ors driving the pumps is properly taken as a measure of the energy required operating the pumps; this may range from about 2 to 8 per cent of the put of the main generators.

LOCATION AND ARRANGEMENT OF CONDENSERS. — Wh there is only one engine installed the condenser is usually placed close to it just below the engine, so that all condensation may gravitate into it. In sm large vertical steam turbine outfits the condenser (surface type) is at the ba of the turbine and forms an integral part of the structure. When seve engines or turbines are installed in a power house a separate condensing outf may be used for each engine, or the so-called "central system" may be employ in which one condensing outfit serves several engines. This arrangement particularly well adapted to plants in which the individual units are subject to extreme variations in load, as in rolling mills.

Additional data on the location and arrangement of condensers will be fou in the article on *Power Stations*.

COST OF CONDENSING EQUIPMENT (Pre-war figures). — approximate formula that is sometimes used for determining the cost of condensers is,

$$\text{Cost in dollars} = 500 + 1.0 \times \text{h.p.},$$

Potter (*Power*, Dec. 30, 1913) gives:

Type	Capacity	Cost, dollars
Barometric (28-in. vac.)....	Up to 30,000 lb. steam per hour	1055 +0.112 X lb. steam cond. per hr.
Jet (28-in. vac.).....	Up to 30,000 lb. steam per hour	1176 + 0.1138 X lb. steam cond. per hr.
Surface (28-in. vac.).....	Up to 35,000 lb. steam per hour	1630 + 0.2038 X lb. steam cond. per hr.
Surface (26-in. vac.).....	Up to 30,000 lb. steam per hour	413 + 0.1015 X lb. steam cond. per hr.

Twenty-eight inch vacuum surface condensers with pumps cost from $1 $1.80 per square foot of surface, depending on price of copper, or from $150 $250 per 1,000 pounds of steam condensed per hour.

J. R. Bibbins (*Power, Jan, 1905*) gives a curve showing the relative c of high-vacuum surface condensers compared with 26-inch-vacuum surfa condensers. The following figures are taken from this curve.

Degree of vacuum, inches.....	26	26.5	27	27.5	28	28
Relative cost, per cent.....	100	111	123	137	158	1

Maintenance of Condensers. — The cost of maintenance of a surfa condenser is subject to wide variations, depending upon the corrosion and e terioration of the condenser tubes, the exact cause of which is not often und stood. With clean, fresh water, free from acid, the tubes of a condenser l indefinitely, but where the cooling water contains sulphur, as in drainage fr coal mines, or sea water contaminated by sewage, such as harbor water, t deterioration is exceedingly rapid.

The maintenance of a jet condenser is much less affected by impurities the water.

BIBLIOGRAPHY. — Gebhardt, *Steam Power Plant Engineering*, contai 62 pages on condensers and a full bibliography of the subject.

Underground cables are now almost universally installed in either of glazed tile, wood or paper fiber. The pipes or condu as to form a series of continuous ducts for a length of not and are terminated in brick or concrete chambers, from which pulled into the ducts.

TERMINOLOGY. — While there is some confusion in t of conduit lines, the best recent literature, except the specif American Electric Railway Engineering Association, sanction definitions.

Conduit, a pipe or tube designed or used for containing e cables.

Duct, a passage or opening, designed or used for accomm wires or cables.

Conduit Line, a group of installed conduits. (The expre largely used for conduit line, but will not be used herein, as it is such expressions as "the subway subway," meaning the cond underground railway.)

Splicing Chamber, a chamber built to give access to the duc line; frequently called a manhole. Properly, a manhole is the access to the splicing chamber.

Manhole, an opening giving access to an underground spl from the surface of the ground; frequently, but improperly, us the entire splicing chamber.

Service Box, a part of a splicing chamber with facilities distributing conductors to the mains. Service boxes are usuall iron and set on the roof of the splicing chamber like a manhole c

USE OF CONDUIT LINES. — Conduit lines are used f tion of electrical energy wherever the unsightliness, danger o pole lines prohibits the use of the latter. It is therefore in large have found their principal application. They are used for tl and distribution cables of lighting systems, power plants and ra telephone and telegraph lines.

Since the invention of the Pupin loading-coil, the use of c telephones has received considerable impetus. Underground now extend from Boston to Washington, a distance of nearly 500 pump-log being used for the conduit the greater part of the w notable installation of conduit for trunk-line railroad electrific

Digitized by Google

the New York Central which comprises over 1,600,000 duct feet, partly in tile conduit and partly in iron pipe.

Advisability of Double-conduit Line. — A conduit line of a large number of ducts should be avoided wherever possible. While a large line may be permissible for telephone work, it certainly is not desirable for light or power work. The entire output of a station or substation of considerable size should not be carried out through one conduit line, but should be divided between two or more lines kept well separated.

TYPES OF CONDUITS. — While tile conduit is used far more than any other kind, there are four other kinds in fairly extensive use; namely, fiber conduit, wrought-iron pipe, cement-lined iron and pump-log.

Tile Conduit. — Fig. 1 shows the tile conduits used in the Electric Zone of the N. Y. C. & H. R. R. R. near New York and Fig. 2, the standard of the

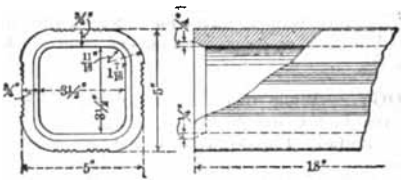

Fig. 1.

A.E.R.E.A. They represent what is probably the best practice up to date. The conduit shown in Fig. 1 weighs 16½ pounds per length of 18 inches. Four-

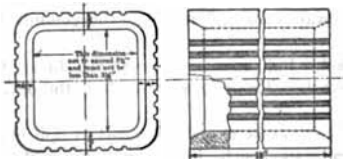

Fig. 2.

duct conduit is now comparatively little used; it weighs about 100 pounds per length of 3 feet.

Fiber Conduit consists of tubes, made by rolling paper saturated with asphalt or bituminous compound around a mandrel. Like iron pipe, which it resembles in appearance, lengths of fiber conduit are usually joined by screw and coupling although it is also made for socket, sleeve and drive joints. It is lighter and easier to handle than iron pipe with which it compares favorably in cost, but is more expensive than tile conduit. It is mechanically inferior to other types of conduit, and difficulty is often experienced in drawing heavy cable around bends without breaking the conduit. For some classes of work this disadvantage is entirely compensated for by superior gas and water tightness.

The dimensions of fiber conduits are given as follows by the Johns-Manville Company and substantially the same by the Fiber Conduit Company.

Socket joint				Sleeve joint			
Inside diameter, inches	Thickness of walls, inches	Approximate average weight per foot, pounds	Length of section, inches	Inside diameter, inches	Thickness of walls, inches	Approximate average weight per foot, pounds	Length of section, inches
1	¼	0.45	30	1	¼	0.45	30
1½	¼	0.75	60	1½	¼	0.75	60
2	¼	0.90	60	2	¼	0.90	60
2½	¼	1.05	60	2½	¼	1.05	60

1½	5/16	0.85	60	2	¼	0.90	60
2	5/16	1.35	60	2½	¼	1.05	60
2½	5/16	1.70	60	3	¼	1.30	60
3	7/16	2.20	60	3½	¼	1.60	60
3½	7/16	2.50	60	4	¼	1.85	60
4	½	3.20	60				

Wrought-iron Pipe is used in city streets where the conduit line has to twist about sub-surface obstructions. It is more expensive than tile conduit and does not last as long on account of rusting. The usual sizes are 3-inch and 3½-inch pipe, 20 feet long, provided with threaded ends and couplings. (For weights and dimensions see article on *Pipes*.)

Cement-lined Iron Pipe consists of thin sheet-iron cylinders, like stovepipe, with a lining of hydraulic cement. When the conduit is old the iron usually rusts away without detriment to the construction.

Pump-log Conduit is used only on telephone lines, as its inflammability renders it dangerous for power work. It consists of wooden blocks with the

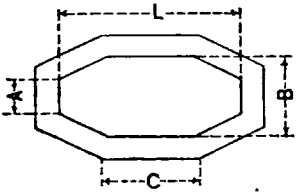

Fig. 3.

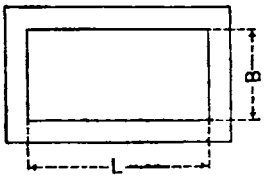

Fig. 4.

duct hole drilled out. A description of a typical pump-log installation is given below under Installation.

SPLICING CHAMBERS. — Splicing chambers, for straight runs, are usually built in the shapes shown in Figs. 3, 4, 5 and 6. That shown in Fig. 3 is usually regarded as ideal, as the excavation is a minimum, and the cables can

follow the walls very closely without being bent to a dangerously small radius, a frequent occurrence in chambers with square corners. The rectangular form shown in Fig. 4 is somewhat more common, but requires more excavation and more wall material than the first form, and is conducive to sharp bends in the

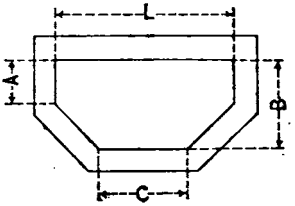

Fig. 5.

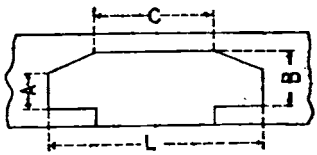

Fig. 6.

cable. The type shown in Fig. 5 is convenient where it is desired to have a wide chamber without occupying much space on one particular side of the duct line as, for example, where two duct lines run parallel and a short distance apart. In this case, economy may be obtained by the use of a common wall on the long side of the chamber.

Fig. 6 shows the side-wall type of chamber, which is entered from the side instead of the top. This form is used in the side walls of tunnels or in retaining walls, and usually takes the form of a long niche in the wall. When built in tunnel walls not far from the surface of the ground, it is desirable to have them open from the street above as well as from the side, in order to avoid the necessity of having the use of a tunnel track when work is to be done in the chambers.

Material of Splicing Chambers. — Monolithic concrete is the cheapest and best material to use where a large number of identical chambers have to be built, as the same form can be used over and over again. Where such uniformity cannot be attained, as in streets congested with sub-surface construction, brick or concrete hollow tile are better and cheaper materials.

Dimensions of Splicing Chambers. — The height of large splicing chambers is usually determined by the height in which a man can stand upright and is seldom less than 6½ feet. The width is similarly influenced by the space required to work in, which is about 4 feet. The length depends upon the length of splice and the space required to curve the cable from the ducts to the supporting shelves or racks, considerations which make a length of 8 feet the practical minimum where there are large cables.

Special chambers, such as those for bare grounded cables, for a small number of telephone or other small cables, may be made of smaller dimensions than stated above, because a man can work on his knees in a chamber 4 feet high and 3½ feet wide, and the length may be reduced to about 4 feet if the cables are small and flexible.

Table I gives the dimensions of standard splicing chambers used by several large traction and lighting companies. The letters refer to the dimensions on Figs. 3, 4, 5 and 6. The average volume of a splicing chamber is about 16 cubic feet per splice, although a maximum of 40 and a minimum of 6 are sometimes found.

Spacing of Splicing Chambers. — It is found that the greatest length of cable that can be pulled through a glazed tile conduit without injuring the cable or requiring special apparatus is about 400 or 500 feet on a straight or slightly curved run. Hence at distances of 400 or 500 feet along a conduit line it is necessary to provide splicing chambers, where the separate lengths of cable may

be pulled in and spliced. Local conditions and curves may prevent the full length being attained in all cases, but it is desirable to have no lengths greater than the standard, in order to avoid the necessity of keeping special long pieces of cable in stock.

Service Boxes. — Service boxes are usually iron castings similar in shape and size to an ordinary manhole casting, but provided with a completely waterproof inner cover which screws down on a gasket. The outer cover resembles that of a manhole. Inside the inner cover is a distribution board with copper bus bars, to which the main and feeder cables in the chamber connect through the bottom of the board.

Waterproofing and Drainage. — There is some diversity of opinion with regard to the value of waterproofing splicing chambers, although the modern tendency is to omit waterproofing and provide efficient drainage. Waterproofing is futile unless the duct lines leading to it are waterproofed. This is a very difficult and expensive process which seldom shows good results. Water will also enter chambers from the top and will be retained if the chamber is waterproof.

Every chamber should be provided with a sump into which the water can drain, Fig. 7. It is desirable to connect the sump to the sewer through a syphon and back-water valve. If this is not practicable the sump may be drained through the manhole by a hand pump.

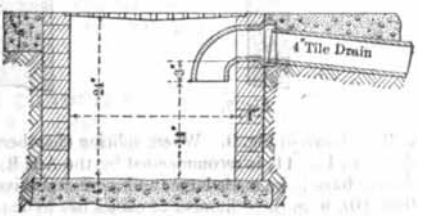

Fig. 7.

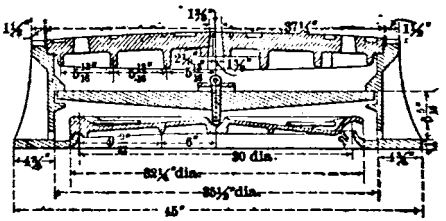
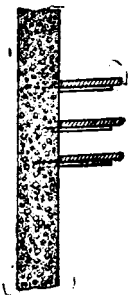
Where natural drainage cannot be secured, as, for example, where the chamber is below the sewer level, it is good practice to provide a special drain pipe to which all the chambers are connected, the drainage being towards a general sump pit, which is kept

dry by an automatic sump pump. The cost of such a system often compares favorably with that of waterproofing, besides yielding superior results.

The sump of a splicing chamber should be covered with an easily removable grating; wooden ones are often used on account of their property of floating when the chamber is flooded, thereby leaving the sump open for the pipe of a hand pump.

Manhole Castings. — Manhole castings are usually made with two covers (Fig. 8), the outer of which should be made strong enough to stand the weight of the heaviest vehicle, and the inner should be as light as consistent with the rough usage they receive in handling. Both covers should be provided with means to grip them with a hook-bar. Where power cables are used it is essential to provide ventilating holes. It is usual to lock the inner cover with a substantial brass padlock with protected keyhole.





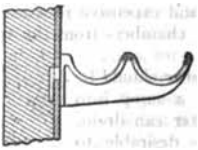


Fig. 8.

Cable Supports. — (*See also article on Wires and Cables, Insulated.*) Cables in splicing chambers are usually supported on iron brackets attached to the chamber walls. This construction is very satisfactory, especially if the power cables are properly wrapped with asbestos, but some engineers consider a shelf to be preferable, as it affords insulation and provides more protection between cables.

Concrete reinforced with expanded metal or wire cloth has proved satisfactory for shelves one inch thick, and is inexpensive. A good support for shelves in concrete splicing chambers is a pair of iron pins set in iron pipes, which are sunk in the chamber wall at a slight angle, so as to tilt the shelves toward the chamber

Fig. 9.

Fig. 10.

wall as shown in Fig. 9. Where splicing chambers are made of brick, the design shown in Fig. 11, is recommended by the A.E.R.E.A. Splicing chambers with shelves have to be made larger and more expensive than those with duplex racks (Fig. 10), if an equal number of cables has to be carried.

RODDING AND WIRING OF CONDUIT LINES. — The only test which it is usual to apply to conduit lines is rodding with a mandrel in order to ascertain whether the ducts are continuous and unobstructed.

The rods used for this purpose are of hickory about one inch in diameter

and three or four feet long and are fitted at the ends with steel couplings such as that shown in Fig. 12. The first rod is attached to a mandrel and pushed into the duct. Another rod is coupled to the first and the pair pushed further

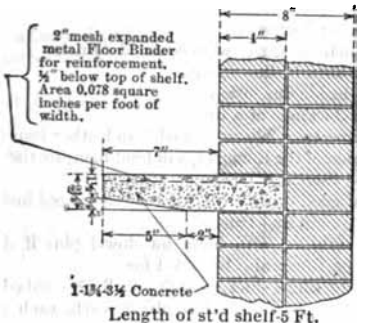

Fig. 11.

into the duct. By successively coupling other rods and pushing them into the duct, the mandrel is made to travel from one chamber to another. As soon as the mandrel emerges into the receiving chamber, the rods are pulled through and uncoupled. If an obstruction stops the mandrel an attempt is made to force it through by repeated blows, failing which, it becomes necessary to cut into the conduit line from the side.

Mandrels for Rodding. — Various types of mandrels are used for testing ducts, some hollow and smooth with sharp cutting edges, others fitted with numerous sharp projections and known as hedgehogs (Fig. 13).

Fig. 12.

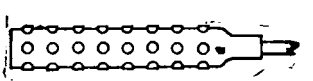

Fig. 13.

"Wiring" the Ducts. — It is usual to attach a galvanized steel wire (No. 10 or 12) to the last rod and leave the wire in the duct after the removal of the rods. The ducts may also be "wired" by the use of a conduit machine. This consists of a reel of steel tape and means for winding and unwinding the tape into the duct at the rate of about ten feet per second. This tape or "snake" having been pushed through the duct is pulled out again with the wire attached to its end.

SPECIFICATIONS FOR CONDUIT LINES. — (*See also article on Specifications.*) By far the greatest number of cable breakdowns occur from injury to the lead sheaths either by electrolysis or by abrasions during installation. Sharp projections in the ducts should therefore be carefully guarded against, as a cable pulled over such a projection will have a groove cut along its entire length and the effective thickness of the sheath will be thereby materially reduced. The specifications for inspection and rodding given below are typical of the best modern practice, but unfortunately duct inspection is usually so lax that often in a large installation scarcely a single duct conforms in every particular with the specifications. Engineers are now beginning to realize the practical importance of giving each duct a rigid inspection, and rejecting those which have any

roughness or irregularity. Scarcely less important is rigid inspection during installation, in order to assure the most perfect alignment.

Details of Construction. — The following items should be covered:

Conduits. —

Single-way, or four-way.
Holes circular or square with rounded corners.
Maximum outside dimensions.
Minimum inside dimensions.
Minimum thickness of walls.
Shall be free from blisters, cracks and other imperfections which, in the opinion of the Engineer, will tend to injure the cables to be accommodated therein.
Shall be of good quality tile, thoroughly glazed inside and outside.
Shall be straight and true.
Shall be provided with holes for dowel pins if ducts are four-way. Dowell pins may also be called for.
The sides of single duct conduits shall be combed with two (2) sets of three (3) longitudinal combings each, each combing to have a width of one-quarter (¼) inch and a depth of one-sixteenth (1/16) inch. Multiple-duct conduits shall be scored transversely near the ends.
Conduits shall be of stated length. It is usual to call for a certain percentage of shorter lengths (generally 1 per cent), in order to finish runs or stagger joints. The permissible variation from the specified length should be stated.
(If fiber conduit is to be used, substitute the corresponding requirements.)

Cement. —

Shall be of approved brand.
Briquettes made of neat cement and kept one day in air and six days in water shall show a stated tensile strength. A corresponding strength may be similarly required of briquettes made of one part cement and two and one-half parts sand.
Shall be protected from moisture during work.

Sand. —

Shall be clean and free from loam or salt.
Shall be sharp and of stated coarseness.

Stone. —

Shall be of crushed granite, lime stone, trap rock or other approved variety.
Shall pass through a sieve of stated mesh.

Brick. —

Shall be of good commercial hard-burned sewer brick, or other stated variety.

Concrete. —

Stated proportions of cement, sand and stone. (Usually 1 part of cement, 2 parts of sand and 4 parts of stone.)
Maximum size of aggregate. (Usually ¾ inch.)
Sand and cement shall be mixed dry and wetted with only sufficient water to make a stiff paste. The stone having been previously wetted shall be added while wet and thoroughly mixed until all the stones are covered with mortar. It shall then be deposited as rapidly as possible. Machine-mixed concrete will be accepted if made in a manner approved by the Engineer.

Cement Mortar. —

Stated proportions of cement and sand. (Usually 2½ to 1 of cement.)

Concrete mortar shall not be laid in freezing weather, and shall not be used after initial set has taken place.

Excavation. —

Shall always be of such depth as to leave a stated minimum distance between the top of the concrete over the conduits and the surface of the ground.

Ground on which conduits are laid shall be rammed solid before any concrete is laid.

Refilling Excavations. —

The best part of the material excavated shall be used.

Surplus material shall be carted away by the contractor (or will be carted away by the company).

Filling shall be thoroughly tamped and rolled, or flushed, as seems necessary to the Engineer, and shall be done in a manner to prevent, as far as possible, a settling of the earth after completion.

Obstructions. —

Obstructions encountered in the course of the work shall be overcome in a manner to be approved by the Engineer.

Laying Conduits. —

Shall be laid with ends square so as to leave a tight, well-fitting butt joint.

Joints shall be staggered horizontally and vertically.

Conduits shall be laid in a bed of cement mortar of about ¼-inch thickness.

Each joint shall be wrapped with two strips of burlap 6 inches wide and coated with neat cement mortar, the ends of the wrap to lap 4 inches. (It will insure more careful work if it be specified that the contractor shall supply rubber gloves to the men who lay the burlap.) Where conduits are laid on curves, the wraps shall be doubled if required to protect the openings between the ends of the conduits on the outside of the curve, and to exclude mortar from said openings. (This method of wrapping is not universal. If another method is to be used, corresponding details should be given.)

Conduits shall be laid with a mandrel of specified length and width and provided at the end with a rubber washer for wiping the joints.

Conduits shall be laid on a bed of concrete of stated depth, shall be covered at the top with a stated depth of concrete, and shall have a stated thickness of concrete on each side. Where the conduit line goes under railroad tracks, the concrete shall be suitably thickened and reinforced.

If conduits are four-way, they shall be laid with dowell pins at joints.

The alignment horizontally and vertically shall be satisfactory to the Engineer.

Drainage of Conduit Lines.— The grade of all conduit lines shall be such that water cannot stand in the ducts but shall drain into one or both splicing chambers.

Repairing. — All repairing shall be done in a manner satisfactory to the Engineer and the municipal authorities.

Extras. — No extras will be allowed the contractor for irregular work except

Rock blasting, if necessary.

Removal of pipes or other obstructions, if necessary.

Digitized by Google

Such work shall not be done without the consent of the Engineer. T
tractor shall specify the cost of such work before it is begun.

Details of Terminals of Conduit Lines. — (Whether they
power stations, etc.)

Splicing Chambers. — Shall be built according to plans supplied
local conditions interfere, in which case the suggested modifications s
approved by the Engineer.

Chambers to be not more than a stated distance apart.

State any details pertaining to the design of the chamber as
supports which may not be clear from the plans.

Tests. — The contractor shall notify the Engineer sufficiently in a
of the completion of the conduits to enable inspection at the factory
arranged for.

Rodding, Cleaning and Wiring. — After the conduits are la
the cement is sufficiently set, they shall be rodded and the contractor shal
after such rods, wire brushes and a mandrel of specified dimensions. All r
and other foreign matter shall be removed. If obstructions are found
cannot be removed by cleaners so as to pass the specified mandrel, the
shall be removed and relaid. Any expense incurred by such work sh
borne by the contractor. A galvanized wire of stated size shall be left i
conduit from splicing chamber to splicing chamber, and sufficient length
be left at each end to permit it to be bent in order to prevent it from sli
into the duct.

Inspection. — During the process of construction, the Engineer re
the right to inspect and the right to reject any and all parts which are not st
in accordance with this specification.

INSTALLATION OF CONDUIT LINES. — The problems conn
with the installation of conduits vary greatly with the local conditions.
involve the choice of trench excavation, drainage, removing or avoidin
structions, concrete mixing and so on. The following details are gleaned
first-class examples of the various kinds of work described but should i
sense be regarded as standard.

Cross-country Conduit Lines. — The excavation for the conduit lin
the American Telegraph and Telephone Company, between New York
Washington, was made partly by a trenching machine and partly by a tr
plow. The trenching machine was of the Austin "caterpillar" type and
a trench 18 inches wide and 3 feet deep at the rate of 3 feet of clean trench
each minute of actual working time. An engineer and two assistants
required to operate the machine, replacing, it is estimated, 50 laborers. O
sections were excavated by a trench plow drawn by two mules or horses.
furrow being made a few inches deeper at each pass, and the loose earth remo
by shovelers. The conduit used in this installation was "pump-log" m
of southern yellow pine 4½ inches square and 7 feet long with a circular
3 inches in diameter. These conduits were creosoted by the pressure pro
with 15 pounds dead oil of coal tar per cubic foot of wood. Splicing cham
having concrete-block walls were built every 500 feet.

A wheel type trenching machine made by Pawling & Hornischfeger Co.
been successfully used by the Wisconsin Telephone Co. This machine h
cutting wheel 7½ feet in diameter, digging a trench 15, 18 or 21 inches wide
with a maximum depth of 5½ feet. The machine weighs 9 tons and is oper
at a speed of 3½ feet per minute, by an operator and one helper.

Conduit Lines for Railroads are usually difficult to construct and op
for the following reasons:

Digitized by Google

Owing to the right-of-way being usually on made ground, excessive tities of concrete and reinforcement are required to make a reasonably g duct construction.

Owing to the width of the right-of-way being usually very restricted it essary to shore-up tracks in order to excavate close to them.

) Owing to the vibration caused by heavy trains, it is necessary to bury onduits at a greater depth, first to avoid undue stress on the conduit, and id to avoid crystallization of the cable sheaths.

order to have the conduits below the frost level, the depth of ballast must eglected, as it has been found that with stone ballast on top of the ground, frost penetrates the ground about as far as if the ballast were not there, as the ballast is very dirty.

) There is considerable difficulty in obtaining best results from labor where e are continual interruptions from trains. On a busy section a duct conction gang engaged for ten hours can possibly work two full hours.

;) Owing to the right-of-way being often quite low, in many cases along- of rivers, duct construction is likely to be seriously impeded by the flooding reaches.

5) Where the right-of-way shows signs of settlement, as, for example, on shy ground, continuous piling is necessary to support the ducts. This olves the use of the track for construction purposes for long periods, and reby not only impedes, but also endangers traffic.

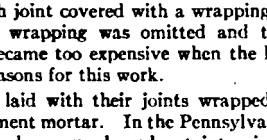
(7) Duct-line construction generally involves interference with signal and erlocking apparatus, thereby introducing danger and expense.

8) Bridge abutments, bridges, culverts, and in fact all special right-of-way conoction, present complicated problems which can be solved only at great expense.

Conduit Lines in Cities. — The obstructions due to sewer, water and gas es, car tracks and foreign conduit lines, also render conduit construction in cities a complicated problem. Plans made in the office can seldom be folred in the field, as the municipal pipe plans are seldom reliable, and the ervision of an experienced civil engineer is needed to solve the numerous oblems which constantly arise. Excavation is almost invariably performed hand labor, and when the conduits have been laid and covered with concrete, is usual to lay a plank over them in order that future excavators may not ve picks into them. Obstructions are often avoided by changing the group- ; of the conduits.

Laying Conduits. — Conduits must be laid so that joints are mechanically ong and the ducts unobstructed. With this in view joints should be staggered rizontally and vertically, and each joint covered with a wrapping impervious mortar in bulk. Formerly the wrapping was omitted and the conduits ined with stiff mortar, but this became too expensive when the labor unions sisted upon the employment of masons for this work.

Single-duct Conduits are laid with their joints wrapped in a light- eight fabric saturated with thin cement mortar. In the Pennsylvania Tunnels, anvas weighing 10 ounces per yard was used, and cut into six-inch strips. heese cloth doubled has also et with favor. When laying nduits it is necessary to ve a long mandrel (Fig. 14) remove loose cement from e ducts. This mandrel is sually provided with a rubber asher at the rear, and a hook- ye at the front end. The conduit layer is provided with a hook rod by means f which he draws the mandrel after him as he lays the conduit.



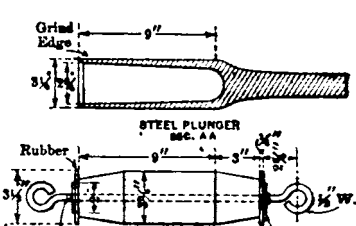


Fig. 14.

Four-duct Conduits are usually provided with holes for dow by means of which the ducts are aligned. The joints are wrapped in soaked in asphalt and afterwards painted with asphalt. No mandrel in this type of construction.

Concrete Covering. — However the conduits may be laid, the group is always inclosed in concrete to secure rigidity and protection finished ducts are cleared of rubbish and obstructions by pushing a steel through them by means of the rods described above. A steel plunger purpose is shown in Fig. 15, in which is also shown a wooden plunger with rubber washers, which should be drawn through the ducts to collect the loose particles left behind the steel plunger.

Steel Plunger, Steel Wire Flue Brush and Wooden Plunger to be passed through ducts in order named.

Fig. 15.

MAINTENANCE OF CONDUIT LINES. — The principal items of conduit-line maintenance are those relating to keeping the line clean and safe, namely, pumping out water, blowing out gas, rem mud, opening and closing manholes for the benefit of cable workers an specting the line to guard against theft and injury. Large systems have u one or more wagons equipped with apparatus required for these purposes, have men ready to go out with it upon emergency calls.

Removal of Water is usually the most important of operating tro especially where no drainage system is installed. When cable accidents o it is important to have the chambers accessible without delay and a por pump is required. For this purpose a small gasoline or electric pump is u having a capacity of about 50 gallons per minute. Such a pump which has good service is of the horizontal centrifugal type with horizontal discharg costs about $200 complete with electric motor, hand priming pump and st rheostat.

Ventilation does not occur naturally in conduit lines, because the cold contained in them has no tendency to rise. Noxious gases therefore tend accumulate in splicing chambers, endangering workers and making explos possible. No permanent system of ventilation has proved successful, as it found that pressure is maintained only at or near the blowing points. Wh it is necessary to blow out the chambers, it is therefore usual to employ a por able blower in conjunction with an air-tight false manhole cover.

Cooling duct lines is sometimes desirable in order to increase the carrying c pacity of the cables in them. L. E. Imlay has accomplished this at Niagara keeping the surrounding soil moist. The Duquesne Light Co. of Pittsbu installed several blowers each of 600 cubic feet per min. capacity and forced into alternate splicing chambers. A reduction of temperature from 125° F 96° F. was obtained.

Protection from theft of cable is secured (1) by locking the inner manh cover and having the lock combination periodically changed; (2) by patrol's

Digitized by Google

the line and (3) by using cable differing in some way from that used by neighboring companies, so that it can be easily identified if stolen.

Electrolysis is more fully treated in the article on *Electrolysis*. It should be noted that the prevention of electrolytic corrosion of cable sheaths depends more upon efficient drainage than anything else.

Maintenance of Conduit Lines Along Railroads present the following peculiar operating difficulties.

(1) Owing to the right-of-way being often on made ground, duct lines settle and crack, injuring the cables in them and preventing the removal and replacement of injured cables.

(2) Owing to the great depth of splicing chambers necessitated by railroad conditions, they are often full of water and cannot be cleared for repairs without pumping water out of as much of the system as is at the same level, a process which may take many hours to complete, possibly interfering with traffic during that time. Drainage is usually out of the question, owing to the absence of any kind of a drainage system below the surface system.

(3) The great depth of chambers requires the use of narrow chimneys connecting the chambers to the surface of the ground. This makes it almost impossible for employees to escape from chambers in case of trouble.

(4) Where improvements are made involving the raising of the right-of-way, as, for example, in eliminating grade crossings, ducts laid previous to the improvements become so deep that they are practically inaccessible for repairs and splicing chambers are correspondingly dangerous on account of their distance from the surface.

(5) The existence of water in low splicing chambers renders the cables particularly liable to electrolytic corrosion. This is a very serious matter where the grounded return is only a few feet away, as is almost invariably the case on a railroad. Electrolytic trouble cannot always be reduced by grounding the cable sheaths to the track rails, as such connections are seldom permissible where electric signals are used.

REPAIRS. — The principal repairs to conduit lines are those due to settlement and to damage done by adjacent building operations, such as the construction of sewers or railway tracks. It is sometimes desirable to replace the conduit line without disturbing the cables they contain. In such cases, the conduits are broken, the utmost care being taken to avoid injuring the cables. New conduits are then relaid on a firm foundation, after having been split longitudinally so as to fit over the cables. The whole construction is then rendered rigid by being inclosed in concrete.

COSTS. — The costs of conduit lines published from time to time are of merely local value, the labor of preparing a dry trench free from obstructions being an item whose variations are so great as to render insignificant the items of constant cost. Costs as low as 20c, and as high as $3.00 per duct foot, are recorded.

The items to be considered in making an estimate of the cost of a conduit line are the following, the quantities all being per foot of trench.

Labor: excavating trench; excavating for splicing chambers; boxing and bracing; removing obstacles, such as gas and water pipes; mixing and placing concrete; placing conduit; carting and dumping; repaving; superintendence, outside; office expense.

Material: conduit; manhole and service boxes; covers, shelves, etc.; sand, stone and cement; brick for splicing chambers (unless made of concrete); lumber for protecting top of ducts; lumber for bracing; incidentals.

Depreciation. — (*See also article on Depreciation.*) Conduit lines depreciate

very slowly from the effects of deterioration or obsolescence. There are few conduit lines in existence which have lost much of their value from age unless unforeseen circumstances have deprived them of some useful association upon which their value depended. The value of conduit lines often increases with age especially where they have been laid in growing districts, where the demand for duct space increases more rapidly than the supply.

CONTROL SYSTEMS FOR RAILWAY MOTORS. — (*See also Controllers; Motors; Railways, Electric Traction Systems for.*) The function of the control equipment is to regulate the speed and direction of the motors by certain definite systematic changes in connections. The speed of direct-current railway motors is controlled in two ways: (1) by connecting suitable resistances in series with the motors, which will reduce the voltage across the motors and thereby the current which they will take; (2) by changing the connection of the motors so that they will be connected at first in series, thereby applying half of the line voltage to each motor, and then in parallel across full line voltage. In most control equipments a combination of both methods is used. For the speed control of alternating-current railway motors an auto-transformer, or compensator, is used instead of the resistances.

The direction of rotation of the motors, d-c. or a-c., is changed by changing the direction of the current in either the fields or the armatures; it is customary to connect the terminals of each field coil to a reversing switch in order to accomplish this effect.

TERMINOLOGY. — The following terms are in general use.

Cylinder or Drum Control or Direct Control are names commonly applied to an equipment in which all the connections are made by contacts on a cylinder or drum which is manually operated by the motorman and located on the platform. This may, therefore, be called direct control.

Multiple-unit, Indirect, Remote Control or Train Control are names applied to an equipment in which the changes in connection of the main power circuit are made by switches called "contactors," usually located underneath the floor of the car, and controlled by electric circuits coming from a small master controller on the platform. There are two systems of multiple-unit control in use in this country, viz.,

Sprague-General Electric System. — In this system the contactors are closed by electromagnets which force a plunger against a spring, the latter normally holding the switch open.

Westinghouse "Unit Switch" System. — In this system the contactors are closed by compressed air, from the air-brake cylinders, the air valves at the switches being controlled electrically from the master controller.

Hand Control is a term applied to that method of control in which the motorman has it in his power to regulate the current to any value he pleases by moving the controller handle, the change in connections depending only upon the motion of the latter.

Automatic Control, as distinguished from hand control, is a type of control in which certain automatic devices prevent the motorman from causing the motors to take a current greater than a predetermined value. With this method of control the motors start with a definite current and as soon as the current has decreased to a specified value a change in the connections is automatically made. Thus the rate of acceleration and the current are kept practically uniform throughout the period of control. It is nearly always used in connection with multiple-unit control.

Rheostatic Control consists in connecting a resistance in series with the motor and short-circuiting consecutively parts of this resistance. It is seldom used at present, except on mining locomotives and for single motor operation.

Series-parallel Control, which is used on practically all railway equipments, includes the feature of connecting two motors and their resistances in series on the first step, then short-circuiting portions of the resistance consecu-

tively until all resistance is cut out, under which condition the motors will operate efficiently at approximately half speed. On the next step of the controller the two motors with resistance in series are connected in parallel and subjected to full line voltage. There are three methods of accomplishing the change from series to parallel.

Transition with Power Off. — In the so-called type L controller power is entirely cut off from both motors while the change in connection is being made. This was formerly used for large-size motors and locomotives but is not at present much used.

Transition with Series Resistance. — During the transition from series to parallel a resistance is placed in series with one motor and the other motor is first short-circuited, then disconnected from the main circuit, and finally, placed in parallel with the other motor. This method is in general use in equipments of small motors with the so-called type K controller.

Bridge Transition. — The so-called "bridge" method consists in grouping the motors and their resistances like the arms of a Wheatstone bridge, so that after the two motors are in full-series position the resistances may be placed in circuit again in parallel with the motors, without opening the circuit; the two motors are then connected in parallel with each other and each in series with its own resistance. This method is preferable to either of the other two in that both motors are in operation throughout the whole control period. There is no noticeable jerk and it is not necessary to open the circuit, which would cause flashing at the switches. It is used in certain forms of the K control and in most of the multiple-unit control equipments, particularly for motors of large capacities and for locomotives.

Series-parallel Control with Four-motor Equipment. — Whereas the three methods just described apply particularly to two-motor equipments, they are equally applicable to four-motor equipments by connecting two motors permanently in parallel and treating them as a unit.

TYPE K CONTROL. — The type of control as well as the construction of the controllers for ordinary single-car equipments has been practically standardized in this country, the large manufacturers supplying control equipments which are practically identical. This type of control is known as the type K. The various sizes of type K controllers are listed in the table below.

Where type K controllers are used for motors of large capacity they are sometimes adapted with a modification of the remote control by the addition of two electrically-operated main switches placed underneath the floor of the car, the function of which is to open the main power circuit every time it is necessary that it should be opened and thus remove all flashing and arcing from the controller. This expedient makes it possible to use a smaller controller for a given capacity of motors and obviates all danger to the passengers from fire and fright. The scheme is accomplished by substituting for the main power circuit on the controller an auxiliary circuit carrying only one or two amperes and every time this auxiliary circuit is opened in the main controller the main switches underneath the car open the power circuit. When the auxiliary circuit is closed the main switches close the main circuit. By means of an overload trip operated by a coil in the main circuit these switches are also used as circuit breakers and if the current taken by the car exceeds a certain value a relay opens the auxiliary circuit which in turn causes the main switch to open.

Capacity and Weight of Type K Controllers. — The more usual forms of type K controllers and the capacity in motors for which they are adapted are as follows:

Digitized by Google

TYPE K CONTROLLERS

Designation	Number of motors	Total h.p.	Number of points	Weight, pounds*
K-10-A	2	80	5 series 4 parallel	940
K-10-H	2	80	5 series 4 parallel	
K-11-A	2	120	5 series 4 parallel	1020
K-11-H	2	120	5 series 4 parallel	
K-12-A	4	120	5 series 4 parallel	1175
K-12-D	4	120	5 series 4 parallel	
K-28-B	4	160	5 series 5 parallel	1350
K-28-F	4	160	5 series 5 parallel	
K-34-D	2 or 4	360	6 series 4 parallel	2250
K-34-F	2 or 4	360	6 series 4 parallel	
K-35-G	2 or 4	240	5 series 3 parallel	1800
K-35-M	2 or 4	240	5 series 3 parallel	

* Weight includes cables, etc., but not motors.

The 10 H, 11 H, 12 D, 28 F, 34 F and 35 M have auxiliary contactors for opening the main circuit.

The K 34 and K 35 have "bridge" transition. All others short-circuit one motor during transition.

The letter "B" in the designation of a controller indicates that it has contacts added to it to make it possible to operate electric brakes by causing the motors to act as generators to energize electric brake shoes, either of the axle or rim type.

Method of Operation of Type K Control. — The principle of the type K control for small and moderate-size motors is shown in Fig. 1. The controller has an operating handle which moves the main cylinder and thereby changes the connections, and also a reversing handle which moves the reversing cylinder. The latter merely changes the direction of the current through the fields of all the motors with respect to the armature. These two handles or cylinders are interlocked so that the reversing handle can only be moved when the operating handle is in the off-position, thus preventing reversal with voltage on the motors.

One terminal of one of the motors is grounded throughout. The first three points are known as accelerating steps. As resistance is in circuit for each of these points the controller should not be left on any of them for a considerable

length of time, for there is a considerable power loss in the rheostats and t are not designed for continuous operation. The fourth step, full series, is efficient "running point," giving about half normal speed. The next two steps are transition steps and are not marked as points on the controller as they must be passed over rapidly. During this period one terminal of the second motor is grounded, thus short-circuiting the motor which has one terminal grounded initially; the connection between the two motors is then opened; finally the two motors are connected in parallel but in series with a part of the rheostat. Points 5, 6, and 7 are accelerating steps with motors in parallel and resistance in series and are therefore not to be used continuously. At the last point the motors are in parallel, and all resistance is cut out; it is therefore an efficient high-speed running point. The two terminals of the armatures of each motor are led to fingers on the reversing cylinder as are also one terminal of each field and the two points of the main circuit to which the motors are connected. Thus, in reversing, the current is reversed in the armatures, but in the fields.

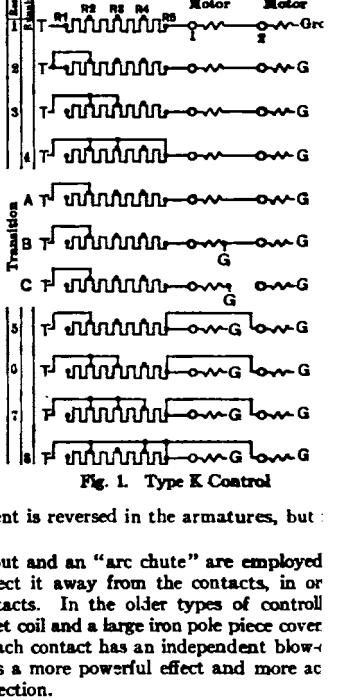

Fig. 1. Type K Control

In all controllers a magnetic blow-out and an "arc chute" are employed interrupt the current quickly and direct it away from the contacts, in or to prevent short-circuiting other contacts. In the older types of controll this was obtained from one large magnet coil and a large iron pole piece cover all the contacts. In the later forms each contact has an independent blow-coil and small pole pieces. This gives a more powerful effect and more ac rately directs the arc in the proper direction.

EFFICIENCY OF TWO- AND FOUR-MOTOR CONTROLLERS. See *Railways, Energy Requirements for*.

REASONS FOR MULTIPLE-UNIT CONTROL. — When the to capacity of the motors on a car or locomotive exceeds 300 horse-power i advisable, and when the capacity exceeds 400 horse-power it is necessary use the indirect or multiple-unit control, for the cylinder type of control required to handle the large currents become too bulky and dangerous to pl on the platforms of passenger cars. The cylinder control is also inadequ when it is desired to control simultaneously the motors on the several cars i train, which is necessary in order to obtain the high tractive effort necessary high-speed service on elevated and underground railways.

For these two reasons the system of multiple-unit or train control was de oped. As originally proposed by Sprague this consisted of a large cyli controller on each car and each controller was actuated by a small motor inst of by hand. These small motors were controlled synchronously from a si point by means of auxiliary control circuits. With the growth in the capa

the motors this system became inadequate and was replaced by the systems w in use.

SPRAGUE-GENERAL ELECTRIC CONTROL. — There are two types use, the type MK and the type MA. The chief difference in these two pes is that the type MK is non-automatic whereas the type MA is provided

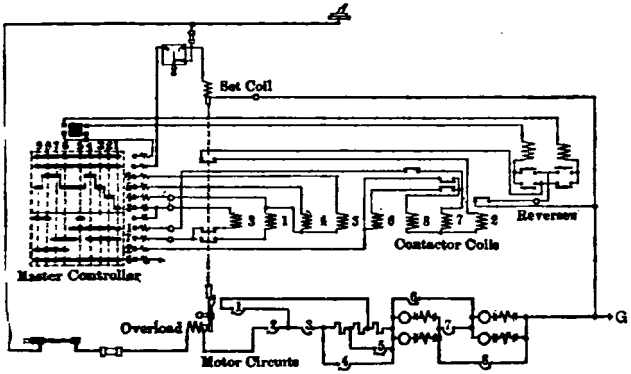

Fig. 2. Sprague-General Electric Type MK Control

with a current-limiting relay. Fig. 2 is a diagram of the type MK, showing the control circuits in light lines and the motor circuits in heavy lines.

The material included in the control equipment of a motor car consists of:

2 master controllers;
1 motor controller containing 8 or 10 contactors and a reverser;
3 master control switches;
1 main switch;
1 main fuse box;
1 set of rheostats;
Cables, Train Couplers.

Master Controller. — This is very similar to an ordinary railway drum-type controller but is much smaller, as the current carried by it is small. Each master controller is equipped with an operating handle, reversing handle, individual magnetic blow-outs and (optionally) a "deadman's handle," which automatically interrupts the current and applies the brakes when the motorman's hand is removed from the button located in the top of the handle.

Motor Controller. — This consists of an iron box lined with asbestos in which the several contactors and the reverser are placed, and is mounted under the car.

Contactors. — Each contactor consists of a powerful magnet operating an arm by means of a toggle joint against a spring pressure. This arm closes and opens the circuit in a strong magnetic field which acts as a blow-out. As one contactor can carry and break currents of several thousand amperes no extra circuit breakers are required. Each contactor is provided with interlocks in the form of relays so that contactor No. 2 cannot be operated until after No. 1 is closed, thus providing the proper sequence of operation under all conditions.

Digitized by Google

Reverser. — This is a switch with several circuits and contacts and comparable to the reverser cylinder in an ordinary controller. These contac are mounted on a rocker-arm actuated by two electromagnets, one for movin the switch to the forward and the other to the reverse position. The electr magnets receive their current from the master controller and are interlocke so that only one can be operated at a time.

Switches and Fuses in Control Circuit. — Motor cut-out switches ar located on the reverser to permit cutting out a disabled motor. In the contro circuit there is one main control switch and fuse to protect the control circuits and near each master controller is located a "control and reset" switch, whic in one position closes the circuit to the resetting coil of the overload relay i the main controller and in the other position closes the supply circuit for th master controller.

Main Switch. — A knife-blade switch is placed in the power circuit and i intended to disconnect the motor circuits from the trolley when it is desired t test the motor controller.

Train Couplers are provided where cars are to be operated in trains. Thes couplers or jumpers provide a means of connecting together similar contr circuits of the different cars. They contain from 8 to 12 wires and are s designed that it is impossible to couple the cars together improperly.

Current-limiting Relay. — For automatic control, or acceleration at predetermined current, a current-limit relay is provided on each car and thi prevents each successive contactor from operating until the current in th motors has decreased to a predetermined value. On roads having a fairly lev profile and operating with frequent stops this refinement is desirable, as i makes it possible for the motorman to accelerate the train every time at th maximum allowable rate and yet never exceed that rate except on a dow grade. When this relay is provided the control equipment is known comme cially as the type MA control.

WESTINGHOUSE "UNIT SWITCH" SYSTEM. — The Westinghous multiple-unit control is known as "Unit Switch Control" and is designed eithe for the operation of several motor cars in a train or of single cars or locomotive using either large currents or high voltage. There are four types of unit-swit control classified as follows:

Type H. L. — Hand-operated (non-automatic), using line voltage fo the control circuits and having as many points on the controller dial as ther are steps in the operation; also has a seperate reverser handle. One motor o group is short-circuited during transition from series to parallel.

Type A. L. — Automatically operated, using line voltage for the con trol circuits. The controller dial shows three points forward and three reverse corresponding to switching, series running and parallel running, although ther are more steps in the operation. Uses bridge transition from series to par allel.

Type H. B. — Hand-operated, using current from a storage battery fo the control circuits. Otherwise similar to the H. L.

Type A. B. — Automatically operated, using current from a storag battery for the control circuits. Otherwise similar to the A. L.

Operation of Type H. L. Control. — As typical of all of these classes th diagram in Fig. 3 shows the connections of the H. L. type for a four-moto equipment for either a car or a locomotive (*Cole, Electric Journal, Oct. 1912*)

s many as five motor cars per train may be operated by one man with this ntrol system.

The main-circuit connections are made by means of a number of independent eumatically-operated switches, known as unit switches, each provided with strong magnetic blow-out and normally held open by a powerful spring. he overload trip that controls the opening of all switches in case of overload

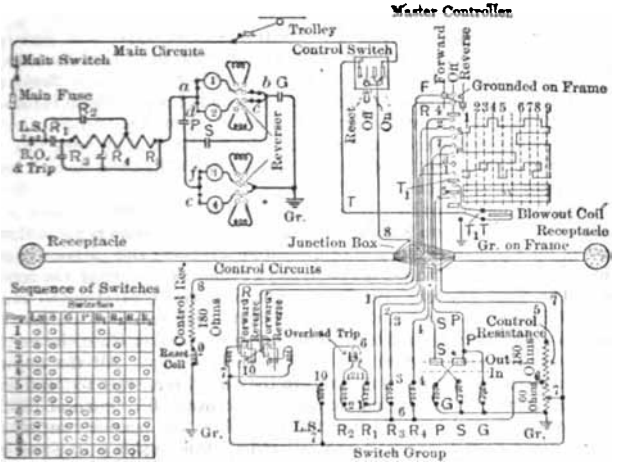

Fig. 3. Westinghouse, Type H. L. Unit Switch Control

r short-circuit is actuated by the magnetic pull produced by one of the blow-nt coils, which is in the main circuit. When a predetermined current value is ceeded, a plunger carrying two contact discs breaks the control circuit, which uses certain switches to open in the line and switch group. This trip can nly be reset when the controller is in the off-position.

A pneumatically-operated reverser controls the direction of operation of the ar. This reverser consists of two pistons similar to those attached to the unit witches, which serve to move the reverser drum to forward or reverse position. The air-brake system furnishes compressed air for operating the reverser and witches.

A multi-conductor train line extends the length of each car and is tapped off at the master controllers and at the unit switch group to form the circuits needed. This train line is made continuous throughout a number of cars by multi-conductor jumpers between cars fitted into receptacles on each car. The current for the electromagnets which operate the valves of the unit switches is taken from low-voltage taps on a resistance connected across line potential.

Operation of Type A. L. Control. — The A. L. control differs from the hand-operated control in that the acceleration of the train is automatic. The master controller has only three positions, switching, series running and parallel running. The "off" position is in the center. The unit switches are provided with interlocks which are electrically connected with the valve magnet in such a manner that the closing of one switch energizes the magnet of the next, thus producing automatic progression of the switches, under the direction of the limit switch. This limit switch controls the rate at which the resistance

is cut out of circuit so as to give uniform accelerating current. The limit swi consists of a solenoid operated by the current of one motor or a pair of mote When this current exceeds a specified limit for which the switch is adjusted, t circuit is opened through a pair of contacts in the operating circuit. The circ remains open so that no more unit switches can close until the accelerati current falls below the predetermined limit, when the control circuit is ag closed and allows the unit switches to continue their progression.

Operation of Type PK and PC Control. — This type was first int duced in 1914 and is a simplification of the older Multiple Unit Systems. uses air from the air brake system to operate the switches in groups thus requ ing only two or three air cylinders and valves instead of many which is the ca of its simplicity and improved reliability. The two forms PK and PC are ma by different manufacturers but are sufficiently similar so that cars with bo forms may be operated in the same train. On account of its cheapness, it is qu generally used for single cars as well as trains.

The PK (manufactured by the Westinghouse Co.) is the simpler as it mer consists of a standard form K controller (which see) whose drum is rotated, not by notch, by a pair of electrically controlled air cylinders and pistons to whi is added an air operated main-line switch and a cylinder for rotating the reversi drum. The small Master Controllers on the platforms control small curre at low voltage in 7 or 9 control wires which admit or exhaust air at definite int vals to the cylinders which move the reversing drum, open or close the main-li switches and advance or return the main control cylinder. All the apparat except the master controllers is underneath the car. From start to "full serie the change is gradual and automatic under the control of a "current-limiting device, and similarly from series to "full parallel." The master controller h three positions "Off," "Series" and "Parallel" thus making it possible f equipments with different numbers of steps to be operated in the same tra It is possible to adapt old "K" controllers by merely adding the "PK Hea and main line switch to one of the old controllers and placing it underneat the car.

The "PC" Control (manufactured by the General Electric Co.) uses a simil combination of electrically controlled pneumatic cylinders to rotate, notch notch, a main cam shaft and the cams on this shaft open and close spring actuat switches or "Contactors." These cam operated switches cut out the starti resistance and change the motor connections from series to parallel. Cams al operate the main line switch while other cylinders actuate the reversing dru The main line switches have suitable magnetic blow-out coils and serve as a c cuit-breaker by means of a series trip coil.

The advantages claimed for both forms of this type of control are:

1. All power circuits and the weight of the main control apparatus are remov from the car platforms, i.e. the system is operated by remote control.

2. The main line current is always broken by large, suitably design switches.

3. Multiple unit operation may be secured with less apparatus and therefo adapted to smaller equipments.

4. The operation of the switches being mechanical it is more positive a therefore the time element is definite.

5. Automatic or selective acceleration may be provided with less complexit

6. A greater number of motor cars may be operated in multiple in one trai (16 motor cars in one train is claimed).

7. The current from the control circuits is so small that storage batteries ma be used, thus making this control easily adaptable for operation on a-c. or hig voltage d-c. systems.

SPECIFICATION FOR MULTIPLE UNIT CONTROL EQUIPMENT.

The following memoranda are intended to assist in writing specifications for complete equipment for the electrical control for a multiple unit car or locomotive exclusive of motors and collecting shoes. See also article on *Specifications*.

Give a complete description of the service in which the equipment is to be used, including the maximum number and weight of cars or locomotives per train.

Similar motion of the master-controller handle shall always produce similar train motions.

A device shall be provided (this is optional) which will limit the rate at which the controller increases the motor voltage, and will assure even acceleration without surging, at the changes from series to series-parallel, and series-parallel to parallel, etc.

A relay shall be provided (this is optional) limiting the current to a specified maximum. (The use of such a relay is more usual on heavy, than on light, equipments.)

Provision shall be made so that acceleration can be arrested at any position of the master controller and so that the motor-circuit combinations shall never be beyond the position indicated by the master controller.

The controller shall automatically return to initial or open-circuit position when the general current supply fails, and when current is restored the control shall progress, as specified, to its former advanced position.

The reverser shall be interlocked so that it cannot be thrown when the motors are taking current.

The control apparatus shall operate satisfactory with a maximum line voltage of . . . . and a minimum line voltage of . . . . and shall never take current exceeding . . . . amperes per car.

In the event of a train breaking in two, provision shall be made so that power shall be cut off from the detached rear portion without affecting the control of the front portion.

The master-controller handle shall be designed (this is optional) so that if the motorman releases it while operating a train, the power will be automatically cut off.

State whether controller is to be interlocked with air brakes.

Main circuit switch (for street cars only) shall be within easy reach of motorman at each end of car.

Each car or locomotive shall be provided with a control-circuit cut-out switch, which will enable the contactors on any car or locomotive to be disconnected from the control circuits.

Each car shall be provided with an automatic circuit breaker and devices for tripping it from any car of the train.

Number of motors	H.P. of each motor	Type of control	Weight of control equipment, pounds	Weight of each motor, pounds	Total weight of equipment, pounds	Cost of equipment, dollars
4	25	*K*	1200	1900	8,800	2400
4	50	*K*	2200	2450	12,000	3600
4	75	*K*	2200	3200	15,000	4800
4	75	Multi-unit	2800	3200	15,600	5100
2	125	Multi-unit	2700	4150	11,000	4000
2	200	Multi-unit	3200	6400	16,000	5600

CAPACITY, WEIGHT AND COST OF CONTROL EQUIPMENT. — The preceding table gives the capacity and weight and the approximate costs of some typical control equipments.

CONTROL OF HIGH-VOLTAGE D-C. MOTORS. — The motors operating on systems of from 1200 to 1500 volts are usually designed to operate two in series, thus each receives normally 600 or 750 volts. However, the insulation of each motor must be designed to withstand the whole line potential and each motor must be able to withstand momentarily the line voltage across its commutator, for if one motor slips the voltage will be unevenly divided between them. For operation on high voltage two motors in series are normally treated as a unit and the series and parallel connection made with the double units. The multiple-unit control is preferable with these high voltages and contactors or unit switches similar to those for 600 volts are used. To operate the control it is customary to supply a self-starting dynamotor (q. v.) which provides 600 volts for this purpose as well as for the lights and other auxiliary apparatus.

Provision for 600-volt Operation. — Since these equipments usually operate also over 600-volt sections of road, provision has to be made to change the connection of the dynamotor when the transfer is made. If the cars are to operate at reduced speed on the lower voltages, as is usually the case on entering the city districts, no change need be made in the motor connections. But if the cars must operate at 600 volts at high speed over an interurban section then provision must be made to separate the pairs of motors so that all motors will be in parallel for full-speed operation on 600 volts. This requires a commutating switch with automatic protection in order to provide that it is always changed when the car passes from one section to another.

2400-volt Systems. — For locomotive work 1200-volt motors are constructed to operate two in series on 2400 volts. The control for such a locomotive is similar to the control for a 1200-volt equipment.

CONTROL OF A-C. COMMUTATOR MOTORS. — A transformer or compensator is always used to transform the line voltage (3000, 6000 or 11,000 volts) to a voltage suitable for the motors, which is usually from 400 to 500 volts for two motors in series. Taps on the low-voltage side of the compensator (or auto-transformer) provide the various voltages necessary to start and control the motors and thus there is no need of series-parallel control or rheostats, and the energy lost in the rheostats is obviated. A compensator or auto-transformer is usually preferred to a transformer as it is lighter for a given capacity. It is usually placed in oil in a tank suspended from the bottom of the car body. Fewer steps (5 or 6 in all) are required for the control of a-c. motors on account of the reactance of the circuits. To avoid open circuiting the connection to the motors in changing from tap to tap or short-circuiting the portion of the transformer between the taps a "preventive resistance" is connected in the circuit momentarily during the transition. A reverser is provided to reverse the connection of the series fields or exciting windings.

The control may be either of the cylinder or multiple-unit type. In the former type a standard controller may be adapted for the work. If the multiple-unit control is used the cores of all the magnets and contactors must be laminated iron and a special design of magnet used on account of the differences in characteristics of a-c. and d-c. magnets. In some a-c. multiple-unit equipments a storage battery is used to supply current for the control circuit, in which case d-c. electromagnets may be used in the contactors.

Provision for D-C. Operation. — For operation on direct current as well as alternating current provision must be made to perform the following operations:

(1) cut the transformer out of circuit, (2) connect the motors for series-parallel control, (3) connect rheostats in circuit, (4) change the field connection of the motors, (5) change the connections of the compressor motors, (6) change the connections of the lighting circuits. All this is done by a "commutating switch" which is thrown over at the instant the change is made. This is so arranged that it can only be moved when the controller is at the off-position. The commutating switch is frequently operated automatically, so that when the car reaches a dead section of the trolley between the a-c. and d-c. sections, a no-voltage release throws everything to off-position and when the car reaches the new live section a "selector" coil moves the commutating switch to the proper position.

CONTROL OF THREE-PHASE INDUCTION MOTORS. — Three-phase induction motors for railway work may be controlled by three methods, viz: (1) Changeable pole windings, (2) concatenation of two motors, (3) variable resistance in secondary.

The first two methods were given a considerable trial by German manufacturers some years ago, and have been practically abandoned on account of their complications. In addition to their complications the variable resistance method must also be used with them to provide the smaller gradations of speed.

Variable-resistance Methods. — The secondaries of the motors have a definite winding and the terminals are brought to collector rings by means of which a three-phase starting resistance is connected into the circuit. The speed of the motors is controlled by varying this resistance. Under these conditions the operating characteristics of the motors are similar to those of a d-c. shunt motor. At all fractional speeds a considerable amount of energy is wasted in the rheostats and there is only one efficient running speed. For prolonged running at fractional speed the rheostats must have considerable heat-dissipating capacity. To reverse the direction of the motors a reverser is employed which reverses the connections of two of the three primary leads on each motor. Either the cylinder or multiple-unit control may be used. With induction motors it is desirable to provide a separate set of resistances for each motor to avoid the tendency of the motors to exchange current and "buck," which would occur if the driving wheels were not of exactly the same diameter and one set of resistances were used for all motors. With several induction motors on one car it is desirable to accurately maintain the same diameter of driving wheels on all axles in order to divide the load equally between the motors.

CONTROLLERS. — (*See also Control Systems for Railway Motors; Regulators; Rheostats; Switchgear Equipment for Power Stations.*) Any device for regulating the current or voltage of an electric circuit may be called a controller. Various kinds of controllers have been given different names by users and manufacturers.

DEFINITIONS. — To avoid confusion the various names are used throughout this book as defined below.

Compensator or Induction Starter, an auto-transformer for supplying reduced voltage to the terminals of an induction motor during acceleration; see *Starters, Motor.*

Controller, a device which controls, in some predetermined manner, the operation of the apparatus to which it is connected; generally it controls the running speed of a motor. This article deals only with the latter type A controller frequently combines starting with running features; see *Starters, Motor.*

Regulator, any device for adjusting the voltage of a circuit. A compensator is a special form of regulator. The term regulator is sometimes reserved for devices which utilize inductive action for their control properti s; such a device will be designated specially as a potential regulator; see *Regulators.*

Resistor, the resistance portion of a controller or starter, through which flows the main current of the circuit whose voltage is controlled. A field rheostat is any device employing a variable resistance to control the voltage across the field windings of a generator or motor. The field rheostat of a d-c. motor indirectly controls the speed, because it controls the voltage and current of the field winding; see *Rheostats; Starters, Motor.*

Motorstarter, a controller designed for accelerating a motor to normal speed in one direction of rotation.

FUNCTIONS OF CONTROLLERS. — Controllers are designed to be used with motors of different kinds and to take care of the functions not incorporated in the motor design in order to enable the latter to operate under the specified conditions of load. The functions usually supplied by the controller are the following:

To limit the current during the acceleration of the motor.
To limit the torque during acceleration.
To change the direction of rotation of the motor.
To limit the load on the motor.
To disconnect the motor on failure of voltage.
To regulate the speed of rotation.
To start and stop the motor at fixed points on the cycle of operation, or at the limit of travel of the load.
To stop the motor.
To protect the operator from injury.

Not every controller has to embody all of these features in the same degree but these are the underlying points of controller design and they must be procurable when they are needed.

TYPES OF CONTROLLERS. — Controllers may be divided into the following classes: Face-plate, drum, drum-contactor, and magnetic contactor, controllers.

Face-plate Controller. — The simplest form of controller for starting and regulating the speed of d-c. motors is the face plate type shown diagrammati-

cally in Fig. 1, and intended for use with a variable speed motor connecting resistors in the armature and field circuit. With this type of controller the contacts are mounted on the face of a suitable base and a moving arm makes the connections to the armature and field circuits, the speed of the motor being changed by varying the field strength. The rheostat arm is made in two parts, the under part making contact with the segments R–1 to R–12 and with the contact ring E, while the top arm engages the upper row of round contacts. When starting the two arms are held together by a spring. The bottom arm is provided with a notched segment engaging the plunger forming part of the low voltage release magnet. The notched segment and pawl hold the arm in any operating position after the low voltage magnet is energized. To start the motor

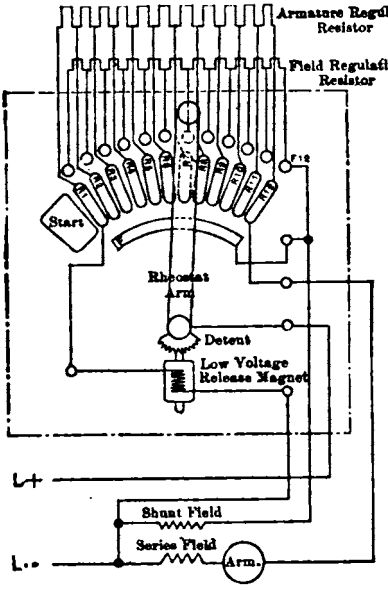

Fig. 1.

the contact arms are moved from the off position to contact R–1, and the connections can readily be traced from that point. The arms are gradually moved to the right eliminating successively each section of the armature resistor until the bottom arm makes contact with R–12. In this position the armature is connected directly across the lines and the segment E is disconnected from the rheostat arm. The shunt field circuit now is from the positive side of the line to the upper rheostat arm to the right-hand field contact F–12, thence to the field winding. This gives a motor speed due to full field strength. If it is desired to increase the speed of the motor the upper arm can be moved to the left across the field contacts to insert resistance gradually in the shunt field circuit, and thus within its range, give the increased speed desired, while the low voltage release magnet holds the lower arm on contact R–12. If the circuit is interrupted the low voltage release magnet will allow the lower arm to be carried to the off posi-

tion by means of a spring. This in turn picks up the upper arm and the two are moved quickly to the off position.

Drum Controller. — Another type of controller in common use is the drum controller. This is used with machine tools for varying the speed and reversing the direction of rotation of adjustable speed d-c. motors by means of armature and field resistance. On the larger sizes magnetic blowouts are used. The drum controller usually has two rows of contact fingers attached to the framework of the controller but insulated from it so as to be electrically separated from each other. Between these rows of fingers is mounted an insulated cylinder or drum which is revolved by the handle. On this drum are mounted copper segments of different lengths which engage the contact fingers. The length and location of these segments are such as to make different connections for each position of the controller handle.

Drum-Contactor Controllers. — A type of controller which, due to its wide application has found very extensive use, is the drum-contactor controller. It is used with series and compound wound motors for adjusting the motor speed by regulating the resistance in series and shunt with the motor armature or for crane hoist service requiring graduated dynamic braking while lowering. This controller consists of a series of spring closed contactors mounted on steel rods and a cam shaft for operating these contactors. In outward appearance it resembles an ordinary drum controller and in internal appearance and operation it is very similar to the magnetic contactor controllers, except that the contactors are operated by a cam shaft instead of by magnetic coils. The line contactors are provided with magnetic blowouts and the same type of rolling contact is used as has been so successful on magnetic contactor controllers. It has relatively quick make and break in operation, is small in size and is easy to operate and inspect. Repairs can be easily and cheaply made. Contacts have exceptionally long life.

Magnetic Contactor Controllers. — These controllers have many advantages which, notwithstanding their increased initial cost, recommend their use wherever rapid and frequent operation is required or where continuity of service is essential. These controllers consist of a series of magnetically operated contactors and accelerating relays which first connect the motor to the line with all resistance in circuit and gradually cut out resistance in series with the motor armature. The rate of acceleration is always dependent on the load of the motor. They are absolutely positive in operation. The motor may be completely controlled by a small master switch, field rheostat, or push button station, any one of which may be placed at a distance from the controller proper. The motor is always accelerated at the proper rate and can be provided with protection against overload and voltage failure. All safety features can easily be incorporated.

CONTROLLERS FOR INDUCTION MOTORS. — Controllers with squirrel cage secondaries usually operate by supplying the motors with various voltages obtained from transformer taps. If the motors are provided with wound secondaries the controllers frequently operate by varying the resistance in the secondary circuit. The resistors must then be designed to carry the running current of the motor continuously without overheating (*see Motors, Polyphase Induction; Starters, Motor*).

With a reversing motor, as in crane or rolling mill service, a similar method of control is used except that the controller is provided with two drums which are operated by a single handle. Primary reversing contacts are located on one drum so that the motor will run in one direction when the handle is turned to the right, say, and in the reverse direction when it is turned to the left. In going from the off position the first step connects the primary circuit of the motor

e line and subsequent steps cut out the secondary resistance. In passing full speed in one direction to full speed in the other the resistance is all cut circuit before reversing. In the off-position the motor is entirely disconnd from the line.

e of Contactors with A-C. Controllers. — For reversing mill or hoistork using induction motors with wound secondaries many very ingenious ighly satisfactory installations have been put in service which use solenoidted magnet switches, or contactors, for the secondary and occasionally e primary circuits. These are worked from a master controller or similar e, or are operated automatically by the positions of the rolls, hoist, etc. matic acceleration can be obtained in the same manner as with directst motors and various safeguards, such as dynamic breaking, can also be oyed.

Automatic Control of Input to Flywheel Motor-generator Set. — her application for contactor control with automatic features is with eel motor-generator sets which use a very heavy flywheel in connection a d-c. generator and an a-c. motor with wound secondary. The power nto the flywheel or delivered up by it depends upon the variation in speed e motor generator. By varying the resistance in the motor secondary peed regulation can be secured. By the use of suitable relays the input e motor and consequently the load on the a-c. system can be kept practiconstant, while the output of the d-c. generator supplying power to a d-c. or rolling-mill motor is undergoing wide fluctuations, the energy in the eel taking care of the difference between the constant input and the variable t. See also article on *Flywheels for Load Equalization*.

OST OF CONTROLLERS. — The following figures will serve as a rough ation of the cost of various sizes and types of controllers. Costs of conrs vary through wide limits depending upon the design, the amount of l variation desired, etc.

COST OF CONTROLLERS FOR 220-VOLT MOTORS *

H.P. of Motor (approximate)	5	25	50	100
e plate type speed adjusting	$38	$70	$100	$220
m type	64	100	158	...
m contractor	85	155	125	...
gnetic contactor L.V.–O.L. Reversing	318	377	545	887
ersing controllers for wound rotor induction motors	80	100	200	400

*ntrollers for 110 and 550 volts cost relatively the same as for 220-volt motors.

CONVERTERS, SYNCHRONOUS OR ROTARY. — (*See also* i *erators, Alternating-current; Generators, Direct-current; Motor Generators; Ma Synchronous; Transformers; Substations, Railway.*) Since in general it is n economical to transmit electrical energy in the form of alternating curr and more convenient to utilize it in the form of direct currents, some m of converting from one form of electrical energy to the other is desirable. this purpose synchronous converters and motor-generator sets (q.v.) are a able. Synchronous converters are also called "rotary converters."

A synchronous converter is a machine very similar to a d-c. generato which certain commutator segments, or the conductors connected to them, connected to 2, 3, 4 or 6 collector rings as the case may be. When the mov member is caused to rotate, the voltage between any two collector rin alternating. Such a machine, when driven by an engine or motor, ma operated as an a-c. generator or as a "double-current" generator giving a nating current from its collector rings and direct current from its commut If the collector rings are connected to a source of alternating currents machine will run as a synchronous motor and direct current may be obta from the brushes on the commutator; i.e., the machine, with but one s windings acts simultaneously as an alternating-current motor and a di current generator. It has therefore the friction, core-loss and excitation of one machine instead of two, and since the motor and generator currents in the same winding and during at least the major part of each cycle a opposite directions, they more or less balance each other and the arm RI^2 loss is much less than in either a motor or generator alone.

Synchronous Converter versus Motor Generator. — A convert much more efficient and weighs and costs less than a motor-generator s the same capacity. It also occupies less space. However, since only winding is used, there is a definite relation between the e.m.f's. of the a-c. d-c. terminals. The maximum value of the alternating wave bears a de relation to the direct e.m.f. (*see below*). It is therefore necessary to su the converter with a voltage of the same order as the direct voltage and involves the use of transformers, if a high-voltage transmission line is us supply the converter. Motors operating at voltages as high as 13,000 can be used in motor-generator sets.

Relative Efficiencies. — The efficiency of a converter is in the n borhood of 93 per cent and of the transformers 97 per cent, thus the effic of the combination is about 90 per cent. The efficiency of a synchronous m is in the neighborhood of 93 per cent and of a d-c. generator 92 per cent, the combination motor-generator set has an efficiency of 85.5 per cent the supply voltage is greater than 13,000 volts, transformers will also be n for the motor-generator set and the net efficiency would then be 83 per ce

Synchronous Converter versus Rectifiers. — A converter differs fr rectifier (q.v.), since the former gives a direct e.m.f. of constant and uni value and the latter gives a pulsating unidirectional voltage and current the former the energy is stored in the form of magnetism for an instant wh in the latter there is no magnetic field and no storage of energy. A re will not work satisfactorily on an inductive d-c. circuit but a converter will

APPLICATION OF CONVERTERS. — The most common applic of synchronous converters is in electric railway work. The great majori motors for electric traction are direct-current series type, operating at 500 to 600 volts. The energy for these motors must be transmitted over distances, which requires a high voltage a-c. transmission line and conv to link the d-c. distribution with the a-c. transmission. Converters hav

developed for high voltage d-c. traction systems, these converters giving volts d-c. Two such converters may be connected in series for 3000 volt distribution (*Elect. J. 12, p. 154, Apr. 1915*). Synchronous converters are used for lighting and power service and for electrolytic work.

TERMINOLOGY. — The following terms are used to describe certain characteristic features of the various kinds of synchronous converters.

Phases and Rings. — A single-phase converter has two collector rings and ring is connected to the windings by as many equally spaced taps as there pairs of poles. The taps for the two rings alternate at equal spaces. A single-phase converter is therefore a two-ring converter.

A three-phase converter has three rings and three equally spaced taps (one each ring) for every pair of poles. A four-phase or quarter-phase converter four rings and four taps for every pair of poles. A six-phase converter has rings and six taps per pair of poles.

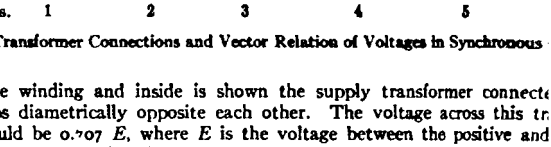
Shunt and Compound-wound Converters. — A converter may be shunt compound wound, depending upon the service for which it is intended. series winding is intended to make the converter take leading current when load increases and thus increase the voltage at the a-c. terminals, but the of the a-c. *terminal* voltage to the d-c. voltage remains unaltered.

Inverted Converter. — Sometimes a converter is operated to convert from to a-c. It is then called an "inverted converter." The machine will rate satisfactorily in this manner, but its speed depends upon the nature of -c. load. An inductive load in the a-c. circuit causes the armature to magnetize the fields, with a resultant increase in speed. It is therefore dangerous to operate an inverted converter on an inductive load unless it is provided with a speed-limit device. This effect does not occur when the machine operating as an a-c. motor, since its speed is fixed by the frequency of the supply circuit.

Cascade Converter or Motor Converter. — This is a combination of an induction motor and converter connected in series or concatenation (*see Motors*, Sections). The converter receives half the power in mechanical form from the shaft and half the power inductively, in the form of alternating current at half frequency, from the secondary of the induction motor. By this means the steady load of a 30-cycle converter is obtained in a 60-cycle unit.

Split-pole Converter. — The "split-pole" or "regulating-pole" converter is used to give a variable ratio of alternating e.m.f. to direct e.m.f., for operation in parallel with storage batteries and similar purposes. The field poles are divided into sections the excitation of which may be controlled independently. The effect of the split pole is primarily to produce a third harmonic in the flux distribution curve, which increases or decreases the *total* flux per pole and thereby the d-c. voltage, but does not change the a-c. counter e.m.f. between slip rings, since these rings are connected to the armature winding at points 120 electrical degrees apart. Split pole converters give a voltage variation of about per cent.

Converter with Series Booster. — A synchronous converter with series booster is sometimes used for purposes similar to those of the regulating pole converter. It is merely a converter with a separately excited a-c. generator on the same shaft as the converter, and the armature of this generator is connected in series with the converter armature and the line. This generator acts as a-c. booster and raises the line voltage.



RATING AND PERFORMANCE. — The standards of the A.I.E.E. specify a maximum rise of 50 degrees C. on any part of the windings and

70 degrees on the commutator for continuous operation. Son are more conservative in their continuous rating and give the temperature rise after operation for two hours at 25 pe occurring immediately after a continuous run. Twenty-five will give momentarily an output of three times their normal rati age or injurious sparking at the commutator, but sixty cycle con sensitive to overloads.

PRINCIPLES OF CONVERTER ACTION. — In this se treated those features of a synchronous converter, in whic differs in action from an a-c. or d-c. generator; see table on summary of the voltage, current and capacity relations.

Connections and Voltage Ratios. — The ratio of voltage c to that on the d-c. side depends upon the number of rings an nection employed.

Two-ring Converter. — The two collector rings are taps to the same winding as the commutator; hence the alternat the same value as the direct e.m.f. at the instant that the taps pas As this is also the maximum value of the alternating e.m.f., the e (i.e., the value to be indicated by a voltmeter) will be 0.707 times or 0.707 times the direct e.m.f. Fig. 1 shows in a simple manner t of a single-phase converter. The external circle represents a tw

Figs. 1 2 3 4 5

Transformer Connections and Vector Relation of Voltages in Synchronous

ture winding and inside is shown the supply transformer connect taps diametrically opposite each other. The voltage across this tr would be 0.707 E, where E is the voltage between the positive and brushes on the d-c. side.

Four-ring Converter. — If two additional collector rings are c to conductors spaced half way between the former taps, there results the phase converter shown in Fig. 2. The voltage across each supply c transformer is the same as before, but the two voltages will differ in 90 degrees.

Three-ring Converter. — If three collector rings are conne taps spaced 120 degrees apart the e.m.f. between adjacent collector ri be the vector sum of AO and OB in Fig. 3. Since AO and OB eac $0.5 \times 0.707\ E$ the voltage AB will be $\sqrt{3} \times 0.5 \times 0.707\ E = 0.612\ E$. in a three-ring or three-phase converter the voltage between adjacent 0.612 times the direct voltage and the connections of transformer an Figs. 3 and 4.

Six-ring Converter — Diametrical and Double Delta Connec — A six-ring converter may be connected diametrical as in Fig. 5 in whic the voltage of each transformer will be $0.707 \times E$ and the result will be li combination of three single-phase groups. A six-ring or six-phase con

may also be connected "double delta" as shown in Fig. 6, which is similar to the combination of two groups of three-phase delta transformers. In both cases the voltage between adjacent taps of a six-phase converter is 0.355 E.

n-Ring Converter. — In general the voltage between taps of any converter having n equally spaced taps per pair of poles is

$$E_{ac} = \frac{E \sin \frac{\pi}{n}}{\sqrt{2}}.$$

Current Ratios. — To determine the ratio of the continuous current I to the alternating current I_3 per collector ring in a three-phase converter, for example, assume the d-c. output equal to the a-c. input with unity power factor; then

$$\sqrt{3}\, E_3 I_3 = EI,$$

and, from preceding paragraph,

$$E_3 = 0.612\, E,$$

where E_3 = a-c. voltage between lines; I_3 = alternating current per line; E = direct voltage; I = direct current. From these two relations

$$I_3 = 0.94\, I.$$

The ratios of currents for other converters are obtained similarly, and are given in the table on page 296.

In actual practice the current on the input side must be greater than that given by these relations, in order to supply the losses in the converter, and the alternating current will also vary inversely as the power factor, which is taken as unity in the table.

Resultant Coil-Current. — In any machine acting simultaneously as a motor and a generator the two currents must flow in opposite directions, and the current in any particular conductor will be the difference between the two. In any particular coil the direct current is constant in amount and direction from the instant the commutator segment connected to this coil passes the positive brush to the instant it passes the negative brush, and conversely from negative to positive brush. In any coil midway between the a-c. taps the alternating current is a maximum when this coil is half way between brushes (at unity power factor), and the current falls to zero as the coil reaches the interpolar position. Therefore, for the period of time that the direct current in a coil remains constant in amount and direction there is also in it a variable current changing from zero to a maximum and back to zero again. The net or resultant current will therefore have a wave shape and frequency somewhat as shown at R in Fig. 7. The heating in this particular coil will therefore be proportional to the product of the resistance of the coil by the square of this current, and it is readily seen that the power lost is less than that due to either the direct or alternating current alone.

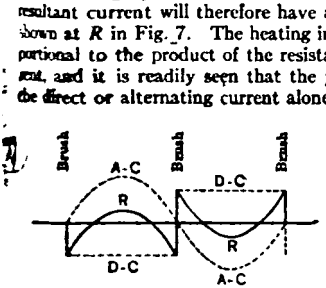


Fig. 7. Current in Coil Midway

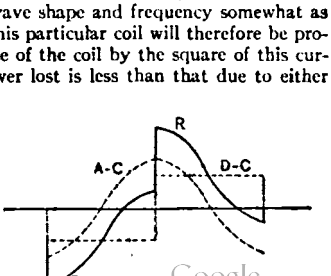

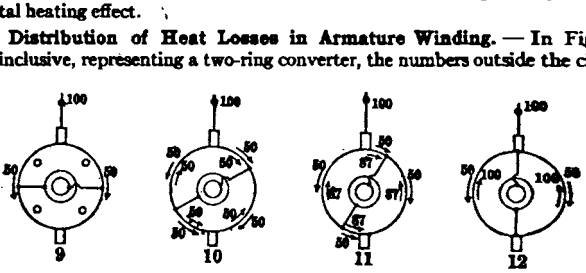

Fig. 8. Current in Coil at Tap in

Digitized by Google

A coil situated very near one of the a-c. taps will carry a direct current sub ject to the same law as before mentioned, but the alternating current in th coil is the same as that in the middle coil and has its maximum value when th middle coil is at the middle of the poles and not when this particular end co is at the middle of the pole. The alternating current in this coil may there fore reach its maximum value soon after the coil has passed a brush, as show in Fig. 8, and the resultant of the two currents is greater than that in the midd coil. The further a coil is situated from the middle coil of a group, the greate is the phase displacement of its alternating current, the greater is the value o the resultant current and the greater is the heating effect. Thus although th heating effect in a rotary converter winding is less than that of a direct-curren machine having the same output it is different in each and every coil, is min mum in the central coil (when the power factor is unity) and is maximum i the coil nearest the tap, and the greater the angle between taps the greater the total heating effect.

Distribution of Heat Losses in Armature Winding. — In Figs. to 12 inclusive, representing a two-ring converter, the numbers outside the circl

Component Currents in a Two-ring Converter

represent the direct current in the winding (corresponding to 100 amperes the external d-c. circuit and unity power factor on a-c. side) and the numbe inside the circles the instantaneous alternating current in the winding. It w be seen that the resultant current in a coil midway between taps, Figs. 9 and 1 never exceeds 50 amperes. A coil 30 degrees from the middle, Fig. 10, has maximum current of 100 amperes. A coil 60 degrees from the middle, Fig. 1 has a maximum current of 50+87=137 amperes, and a coil 90 degrees from t middle (tap coil) may have a current of 100+50=150 amperes. The heating the armature winding is therefore not uniformly distributed, though the co duction of heat from one part of the winding to another tends to equalize t temperature rise.

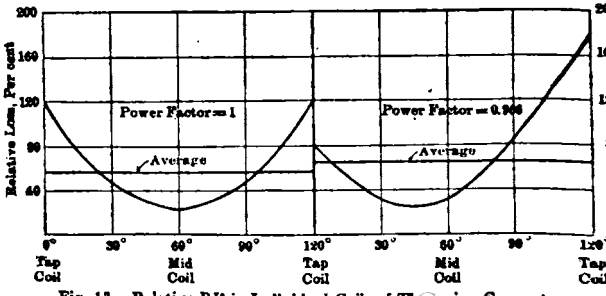

Fig. 13. Relative RI^2 in Individual Coils of Three-ring Converter

Digitized by Google

If the converter operates at a power factor different from unity, the position f minimum resultant current is no longer at the middle coil, but is moved ne way with leading current and the opposite way with lagging current. Thus ne end coil has improved heating conditions, and the middle coil and the other id coil have much worse heating conditions, the result being that the heating i a whole has increased and is more non-uniformly distributed than with unity ower factor.

The power lost in each individual coil of a converter and the effect of the ower factor on this loss is very well shown in Figs. 13 and 14, taken from a aper by J. E. Woodbridge (*A.I.E.E., 1908*). In Fig. 13 the curved line shows ne relative RI^2 loss in a coil having any position throughout 120 degrees of ne phase of a three-phase converter when the power factor is unity. The

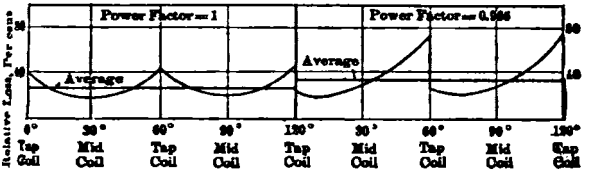

Fig. 14. Relative RI^2 in Individual Coils of Six-ring Converter

ure shows the ratio of the loss compared to the loss in the same machine ning as a d-c. generator of the same capacity. It will be noted that the middle il has a loss of 22 per cent of that of the generator and the end coils 120 per nt., and that the average loss is 57 per cent. For a power factor of 0.966, presenting a phase displacement of current of 15 degrees, the loss in individual ils ranges from a maximum value of 180 per cent at one tap to a minimum ue of 22 per cent in the coil shifted 15 degrees to one side of the middle coil. he other end coil has a loss of a little over 80 per cent of the generator loss. he average value has been increased to 65 per cent.

In Fig. 14 the same ratios are shown for a six-phase converter, in which the nding of one phase is distributed over only 60 degrees. Consequently the nditions are better and the maximum loss due to low power factor is less.

Dependence of Output upon Number of Phases. — As a result of these nditions we have the following relations of the capacity of a given armature th various numbers and connections of taps, the capacity being based on an al total amount of RI^2 loss.

It should be remembered that there are other losses besides coil losses in the nverter, and that therefore practical figures are slightly different from those en in the table on page 296.

Field Excitation. — The variation of the field excitation of a synchronous nverter has much the same effect as in the case of a synchronous motor (*see tors, Synchronous*); that is, if its field is under-excited the armature will aw a lagging current which assists the field and sets up the necessary flux, hereas if the field is over-excited, the armature will draw a leading current hich opposes the field and reduces the flux. By this means the converter ay be made to take either a leading or lagging current. A leading current using over a line having inductance tends to raise the voltage at the receiv- g end of the line.

Line Compounding. — If there is sufficient leading current and suffi- nt inductance in the line, the voltage at the receiving end may be greater an at the sending end in spite of the resistance of the line. This is some-

VOLTAGE, CURRENT AND OUTPUT RATIOS

	D-C. generator	Converters					
		2-ring	3-ring	4-ring	6-ring diametrical	6-ring double delta	12-ring
D-C. volts	100	100	100	100	100	100	10

87 per cent power factor	...	...	99	115	129	129	13

times called "line compounding." The relation between the voltages at two ends of the line may be expressed as follows:

Let

E = voltage to neutral at sending end;

V = voltage to neutral at receiving end;

I_1 = component of line current in phase with V, i.e., the power compon of the line current;

I_2 = component of line current at 90 degrees to V, i.e., the *leading* reactive c ponent of the line current;

r = resistance of one line;*

x = inductive reactance of one line;*

then, noting that I_2 is to be taken positive when leading,

$$E^2 = (V + rI_1 - xI_2)^2 + (xI_1 + rI_2)^2.$$

Use of Series Field. — In practice a series field is added to the c verter and the shunt excitation is adjusted so that the armature current lagging at no load. As the load increases the series field increases, the adj ment being such that at about ¾ load the proper excitation for unity po factor is given. Hence at all loads over ¾ the field will be over-excited, current will be leading and the voltage will be raised or compounded.

DESIGN. — The design of a synchronous converter is very similar to design of a d-c. generator (q.v.), except for certain special conditions due the fact that the frequency is fixed by the frequency of the supply system, that greater latitude is allowed in the choice of the nominal value of the armature reaction and copper density, because the real value of th quantities is the difference between their nominal d-c. values and th a-c. values.

* r and x should include respectively the resistance and reactance not only of line wire, but also the transformers and reactance coils through which the line cur passes.

Speed and Number of Poles. — The revolutions per min
mber of poles are definitely related to the frequency of the s
cycles per second, in accordance with the formula:

$$120 \times (\text{frequency}) = (\text{number of poles}) \times (\text{rev. per mi}$$

he choice of the number of poles usually depends upon the com

Commutator. — The design of the commutator is usually the lin
l therefore the first to be considered. This is particulary true o
equency (60 cycle) machines or when the d-c. voltage is 600 or
ctors must be considered in the design of the commutator to sec
mmutation and life of the commutator, namely, peripheral spee
een bars, thickness of bars. If the peripheral speed or the volt
rs is too high commutation will be bad. If the commutator
m the commutator will not retain its shape and commutation
hese three limiting factors are very closely related and in a high
ive give very little choice. The diameter of the commutator d
e voltage and frequency, and its minimum value is given by t
wing relations. Let

s = pitch of commutator bars in inches. This ranges from c
machines to 0.20 in high-voltage or high-frequency mach
in liberally designed machines. These values include t
bar and about 0.03 inch insulation between bars.

V = peripheral speed of commutator in feet per minute. This
3500 in liberally designed low-voltage, 25-cycle machine
60-cycle machines, and is extended to 6000 under compul

e = average volts per bar = machine voltage divided by the nu
between brush studs. Normal values are from 8 to 14. T
voltage between bars is about 1.57 times this.

f = frequency in cycles per second;

E = voltage between d-c. terminals;

p = number of poles;

n = total number of commutator bars;

d = diameter of commutator in inches.

hen

$$s = \frac{Ve}{10Ef}, \qquad n = \frac{pE}{e}, \qquad d = \frac{sn}{\pi}.$$

Armature Ampere Turns and Current Density. — Since the
rmature reactions are opposed to each other the nominal valu
rmature reaction ampere turns may be chosen much higher th
ues and values of from 4000 to 8000 ampere turns per pole ar
ractice. The nominal or apparent value of the ampere conduct
f periphery varies from 500 to 900, and the apparent current den
armature copper from 2500 to 5000 amperes per square inch.

Diameter of Armature. — The diameter of the armature pe
om 3.5 inches to 6 inches, and the diameter is usually from 6 inch
reater than the diameter of the commutator, the difference depend
ossibility of making a good mechanical construction of the end
he number of slots in the armature and the number of segments
mutator must be a multiple of both the number of phases and t
oles.

Digitized by Google

Armature Winding. — The winding of the armature is usually of the multi drum type, although the series winding may be used The turns per pair poles are divided by equally spaced taps (to the slip rings) into as many grou as there are phases. The number of turns in series between brushes is a justed for the proper direct e.m.f. and a reasonable value of flux per pole. T alternating e.m.f. bears a definite relation to the direct e.m.f. depending upon t type of connection (*see above*), and also to some extent upon the shape a length of pole arc.

Flux Density in Air Gap. — The air gap or pole-face flux density usual has a value ranging from 40 to 60 kilolines per square inch as in generators.

Damping Copper in Pole Face. — In the pole face of every converter squirrel-cage winding should be provided to assist in starting and to preve hunting. The total cross-section of copper per pole ranges approximate from 1/10 to 1/8 of the armature copper per pole and the end rings must be reasonable cross-section compared to the bars. The joints between bars a end rings must be carefully made.

Shunt and Series Fields. — The determination of the length of armatu length of commutator and the design of the field follow the same laws as t design of these parts for a d-c. generator. The proportioning of the seri field results from the considerations given above under *Field Excitation*, t problem being that a certain amount of leading current is required at a giv load and to make the armature take this leading current the field excitati must be increased by a certain number of ampere turns, from which the nu ber of turns in the series field can be determined.

Equalizer Connection. — In large multi-polar machines it is customary connect to a common ring all commutator bars which are at the same potenti these "equalizer connections" avoid local cross-currents in the armature fr flowing through the brushes and causing bad commutation. These cross-c rents are caused by unequal or uneven air gap.

Shaft, Bearings, Etc. — Since the transfer of energy is in the conducto themselves, there is no mechanical torque other than that to overcome fricti and core-loss. Therefore the shaft, bearings and mechanical housing of a rotary converter are quite light and present no particular mechanical difficulties in mechanical design. For the same reason converters do not require very elaborate foundations. Machines of less than 1000 kilowatt capacity are usually supplied with a base and are complete in a piece, while larger sizes are supplied with foundation plates.

Kw. rating	500	300
Frequency	25	60
Core-loss	1.00	1.75
Armature RI^2	0.55	0 60
Shunt field RI^2	0.70	0.60
Brush RI^2	0.40	0.40
Bearing friction	0.55	1.50
Brush friction	0.30	0.65
Efficiency	96.50	94.50

Efficiency and Losses. — The efficiency and distribution of losses of typical 25-cycle and 60-cycle converter are shown in the accompanying tab All values are in per cent of input at full load.

EXAMPLES OF DESIGN. — In the table on the next page are giv design data on four representative converters of different capacities.

Digitized by Google

TESTING OF CONVERTERS. — The following are the usual tests made on converters to determine the efficiency, regulation, heating and to show any defects in construction.

1. **Resistance of Armature, Shunt Field and Series Field.** — The armature resistance is usually measured between points on the commutator diametrically opposite and the equivalent resistance calculated from this value by the equation

$$\text{Equiv. Res.} = \frac{4 \times (\text{diametrical resistance})}{(\text{number of poles})^2}.$$

SYNCHRONOUS CONVERTERS

Design Data

Item	Unit	1	2	3	4
Poles		4	6	6	6
Rating	kw.	500	500	100	300
Speed	rev. per min.	750	500	1000	1200
D-C. volts	volts	600	600	440	600
Frequency	cyc. per sec.	25	25	50	60
Number of phases		6	6	3	3
Armature reaction	amp. turns	15,000	6720	7400	3500
Nominal σ*	amp. cond.	1500	710	675	475
Flux density in gap	kilolines	58	52	23	53
Armature diameter	inches	25.6	36	21	28
Slots per pole		24	24	85%	21
Armature length	inches	11	17.25	7.1	10.5
Commutator diameter	inches	19.7	28	16.5	20
Number of segments		288	288	194	252
Periph. speed of commutator	feet per minute	3800	3650	4300	6280
Volts per bar	volts	8.3	12.5	13.6	14.3
Pitch segments	inches	0.17	0.306	0.266	0.25
Armature diameter per pole	inches	6.4	6	3.5	4.75
Nominal U†	amperes	6000	3600	2630	3400

* σ = ampere conductors (d-c.) per inch periphery.

† U = amperes (d-c.) per square inch.

To obtain the true RI^2 in a converter armature this equivalent resistance is multiplied by the square of the external direct current and by a constant as given in the accompanying table:

	Theoretical	Commercial
Single phase	1.39	1.47
Three phase	0.56	0.59
Quarter phase	0.37	0.39
Six phase	0.26	0.27

These values only hold if the converter is operating at unity power factor. For any other power factor the reactive component of the alternating current per phase must be found and the square of this component times the resistance per phase of the armature gives the additional RI^2 loss due to the lesser power factor.

2. **No-load Saturation Curve.** — The no-load saturation curve, as in a-c. generators and d-c. generators (q.v.) is usually plotted between commutator voltage and ampere turns of shunt field.

3. **Core-loss** as in a-c. and d-c. generators (q.v.).

4. **Phase Characteristic** at no load and at full load as in synchronous motors (q.v.).

5. **Synchronous Impedance** as in a-c. generators (q.v.).

6. **Starting Tests** to determine current and voltage necessary to start the converter on a-c., time to reach full speed, and voltage induced in field windings as in synchronous motors (q.v.).

7. **Heat Run.** — This may be made either with a resistance for load or two similar converters may be tested in parallel by the Hopkinson or "pump back" method; see *Transformers*. In addition to a source of d-c. power of the rated voltage of the converter to supply the losses, either a d-c. booster or an a-c. potential regulator is needed to adjust the load.

8. **Insulation Tests.** — See *Generators, Alternating-current*, and *Standardization Rules of the A.I.E.E.*

9. **Pulsation Test.** — A synchronous converter is very sensitive to any change in impressed voltage or frequency. A sudden change in either of these factors will cause a pulsation which will start the machine hunting, as discussed in the article on *Motors, Synchronous*. This hunting may increase until the machine falls out of step or flashes over. To determine whether a converter has a dangerous tendency of this kind, a test is made in which two similar machines are supplied with power from a common generator. Between each converter and the common connection a resistance is placed in each a-c. line, having a value that will give with full-load current a drop in voltage of 15 per cent of the rated voltage of the machine. Thus there is 15 per cent *RI* drop between each converter and the generator and 30 per cent between the two converters. The two machines are operated at no load and at rated voltage with the shunt fields adjusted for minimum input. The voltage across the commutators is observed for any periodic variation. Then the field of one machine at a time is varied from half normal to twice the normal value and any indications of periodic variations of the direct voltage noted. If the machines have a proper damper winding in the pole faces, they should not develop any dangerous hunting, even under the above unfavorable conditions.

SPECIFICATIONS FOR SYNCHRONOUS CONVERTER. — The following memoranda are intended to assist in writing specifications. See also article on *Specifications*.

Principal Characteristics and Conditions of Service. — Use to which converter is to be put, such as railway, lighting, motor driving or battery charging. Whether it is to convert from a-c. to d-c. or vice versa. Voltages and number of phases. Nominal rating in kilowatts or Institute rating in kilowatts. Frequency and speed.

Style and Description; Details of Construction. — Whether interpole; whether shunt or compound wound, or whether there is a split-pole field winding; whether rheostat is to be supplied for shunt field; if so, its characteristics. Proposed method of starting and whether starting apparatus is to be supplied. Whether a speed-limit device is required; if so, the shunt field rheostat shall have sufficient resistance to speed the machine for testing the speed-limit device, the latter being set at 15 per cent over rated speed. Whether an end play device (or oscillator) is desired and if so, what type or types are acceptable.

Work to be Done by Other Contractors. — Whether the synchronous converter contractor is to furnish and install the following: Main wiring, field

Digitized by Google

ring, field-rheostat grids, dial plate and chains, starting panels, starting ostat or motor generator, foundations.

Performance and Tests. — Temperature rises upon which nominal and stitute ratings are to be based. Overload capacity (*see Standardization Rules the A.I.E.E.*). Commutation limits. Efficiency at 25, 50, 75, 100, 125 and o per cent nominal load. High-potential tests of insulation. Requirements garding effect of moisture upon insulation. Converters shall operate in par- el without "hunting" from no load to stated (say 200 per cent) overload, ovided drop in high-tension lines due to resistance between any converter and y other synchronous apparatus in the system does not exceed a stated value ay 20 per cent), and provided that the phase variation does not exceed a stated lue (say 2.5°). What voltage regulation is required, how it is to be obtained d whether it is to be hand or automatic. If the converter is shunt wound, ne voltage-regulation requirements. What per cent reactance between a-c. s and converter is required?

OPERATION OF CONVERTERS. — In the operation of synchronous nverters the points mentioned below should receive special attention.

Transformer Connections. — The usual methods of connecting transformers supply converters are shown diagrammatically in Figs. 1 to 6 and are dis- sed above in the section on *Voltage Ratios* and also in the article on *Trans- mer Connections*. Of the three-phase to six-phase connections the choice ist be made with some care, as all connections are not equally good for each ecific use of the converter.

Methods of Starting. — The several methods of starting converters are as llows:

Alternating-current Starting, which is the same as the starting of otors; *see Motors, Synchronous.*

Direct-current Starting. — The machine is started as a direct-current unt motor and synchronized on the a-c. side after it is up to speed. This quires less power, but takes more time and more skill in order to synchronize. o secure maximum starting torque, the a-c. side should be disconnected from e transformers, which otherwise act as a shunt to a part of the starting current *Veinberg and Smith, Elec. J., 15, p. 24, Jan. 1918*).

Starting with Auxiliary Motor. — This involves the extra cost and tra continuous loss of the auxiliary induction motor. It is no more efficient an starting by direct current and requires the same amount of time. By the se of suitable relays the starting and synchronizing may be made entirely tomatic (*Wensley, R. J., El. Ry. J. 53, p. 948, May 17, 1919*).

Combination Alternating- and Direct-current Starting. — The ma- hine is started up with direct current, then disconnected from the d-c. mains nd connected to a low-voltage tap of the a-c. supply and brought up to full peed. This method is more economical of power and time but requires more tarting apparatus than either the a-c. or d-c. methods.

Field Break-up Switch. — All converters are supplied with a switch to ren the field in several places to avoid the strain of the high potential induced the field during starting and to reverse the direction of current in the field fter the machine is up to speed in order to reverse the polarity in case it should ot be right. This is usually a double-throw switch with several poles.

End-play Device. — In order to prevent the brushes from wearing grooves n the commutator and collector rings a device is mounted upon one end of the haft to move the shaft end-wise back and forth periodically. In small ma-

Digitized by Google

chines this is a mechanical device consisting of a ball running between tw warped surfaces. In large machines it consists of an electromagnet whi periodically pulls out the armature a short distance. The magnetic pull of t main field poles pulls the armature back.

Speed-limiting Device. — In case a converter should be disconnected fro the main a-c. generating circuit and still remain connected so that it wou tend to operate from the d-c. side there is danger of its speed becoming dange ously high. To avoid this a centrifugal governor is placed on the shaft a arranged to electrically operate the main d-c. switches of the converter.

VOLTAGE REGULATION. — There are several methods of regulati the voltage delivered by the commutator of a converter.

Compound-wound Converter with External Reactance. — This meth is automatic and will give about 10 per cent variation in voltage. It is standa practice for railway work; see also *Substations, Railway*.

Regulating or Split-pole Converter. — With this type of converter t voltage regulation is gradual and normally accomplished by hand, but by t addition of an automatic voltage regulator may be made automatic.

Shunt-wound Converter with Induction Regulator. — A large variati in voltage is possible but this method does not respond to quick changes. is quite generally used in lighting work.

Shunt-wound Converter with Synchronous Booster. — A synchrono generator is carried on the same shaft as the converter and connected in ser between the transformers and the collector rings of the converter. The meth is good but expensive. G. A. Juhlin (*Inst. El. Eng. J. 55, p. 241, Apr. 191* gives a detailed discussion of the relative advantages of reactance and boost regulation.

Shunt-wound Converter and Taps on the Transformers. — The volta ratio of the transformers may be varied. This is usually accomplished by co necting the line to different taps on the primaries, which involves opening t circuit or short-circuiting a portion of the transformer at each change.

WEIGHTS, SPEEDS AND COSTS: — The weights, speeds and costs four commercial lines of converters are given in the following table. T **costs are based on the 1921 price level.** The first group is a line 25-cycle converters without commutating poles, the second 25-cycle converte with commutating poles. The third and fourth groups refer to 60-cycle co verters without and with commutating poles respectively. It will be not that the smaller ratings are three-phase machines while the greater ratings a six-phase machines. The six-phase connection makes possible a saving material at the expense of increased cost in manufacturing labor. The u of commutating poles also makes possible a considerable reduction in size machine at the expense of increased labor, therefore all the higher capaci machines have commutating poles. The costs given are only approximate, such figures vary greatly with commercial conditions. The machines lis are 600-volt converters for railway purposes. Machines for lower voltages wo be somewhat less expensive.

CONVEYORS. — (*See also Power Stations; Telpherage.*) A conveyor is a mechanical device for the continuous handling of materials along a horizontal or inclined plane. There are four general types of conveyors, viz., the scraper or flight, the screw, the bucket and the belt.

THE FLIGHT CONVEYOR consists of a trough of any desired cross section through which are pulled a series of scrapers or "flights" attached to an endless chain. The improved forms of this type of conveyor have sliding shoes or rollers attached to the flights or to the chains, supported on runways.

Capacity. — The following table by S. B. Peck (*Trans. A.S.M.E., 1910*) gives the capacities of flight conveyors in tons of coal per hour when the conveyor is operated at a speed of 100 feet per minute.

CAPACITY OF FLIGHT CONVEYORS

Size of flight, in.	Horizontal				Inclined		
	Flights spaced			Lb. per flight	10°	20°	30°
	18 in.	18 in.	24 in.		24 in.	24 in.	24 in.
	Tons	Tons	Tons		Tons	Tons	Tons
4 by 10	33.75	30	22.5	15	18	14.25	10.5
4 " 12	42.75	38	28.5	19	24.5	18	13.5
5 " 12	51.75	46	34.5	23	28.5	22.5	16.5
5 " 15	69.75	62	46.5	31	40.5	31.5	22.5
6 " 18	.....	80	60	40	49	40.5	31.5
8 " 18	.....	120	90	60	72	57	48
8 " 20	.....	...	105	70	84	66.5	56
8 " 24	.....	...	135	90	120	96	72
10 " 24	.....	...	172.5	115	150	120	90
10 " 30	.....	...	220	147	184	146	116
10 " 36	.....	...	268	179	225	177	142
10 " 42	.....	...	315	210	264	210	167

Power Required. — The following formula gives approximately the horse power at the head wheel required to operate flight conveyors:

$$\text{H.P.} = (ATL + BWS) \div 1000.$$

T = tons of coal per hour; L = length of conveyor in feet, center to center; W = weight of chain, flights and shoes (both runs) in pounds; S = speed in feet per minute; A and B constants depending on angle of incline from horizontal and have the following values.

Angle, deg.	A	B	Angle, deg.	A	B	Angle, deg.	A	B
0	0.343	0.01	10	0.50	0.01	30	0.79	0.009
2	0.378	0.01	14	0.57	0.01	34	0.84	0.008
4	0.40	0.01	18	0.63	0.009	38	0.88	0.008
6	0.44	0.01	22	0.69	0.009	42	0.92	0.007
8	0.47	0.01	26	0.74	0.009	46	0.95	0.007

Digitized by Google

For suspended flight conveyors take B as 0.8 and for roller flights as 0.6 of the values given in the table.

Screw Conveyors. — Screw conveyors consist of a helical steel flight, either in one piece or in sections, mounted on a pipe or shaft, and running in a steel or wooden trough. These conveyors are made from 4 to 18 inches in diameter, and in sections from 8 to 12 feet long. The speed ranges from 20 to 60 r.p.m. and the capacity from 10 to 30 tons of coal per hour. It is not advisable to use this type of conveyor for coal, except the smaller sizes, as the flights are easily damaged by any foreign substance of unusual size or shape.

BUCKET CONVEYORS are of two types, having rigidly connected and pivoted buckets respectively. The buckets are carried by an endless chain driven by sprockets or pawls. Rigid buckets are used to convey coal and other materials over considerable distances when there is no intermediate point of discharge. They are built to carry as much as 2 tons of coal per minute.

Pivoted buckets may be used both as conveyors and elevators, and are particularly well adapted to the handling of coal and ashes in power plants. Their advantages are slow speed, silent operation, adaptability to change of direction without transfer, high efficiency and easy renewal of worn parts. Their disadvantages are danger of buckets sticking or upsetting and jamming in the supports, and the difficulty of preventing spill at the loading and turning points. Spilling in loading may be prevented by the use of special loading devices, by providing overlapping lips on the buckets or by placing small buckets between the main buckets to catch the spill.

Capacity. — Buckets are usually of 2-feet pitch, and range in width from 18 to 48 inches. They run at low speeds, usually not over 50 feet per minute, 30 feet per minute being the usual speed. At the latter speed the capacities when handling coal vary from 40 tons per hour for the 18-inch width to 120 tons per hour for the 48-inch width.

Power Required. — Prof. E. F. Miller gives the following formula for calculating the power required for a bucket conveyor making a rectangular circuit:

$$P = 0.004\,CL,$$

where P is the horse-power required, C is the capacity of the conveyor in tons of coal per hour, and L is the total lift in feet. This is an empirical formula deduced from numerous data on coal conveyors having capacities of from 20 to 150 tons and operating at speeds of from 40 to 55 feet per minute, and making lifts of from 40 to 80 feet. The power given by the above formula is for the conveyor loaded to its full capacity. The conveyor when running empty will require from 40 to 60 per cent of this. The smaller the conveyor the larger the percentage of power empty to power loaded.

BELT CONVEYORS. — Rubber and cotton belt conveyors are used for handling coal, ore, sand, gravel, etc., in all sizes. They combine a high carrying capacity with low power consumption. In the majority of cases the belt is troughed by means of idler pulleys set at an angle from the horizontal and placed at intervals along the length of the belt. Belt conveyors may be used for elevating materials up to about 23° incline. The belt may be run at any speed from 200 to 800 feet per minute, and may be from 12 inches to 60 inches in width. The most serious objection to belt conveyors is the lack of durability of the belts, their liability to destruction from accidental causes and the expense of their frequent renewals.

Link belts (*see Chains and Chain Drive*) are also used for conveying purposes.

Digitized by Google

Capacity. — The following table gives the capacity of the more common size of belt conveyors:

CAPACITY OF BELT CONVEYORS IN TONS OF COAL PER HOUR

Width of belt, in.	Velocity, feet per minute			Width of belt, in.	Velocity, feet per minute				
	300	350	400		300	350	400	450	500
12	34	..	...	20	96	112	128	...	...
14	47	..	...	24	139	162	186	210	...
16	62	72	82	30	218	254	290	326	...
18	78	91	104	36	315	368	420	472	520

For materials other than coal, the figures in the above table should be multiplied by the coefficients given in the table below:

Material	Coefficient	Material	Coefficient
Ashes (damp)	0.86	Earth	1.4
Cement	1.76	Sand	1.8
Clay	1.26	Stone (crushed)	2.0
Coke	0.60		

Power Required to drive a belt conveyor (*C. K. Baldwin, Trans. A.S.M.E. 1908*) depends on a great variety of conditions, as the spacing of idlers, type of drive, thickness of belt, etc. In figuring the power required, the belt should run no faster than is necessary to carry the desired load. If it should be necessary to increase the speed, the load should be increased in proportion and the power figured accordingly.

For level conveyors the horse-power required is

$$P = C \times T \times L \div 1000.$$

For inclined conveyors

$$P = (C \times T \times L \div 1000) + (T \times H \div 1000).$$

C = power constant from table below; T = load, tons per hour; L = length of conveyor, center to center, feet; H = vertical height material is lifted, feet; S = belt speed, feet per minute; B = width of belt, inches.

For each movable or fixed tripper add horse-power in column 3 of table. Add 20 per cent to horse-power for each conveyor under 50 feet long. Add 10 per cent to horse-power for each conveyor between 50 and 100 feet long. The formulas above do not include gear friction, should the conveyor be gear driven.

COOLING SYSTEMS FOR POWER STATIONS. — When t supply of cooling water is limited or expensive, economy requires that it sh be artificially cooled and used continuously. This cooling is accomplished natural or forced evaporation in open ponds, spray fountains, a series of artific cascades or in cooling towers. The latter device is largely used.

COOLING TOWERS. — Cooling towers are usually made in the sha of large cylinders of sheet steel, filled with narrow boards or laths arranged geometrical forms, or hollow tile, or wire network, so arranged that while t water, which is sprayed over them at the top, trickles down through the spa it is met by an ascending air column. The air is furnished either by disk fa at the bottom or is drawn in by natural draft. In the latter case the tow is made very high, say 60 to 100 feet, so as to act like a chimney.

Make-up Water. — When used with jet condensers, the water produc by the condensation of the exhaust steam is sufficient to make up for the evap ration in the tower, and therefore only enough water for the boiler feed ne be supplied continuously. In fact, the condensed steam is, as a rule, more th sufficient to make up for the loss due to evaporation, and there results a slig overflow, which carries with it the oil from the engine cylinders and tends clean the system of the oil that would otherwise accumulate in the hot-well.

When a cooling tower is used with a surface condenser make-up water m be added to the cooling water, the amount ranging from 3 to 15 per cent, b in this case the boiler feed water can be used over and over again with b slight loss, provided the oil (there is none with turbines) is eliminated by su able separators.

Reduction in Temperature Obtainable. — With a properly design cooling tower the temperature of the hot water (and condensed steam in t case of a jet condenser) can be reduced 40 to 50° F. The water can usually cooled to within 2 to 5 degrees of the wet bulb air temperature.

Power Required for Forced Draft in Tower. — The power requir for the fan, when forced draft is used, averages 2 per cent of that developed the main engines during the summer months, when maximum volume of is required, and about 1 per cent during the winter months.

Cooling Ponds. — Where water for condensing is scarce it is found economi to store it in reservoirs where it is cooled by evaporation. Under the con tions prevailing in northeastern United States it has been found that a surf of 250 sq. ft. is sufficient to cool the condensing water required for one boi horsepower (34.5 lb.) at 26-inch vacuum. In countries where the evaporati coefficient is higher, smaller surfaces may be used; see Ruggles, *Transacti A.S.M.E., Vol. 34, p. 561.*

Spray Ponds. — Where the area available for water storage is small recou must be had to the spray system. Here the warm condensing water is spray into the air above the small pond; a portion evaporates, cooling the remaini portion, which falls to the tank to be used again. The sides of the tank are tended to prevent the spray from being carried away by the air currents. Ab 4 sq. ft. of surface are required for one boiler horsepower of steam condensed 26-inch vacuum. It is even possible in small plants to have the spray pond on t roof of the power house. These ponds should not be used in crowded localit as the spray of water is likely to be a nuisance. The loss of water varies betw the amount of boiler feed and twice that amount.

COSTS (Pre-war figures). — Cooling-tower costs vary greatly with clima and operating conditions. When these are relatively favorable the cost may kept as low as $2.50 per kilowatt for natural draft towers and $3.60 for fan dra

Digitized by Google

ler ordinary central-station conditions the costs will probably average $3.50 $5.00 per kilowatt respectively for the two types of towers. Assuming ch vacuum, 70° air and 70 per cent humidity, forced-draft cooling towers about $250 per 1000 lb. of steam condensed. For 24-inch vacuum the cost be one-half this. Natural-draft towers cost about one-half to one-third as th as the forced-draft towers. As a general rule cooling towers do not pay n the pumping head exceeds 75 feet.

lhe following data on spray cooling ponds were given in the *Elec. World*, p. 808, Oct. 9, 1915:

Steam ndensed k. per hr.	Circ. water, gal. per min.	Number of nozzles	Size of pond, ft.	Total cost, pond and equipment	
				Concrete basin	Clay basin
:...000	1320	35	50 ×128	$3385	$2105
2. 500	2420	60	90 × 90	4825	3205
3. 000	4320	110	112 ×120	7710	5010

COPPER. — (*See also Electrochemical Processes, Industrial; Wires and Cab Bare.*) The following discussion applies primarily to copper for electri conductors. Copper mined in the vicinity of the Great Lakes is almost pu That derived from the compound ores of the metal must be refined (usua electrolytically) to reduce it to the same degree of purity.

ROLLING-MILL PROCESSES. — The refined copper comes to the r mill in bars weighing about 200 pounds each. These bars frequently ha ridges along the sides, due to faults in castings, and the surface is often cove with a layer of oxide. They are heated in a furnace until sufficiently soft rolling and are passed through a series of rolls diminishing in size until a r of the proper diameter is obtained. The rod is then coiled up and immer in a pickling liquid (10 per cent H_2SO_4) in order to dissolve the oxide form during rolling. It is then washed and dipped in a fluid tallow mixture.

WIRE-MILL PROCESSES. — The rods having cooled are connected gether by brazing and are drawn through a series of dies of decreasing diame The dies give the wire a dense hard exterior coating which increases its tenac As the strength obtainable is almost a direct factor of the work expended up the wire, the smaller the size the greater the tensile strength per square in so that the strength of the wire is readily varied by changing the size of rod and the number of dies.

Defects in Wire. — One of the most serious defects occurring to wire this point is from ridged bars as above described. Ordinarily the bar will be sufficiently heated to dissolve the copper oxide on the surface so that as softened bar enters the first passes of the rolls, the ridges are lapped over, closing the oxide scale. The subsequent passes and the drawing through dies obscure this flaw almost entirely, but it remains a serious menace to toughness and the resistance to wear of the copper.

A second cause of trouble arises at the same point by overheating the cop in the softening furnace, in which case copper oxide is formed on the surf and quickly dissolves through the entire bar, thereby increasing the oxide c tent and tending toward the production of brittleness. Both of these dang can be avoided by careful selection of the bars and by proper regulating of temperature of the softening furnace.

As the production of the hard surface from drawing is at best a rather delic operation, careless handling, uneven welding of the rods and unequal temp ature of the wire while passing through the dies will all produce noticeable effe in the quality of the finished wire, so that care throughout the mill is absolut necessary for the best results.

It, therefore, appears that the most efficient wire must possess not only h conductivity but the maximum torsion and tensile strength possible in co mercial copper and that to obtain this it is first necessary to use high-grade cop and to prevent an excess of cuprous oxide entering it at any stage of the ma facture, and, secondly, to select as perfect bars as possible and to observe extr care in every treatment through which they pass. (*Adapted from article Carl F. Woods, Electric Railway Journal, 1909, Vol. 33, p. 195.*)

ANNEALING. — All wire when first drawn is more or less hard. It may softened by annealing, i.e., by heating to a temperature between 250° to 400 The hardness is not affected by the rate of cooling. Annealed copper has a c talline structure, whereas hard-drawn copper consists of grains elongated in direction of drawing.

MECHANICAL PROPERTIES. — (*See Wires and Cables, Bare, for ta of tensile strength, etc., of various sizes of wire.*) The more important mechan properties of copper are discussed in some detail below,

Tensile Strength and Elongation of Soft Annealed Copper. — The ten- strength of soft annealed copper is about 30,000 to 33,000 pounds per square h with an elongation of about 25 per cent (in 10 inches) at the fracture. It no true elastic limit, permanent elongation being produced by very small ds.

Tensile Strength and Elongation of Hard-drawn Copper. — (*See Wires d Cables, Bare, for tensile strength of various sizes of wire.*) Modern hard-drawn per is equally affected by drawing throughout the section, no hard skin being duced. According to D. R. Pye, hard-drawn copper in wires up to ½ inch meter varies in tensile strength with the diameter according to a linear law the form

$$T = 70{,}000 - 45{,}000\,D,$$

ere T = tensile strength, pounds per square inch, and D = diameter of wire, hes.

The above constants agree approximately with the tables of the American iety for Testing Materials and represent values somewhat under those usu- obtained.

The elongation at fracture is approximately represented by

$$E = 4\sqrt{D},$$

ere E = per cent elongation at fracture.

Tests by G. C. Batson on 50-foot lengths of hard-drawn copper showed a ile strength only ½ per cent less than that of 10-foot lengths, a fact which licates that the material is very uniform.

Modulus of Elasticity of Hard-drawn Copper. — The modulus of elas- ity of hard-drawn copper varies from 16×10^6 to 20×10^6, the higher values pying to small wires. The following tests by G. C. Batson are typical of mercial copper.

Diameter, in.	0.158	0.138	0.112	0.094	0.079	0.066	0.049
Modulus, lb. sq. in. units	17.7×10^6	17.9×10^6	17.5×10^6	17.7×10^6	17.1×10^6	19.5×10^6	19.2×10^6

An apparent modulus of 12×10^6 is often obtained from an initial test, due to ightening-out. (*See also Wires and Cables, Bare.*) The modulus decreases temperatures above 150° C.

Elastic Limit of Hard-drawn Copper. — The true elastic limit of hard- wn copper, or load at which permanent set begins, is not the same as the point ere the strain begins to increase more rapidly than the stress. The latter nt is usually between 30,000 and 35,000 pounds per square inch and the ner, somewhat below (*see Wires and Cables, Bare*).

Compression Test. — Copper of good quality does not fracture under com- ession; it yields and flattens. According to Thurston the resistance to com- ession may be calculated, within the limits $e < \frac{1}{2}$, from the formula

$$C = 145{,}000\sqrt[3]{e}$$

ere C = resistance in pounds per square inch of original area,
e = fractional compression.

Miscellaneous Mechanical Properties. — The torsional strength, shearing ength, hardness, resistance to impact and fatigue of copper are all discussed Bureau of Standards Circular No. 73 on *Copper*.

Density. — The density of copper or, for all practical purposes, its speci gravity referred to water, is 8.89 at 20° C. This is the value which has be adopted as standard by the American Institute of Electrical Engineers, and mo other authorities in the past. Recent measurements by the Bureau of Standar the Calumet & Hecla Smelting Works, and the Reichsanstalt have indicat this as a mean.

CONDUCTIVITY AND RESISTIVITY. — (*See also Resistance and Co ductance; Wires and Cables, Bare.*) F. A. Wolff and J. H. Dellinger give t resistivities of 89 samples of commercial copper from 14 important refiners a wire manufacturers in this and other countries. The mean for annealed wire Resistivity in ohms per meter-gram at 20° C. = 0.15292; per cent conductivi = 100.25. (Per cent conductivity is computed on the basis of 100 per ce conductivity corresponding to the standard resistivity of 0.15328 ohm p meter-gram at 20° C.) The mean result of data furnished by a large wi manufacturing company, representing tests on more than 100,000,000 poun of copper, is also given; for example, for annealed samples: Resistivity in ohi per meter-gram at 20° C. = 0.15263; per cent conductivity = 100.42.

Conductivity of Hard-drawn Copper. — The conductivity of hard-dra No. 12 B. & S. wires was found to be less than the conductivity of anneal wires by a mean value of 2.7 per cent. The difference between the conductivi of annealed and hard-drawn wires increases as the diameter of the wire decreas The lowest resistivity and highest conductivity found for a hard-drawn w were: Resistivity in ohms per meter-gram at 20° C. = 0.15386; per cent co ductivity = 99.62; and for annealed wire were: resistivity in ohms per met gram at 20° C. = 0.15045; per cent conductivity = 101.88.

Effect of Bending on Conductivity. — Copper wire apparently decreas in conductivity when bent, but the greater part of this is caused by local chang in cross-section. This effect is negligible unless the wire is bent to a very sm radius.

Effect of Melting. — Electrolytic copper which is drawn without havi been melted has a higher conductivity than that which has been melted, J. Dellinger recording copper thus drawn as having a conductivity as high 101.71 per cent after annealing at a dull-red heat. Lake copper likewise dra without having been melted gave conductivities as high as 101.88 after annealin

Temperature Coefficient of Resistivity. — It has been found by J. Dellinger (*Bulletin No. 147, Bureau of Standards, 1910, Vol. 7, No. 1*) that t temperature coefficient of copper is proportional to the conductivity instead being virtually a constant, as hitherto assumed. This fact may be expres by saying that the change of resistivity per degree C. of a sample of copp is 0.000597 ohm per meter-gram or 0.00681 micro-ohm per centimeter cub (Dellinger's original figures were subsequently changed slightly; *see Circ. No. of Bureau of Standards, 1912 ed.*) The 20° C. temperature coefficient of sample of copper is found by multiplying the per cent conductivity 0.0039; and dividing by 100. These rules apply only to copper furnished f electrical use and to the temperature range of 10° C. to 100° C. over which t temperature coefficient was found to be linear. The following table gives t temperature coefficients a_T in the formula:

$$R_t = R_T[1 + a_T(t - T)].$$

CORONA, ELECTRIC. — (*See also Electron Theory; Spark Gap; Transmission Lines.*) If a potential difference is established between smooth parallel wires, or between concentric cylinders, and gradually increased, a voltage finally reached at which a hissing noise is heard. If it is dark, a pale glow, called the electric "corona," will be seen to surround the wires. When wattmeters are inserted in the line a loss is noticed to start at this critical voltage. There is also noted the characteristic odor of ozone, and the air around the wires becomes ionized. These phenomena are referred to as "corona effects."

The corona starts at the conductor surface, because the voltage stress per unit distance, or "voltage gradient," is highest there. The break-down or corona extends out to a point where the stress is below the break-down point of air. If the wires are close together, so that the stress is fairly uniform, the break-down immediately extends from conductor to conductor without corona, and this phenomenon is called a "spark-over." The spark and corona are exactly the same phenomenon. The corona may be considered as a spark-over from conductor to space, as distinguished from a spark-over from conductor to conductor. The spark-over does not extend to the other conductor when the separation is large compared to the wire diameter, because it reaches a point in space where the gradient is below the break-down gradient of air. Increasing the voltage after the corona point is reached causes the corona to extend until finally a spark occurs from conductor to conductor. The power loss increases very rapidly with increase in voltage above the critical point.

Corona is caused by either a-c. or d-c. voltages, and starts at approximately the same maximum stress. At the critical voltage, corona occurs only at the crest of the alternating wave. As the voltage is increased above the critical point the loss extends over a greater portion of the wave. In the a-c. corona the eye sees a superposition of the corona caused by the plus and minus half-cycles of the a-c. waves. If the effects of the half waves are viewed separately, it is noticed that a reddish haze surrounds the wire while it is negative, whereas the surface of the wire glows bluish-white while it is positive. Positive and negative d-c. corona have exactly the same appearance as the positive and negative corona of the correspodning a-c. half-wires. When a negative wire becomes oxidized reddish tufts appear. If there are rough spots on the wire the corona starts at these points at a lower voltage. At points the positive corona extends out as a bluish-white spray; the negative corona appears as a red tuft.

Corona is also caused by transient voltages. Corona produced by voltage lasting less than a millionth of a second can be seen by the eye and distinction can be made between a positive and negative half-wave.

Corona Voltmeter. — For a given conductor arrangement and air density corona always starts at the same maximum voltage. Use has been made of this fact in the corona voltmeter (*Whitehead and Isshiki, J.A.I.E.E., May, 1920*). For this purpose, a wire in the center of a cylinder is generally used. In one form the voltage is applied and the air density varied until the corona appears. The voltage is then readily calculated or read from a scale. A tapered-wire has also been used. The starting point can be detected by the glow, the noise, the odor or by the conducting ionized air.

Laws of Corona-Formation. — The laws of corona have been quite definitely worked out. The chief factors affecting corona formation are:

For a given spacing and air density the corona starting voltage is lowered by decreasing the wire diameter.

Increasing the spacing increases the corona starting voltage but the effect of changing the diameter is relatively much greater.

Digitized by Google

creasing barometric pressure decreases air density and decreases the corona ting voltage.

creasing temperature decreases air density and decreases the corona start- voltage.

ist, water, etc., on the conductor surfaces lower the corona starting voltage ncreasing the stress.

he *apparent strength* of air is not constant in irregular fields but greater at surface of small conductors than large ones. The strength at the start of ona is always constant, however, at a distance from the conductor which is ion a function of the radius. This corresponds to the strength in a uniform d of 76 kilovolts per inch (maximum value in case of a-c. voltage), which ns to mean that the actual strength of air is 76 kilovolts per inch. In order, ever, that a finite thickness only may be brought to this stress in an irregular d the stress at the conductor surface must be higher. At a given spacing corona always starts at a lower voltage on small wires than large ones, ause, although the *apparent strength* of air at the small conductor surface is ater, the stress produced by a given voltage is relatively much higher for the aller wires.

Corona does not start at exactly the same voltages when the wires are alter- ely plus and minus. The difference is at most a few per cent and is greater small wires than large ones.

he perfectly clean, smooth wires of uniform diameter, there is no loss until visual *critical voltage* is reached, when the loss assumes a *definite value* and reases as the square of the difference between the applied voltage and the uptive *critical voltage*. The *visual critical voltage* takes into account the *appar- strength* of the air, which is a function of the wire diameter; the *disruptive* al voltage corresponds to the constant strength of air for uniform fields, ch is about 76 kilovolts per inch, maximum value. The *visual critical* ge is always higher than the *disruptive critical voltage*. *Due to irregularities re is always a loss below the visual critical voltage*. This loss follows the prob- ity curve, because the loss occurs at chance rough spots, but on practical nsmission lines the quadratic law is generally approximated even on this tion of the curve. This is especially so for large conductors at low altitudes, ere the difference between the visual and disruptive critical voltages is not eat

Corona loss increases with increasing frequency.

The formulas for calculating corona on transmission lines are given below.

CORONA ON TRANSMISSION LINES. — It is of great importance the design of high voltage transmission lines to know the various factors that luence the corona formation and to be able to estimate accurately the starting oltage and loss for a given line.

The various characteristics may be calculated from the following formulæ:

Let e = r.m.s. value of the kilovolts to neutral $\left(= \frac{1}{\sqrt{3}} \text{ kilovolts between wires for 3-phase; } = \frac{1}{2} \text{ kilovolts between wires for single-phase} \right)$.

t = temperature in deg. F.,

b = barometric pressure, in inches,

$\delta = \frac{17.9b}{459 + t}$ = specific gravity of air, referred to air at 77° F. and 29.9 inches barometric pressure,

r = radius of conductor, in inches,

$g_0 = 53.6$ = disruptive critical gradient, kilovolts per inch, r.m.s. value,

Google

$g_v = g_0\delta\left(1 + \frac{0.189}{\sqrt{\delta r}}\right)$ = visual critical gradient, kilovolts per inch, r.m.s. value,

s = distance between conductor centers, in inches,

f = frequency, cycles per second.

Then the **disruptive critical voltage**, r.m.s. value of kilovolts to neutral

$$e_0 = 2.302 m_0 g_0 r\delta \log_{10}\left(\frac{s}{r}\right),$$

where $m_0 = 1$ for polished wires, $= 0.98$ to 0.93 for roughened or weathered wires, $= 0.87$ to 0.83 for seven-strand cables.

The **visual critical voltage**, r.m.s. value of kilovolts to neutral, is

$$e_v = 2.302 m_v g_v r \log_{10}\left(\frac{s}{r}\right),$$

where $m_v = 1$ for polished wires, $= 0.72$ for local corona all along cable, $= 0.6$ for decided corona all along cable.

The **power loss in fair weather**, in kilowatts per mile of single conductor

$$p = \frac{390}{\delta}(f + 25)\sqrt{\frac{r}{s}}(e - e_0)^2 \times 10^{-5}.$$

The **power loss in stormy weather**, in kilovolts per mile of single conductor is approximately,

$$p_s = \frac{390}{\delta}(f + 25)\sqrt{\frac{r}{s}}(e - 0.8e_0)^2 \times 10^{-5}.$$

Example. — To illustrate the use of the above formulas consider the case of a three-phase, 60-cycle line, No. 0, A.W.G. stranded cable (diameter 0.374 in.), spacing 120 inches, length of line 100 miles, temperature 100° F., barometer 28.85 inches.

Then $$\frac{s}{r} = \frac{120}{0.187} = 642,$$

$$\log_{10}\left(\frac{s}{r}\right) = 2.81,$$

$$\sqrt{\frac{r}{s}} = \sqrt{\frac{0.187}{120}} = 0.0394,$$

$$\delta = \frac{17.9 \times 28.85}{459 + 100} = 0.925,$$

$$\sqrt{\delta r} = \sqrt{0.925 \times 0.187} = 0.426,$$

$$g_v = 53.6 \times 0.925\left(1 + \frac{0.189}{0.426}\right) = 71.6,$$

$$m_0 = 0.87.$$

The disruptive critical voltage is then,

$$e_0 = 2.302 \times 0.87 \times 53.6 \times 0.187 \times 0.925 \times 2.81,$$

$$= 52.0 \text{ kilovolts to neutral.}$$

Digitized by Google

The power loss is,

$$p = \frac{390}{0.925}(25 + 60) \times 0.0394(e - e_0)^2 \times 10^{-5}$$
$$= 0.014(e - e_0)^2 \text{ kw. per mile of conductor}$$
$$= 0.042(e - e_0)^2 \text{ kw. per mile of line.}$$

The conductor would begin to glow ($m_0 = 0.72$) at

$$e_0 = 2.302 \times 0.72 \times 71.6 \times 0.187 \times 2.81$$
$$= 62.6 \text{ kilovolts to neutral}$$
$$= \sqrt{3} \times 62.6 = 108.3 \text{ kilovolts between wires.}$$

The glow would be pronounced ($m_0 = 0.82$) for

$$e_0 = \frac{0.82}{0.72} \times 108.3 = 123.4 \text{ kilovolt between wires.}$$

The power loss per mile of line under storm conditions would be,

$$p_0 = 0.042(e - 0.8 \times 52)^2$$
$$= 0.042(e - 41.6)^2 \text{ kw. per mile of line.}$$

This last calculation assumes a storm over the whole line at the same time; a condition that is most unlikely to occur. The storm loss will generally be less due to lower temperatures.

The loss on a transmission line will vary from day to day depending upon the temperature and weather conditions. The above losses are calculated for summer temperature. For winter the losses would be much lower.

Methods of Increasing Size of Conductors. — For equal conductivity an aluminum conductor has about a 25 per cent greater diameter than a copper conductor, and, therefore, approximately 25 per cent higher critical voltage.

The advantage of aluminum may be still further increased by the addition of a steel cable core. Such a cable has been in use for several years on a 165–154 kilovolt line in California.

A copper tube may also be used or a copper cable with a suitable core.

Another means of increasing the corona voltage for a given amount of metal is to arrange several conductors of the same potential close together.

Arrangement of Conductors. — In the above formulas it has been assumed for three-phase lines that the conductors are so arranged that they form the edges of an equilateral prism. When the conductors are not so arranged, but are placed symetrically in a plane, corona will start at a lower voltage on the center conductor than on the outside conductors. The actual critical voltage on the center conductor will be approximately 4 per cent lower, and on the outside conductors 6 per cent higher, than for the equilateral prism arrangement with the same spacing.

Voltage Variation Along Line. — In practice, due to the drop in voltage along the line, the corona loss will be different at different points on the line. This may be allowed for by calculating the loss per mile at various points, and plotting a curve with loss per mile as ordinates and length in miles as abscissa. The area of this curve then represents the total loss.

If an isolated system is operating near the critical corona voltage and one conductor becomes grounded, the corona loss will be quite high.

The Corona Limit of High Voltage Transmission Lines. — Safe and Economical Voltages. — It will generally be found that it is safe and economical to operate a line up to, but not above, the fair weather value of the disruptive critical voltage (that is, up to the value of e_0 given by equation 1 for average barometer and summer temperatures. This will give loss during storms, but as storms do not extend over the whole line at one time, it will generally not be serious. During cold weather the critical voltage will be higher and storm loss less.

Besides the loss of energy, corona loss may be undesirable from another standpoint, viz., since the loss occurs only on part of the wave, it may introduce harmonics if it is excessive.

Tables I and II give the values of the fair weather disruptive critical voltage in kilovolts *between wires*, for various conductors at various spacings, at a barometric pressure of 29.9 inches = 760 mm. (standard pressure at sea level) and 77° F. = 25° C.

Table III gives the factors by which these voltages must be multiplied to give the corresponding disruptive critical voltage at various elevations. The correction factor is equal to the ratio of the barometric pressure at the given altitude to the barometric pressure at sea level.

TABLE I.—CORONA LIMIT OF VOLTAGE—SOLID WIRES

(Kilovolts between lines, three-phase, sea level, 25° C)

Size, A.W.G.	Diameter, inches	Diameter, cm.	Spacing in feet

Agreement of Calculated and Measured Losses on Actual Transmission Lines. — In most cases where losses have been measured on transmission lines the check is in close agreement with calculated values. The agreement is in fact within the limit of error of the measurements on commercial lines. Apparent discrepancies have generally been due to the fact that the measurements are often made at voltages below the *visual critical voltage*, when the loss depends upon irregularities, as discussed above. The loss between the *visual critical voltage* and the *disruptive critical* voltage closely follows the quadratic law for large conductors, but for new conductors, and especially for small

conductors at high altitudes, when the difference between e_0 and $e_{0'}$ is large, the loss will generally fall below the quadratic curve.

Special Calculations. — For small conductors the loss, in kilowatt mile of conductor, is given by the expression,

$$p = \frac{390}{\delta}(f + 25)\sqrt{\frac{1 + \frac{0.93}{s} + 0.016}{s}}\,(e - e_d)^2 \times 10^{-5},$$

where $$g_d = g_0\delta\left[1 + \frac{0.189}{\sqrt{\delta r}}\,\frac{1}{(1 + 148\sigma r^2)}\right]$$

and $$e_d = 2.302 m_0 g_d r \log_{10}\left(\frac{s}{r}\right).$$

UPLINGS, DIRECT. — (*See also Belts and Belting.*) Couplings for con-ng electrical apparatus together or to other machines can be divided into distinct classes, namely, solid and flexible.

OLID COUPLINGS (Fig. 1) are usually of the flanged type and consist two steel castings rigidly bolted to-er. This type should be used where two machines are mounted on a com-n iron base and where an exact align-t is possible. Large flanges should be vided for overcoming bending stresses ch may occur when the couplings carry t of the load such as, for example, in e bearing sets. See also article on *Ma-e Tools, Electrical Operation of.*

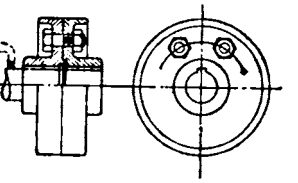

Fig. 1. Solid Flange Coupling

LEXIBLE COUPLINGS are mainly used to connect machines which not be lined up properly or where there is fear that alignment cannot be ntained. Many different kinds of flexible couplings are in use, and they be divided in two general classes, insulated and uninsulated. The insu-d couplings are composed of castings separated by leather or rubber, as a ble and insulating medium. The principal types of flexible couplings in are the leather link, the laced belt, the rubber buffer and the mill-type pling.

Leather-link Flexible Couplings (Fig. 2) consist of two iron castings con-ted together through leather punchings fastened at the ends by bolts to the rnate halves. For the smaller sizes e links are usually replaced by a gle leather disk which connects both lves by means of bolts alternately ned through opposite halves. The ving stresses are transmitted through e links or disks to the bolts which ten them to the castings.

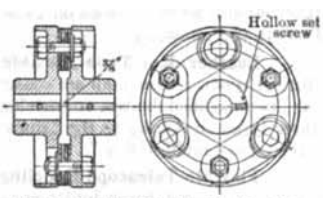

Fig. 2. Leather-link Flexible Coupling

In order to allow sufficient play for t heads of the bolts, alternate holes t bored to a large diameter, the bolts rurately fitting the other holes in the castings. By this means flexibility is ained and a small amount of end or side play is permissible between the fts of the two machines to which each half coupling is securely keyed. is type of coupling is recommended for shafts up to 3½ inches in diameter. shafts between 3½ inches and 5 inches in diameter either this type or the ther-laced type may be used.

Leather-laced Flexible Couplings (Fig. 3) are recommended for shafts er 3½ inches in diameter on ac-nt of their structural advantages. ey consist of two steel rings, an ter and an inner, with cast-iron bs bolted to them. Slots are med in these rings through which endless leather belt is interwoven.

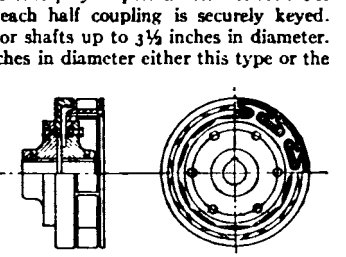

Fig. 3. Leather-laced Flexible Coupling

is construction not only gives great flexibility but, due to the two rings ing concentric, it is not subjected to bending strains and therefore is espe-

cially adapted for transmitting a high torque commensurate with the stren of the belt and the size of the coupling employed.

As the outer ring of the coupling is only connected to the shaft of the mach through the coupling hub which is keyed to the shaft, machines using this fo of coupling can be readily disconnected without unlacing or interfering with t coupling belt. To do this it is only necessary to remove the bolts, holding t outer ring to the hub. This partial disassembling also aids in the replacing o worn-out belt without removing the coupling from the machine.

Rubber-buffer Flexible Coupling. — This coupling is made up of two ca iron spiders, the small interlocking arms of which are separated by cylinders soft rubber. The rubber cylinders are held in place by projecting plates screw to the arms of one of the spiders. The construction of this type of coupli affords great flexibility as well as insulating qualities. This type of coupli was once much used on account of its high-insulating qualities but is now to great extent being superseded by the two previous types.

Mill-type Flexible Coupling (Fig. 4). — Where the conditions are t severe for the belt or rubber of the flexible couplings described above, that where there is much grit or hot vapor present and where noise is not objectionable, the mill-type flexible coupling shown in Fig. 4 should be used. This is a rough sturdy coupling consisting of three steel castings, two of which are identical and called the "pods," while the center is called the "box." The most extensive use for this coupling has been in steel mills. Best results are obtained fr this coupling when it is used on a constant load, as the noise under these con tions is at a minimum.

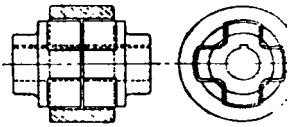

Fig. 4. Mill-type Flexible Couplin

Leather Key Type Flexible Couplings. — These are made in thr distinct types, although all are constructed on the same fundamental princip viz., two modified flanges, one driving the other by means of leather keys, t three types are known as the "single key," "two-piece multiple key," and t "three-piece multiple key."

Flexible Telescope Couplings. — This coupling is specially design for use with motor driven Jordan engine in paper and pulp mills. On the Jord side of the set it consists of a stout split cylinder on which are mounted fo radial columns of leather washers securely bolted. The motor half is a sp cylinder slotted to take the columns of the other half.

PROPER SIZE OF COUPLING. — The selection of the proper coupli should be determined by calculation and not by the method of choosing the bo corresponding to the shaft diameter. The coupling should have sufficie capacity to take care of the overload capacity of the motor or generator, as t case may be.

ANES. — (*See also Blocks and Tackle; Controllers; Hoists, Electric; Tel-*
rage.) A hoist is a machine for raising and lowering weights. A crane is a
s with the added capacity of moving the load in a horizontal or lateral direc-
. That part of a crane carrying the hoist and movable with respect to the
e structure of the crane is called the "trolley." Cranes are divided into
o classes as to their motions, viz., rotary and rectilinear.

Rotary Cranes may be classified as follows:

Swing-cranes. — Having rotation, but no trolley motion.

Jib-cranes. — Having rotation, and a trolley traveling on the jib. When
jib or boom is movable, carrying a sheave on the end, the device is called
ewrick.

Column-cranes. — Identical with the jib-cranes, but rotating around
ixed column (which usually supports a floor above).

Pillar-cranes. — Having rotation only; the pillar or column being
pported entirely from the foundation.

Pillar Jib-cranes. — Identical with the last, except in having a jib and
lley motion.

Derrick-cranes. — Identical with jib-cranes, except that the head of
ast is held in position by guy-rods, instead of by attachment to a roof or
ing.

Rotary cranes arranged so that they may be readily moved from place to
ce may be classified as:

Walking-cranes. — Consisting of a pillar or jib-crane mounted on
heels and arranged to travel longitudinally upon one or more rails.

Locomotive-cranes. — Consisting of a pillar-crane mounted on a truck,
d provided with a steam-engine capable of propelling and rotating the crane,
d of hoisting and lowering the load.

Rectilinear Cranes may be classified as follows:

Bridge-cranes. — Having a fixed bridge spanning an opening, and a
lley moving across the bridge.

Tram-cranes. — Consisting of a truck, or short bridge, traveling longi-
dinally on overhead rails, and without trolley motion.

Traveling-cranes. — Consisting of a bridge moving longitudinally on
erhead tracks, and a trolley moving transversely on the bridge.

Gantries. — Consisting of an overhead bridge, carried at each end by
restle traveling on longitudinal tracks on the ground, and having a trolley
oving transversely on the bridge.

Rotary Bridge-cranes. — Combining rotary and rectilinear movements
d consisting of a bridge pivoted at one end to a central pier or post, and
pported at the other end on a circular track, provided with a trolley moving
ansversely on the bridge.

For descriptions of these several forms of cranes see Towne's *Treatise on*
ranes.

HAND-OPERATED TRAVELING CRANES. — The weight of a hand-
perated traveling crane depends not only upon the capacity of the crane and
e length of the span, but also upon the particular design. The following
pproximate formula will serve as a rough guide when actual data are not avail-
ble:

$$W = KCL,$$

Digitized by Google

where W is the weight of the crane in tons, C the capacity of the crane in to
L the length of the span in feet and K a constant ranging from about 0.01
L = 10 feet to 0.012 for L = 75 feet.

ELECTRIC OVERHEAD TRAVELING CRANES. — Electric travel
cranes usually have 3 motors, one for the hoist, one for the trolley traveling
the bridge and one for moving the bridge. Cranes of over 15 tons capac
are usually provided with an auxiliary hoist of from 1/10 to 1/8 the capacity
the main hoist. Automatic brakes are used to sustain the load when lift
and to regulate the speed when lowering, the hoist motor usually having
drive the load down.

Speeds of Electric Traveling Cranes. — The standard speeds at wh
the various parts travel in the cranes manufactured by Pawling and Harnischfe
are as follows:

STANDARD SPEEDS OF ELECTRIC CRANES, IN FEET PER MINU
(Pawling & Harnischfeger)

Capacity, tons (2000 lb.)	Hoisting speed, ft. per min.	Bridge travel, ft. per min.	Auxiliary hoist	
			Capacity, tons	Speed, ft. per min.
5	25–100	300–450	..	.....
10	20–75	300–450	3	30–75
25	10–40	250–350	3	50–125
			10	25–60
40	9–30	250–350	5	40–100
			10	25–60
50	8–30	200–300	5	40–100
			10	25–60
75	6–25	200–250	15	20–50
125	5–15	200–250	25	20–50
150	5–15	200–250	25	20–50

Trolley travel speed from 100 to 150 feet per minute in all cases.

Weight and Dimensions of Electric Traveling Cranes. — Let

C = capacity of crane, in tons (2000 pounds),
W_B = weight of bridge alone, in tons,
W_T = weight of trolley alone, in tons,
W = total weight of crane, in tons.

Then

$$W_B = K_B CL, \qquad W_T = K_T C,$$
$$W = W_B + W_T = C(K_B L + K_T),$$

where K_B and K_T have the following approximate values (*see paper by S. Wales, Proc. Eng. Soc. Western Pa., 1902, Vol. 18, p. 146*).

L	K_B	C	K_T
25	0.012	1–25	0.3
50	0.012	25–75	0.4
75	0.013	75–150	0.5
100	0.015		

Digitized by Google

For example, for a 50-ton crane for a 60-foot span, the bridge alone would ...gh $0.013 \times 50 \times 60 = 39$ tons, the trolley would weight $0.4 \times 50 = 20$ tons, ... the total weight would be 59 tons, approximately. If the bridge is equipped ... 2 wheels at each end, the maximum load on each wheel when the trolley, ...ying full load, is at the end of the bridge would be approximately

$$\frac{39}{4} + \frac{20 + 50}{2} = 45 \text{ tons},$$

If there are 4 wheels at each end, the maximum wheel load would be 22.5 tons. The following table is taken from a catalogue of the Alliance Machine Co.

DIMENSIONS AND WHEEL LOADS OF ELECTRIC TRAVELING CRANES

60-foot span and 25-foot lift; wire-rope hoist

Capacity, ...ns (2000 lb.)	Distance from runway rail to highest point		Distance from center of rail to ends of crane	Wheel base of end truck		Maximum load per wheel; trolley at end of bridge
	Feet	Inches	Inches	Feet	Inches	Pounds
5	6	0	9	9	0	20,000
10	6	6	10	10	0	27,000
25	7	4	12	11	6	51,000
40	8	0	12	12	3	82,000
50	8	9	12	12	6	48,000*

* Has 8 track wheels on bridge.

Standard cranes are built in intermediate sizes, varying by 5 tons up to 40 ...

Power Required. — The following is adapted from the paper by S. S. Wales ...ve referred to. The frictional losses will of course depend to a certain extent ...n the design of the crane, the use of rope or chain, etc., but the constants ...n below represent fair averages.

The same notation as in the previous section is used. In addition let

R_B = tractive effort in pounds per ton required to move the bridge,
R_T = tractive effort in pounds per ton required to move the trolley,
S_B = speed of bridge in feet per minute,
S_T = speed of trolley in feet per minute,
S_H = speed of hoist in feet per minute.

...en the power required, at shaft of bridge motor, to drive the bridge at speed ... is

$$P_B = \frac{(C + W_B + W_T)\, R_B S_B}{33{,}000} \text{ horse-power.} \qquad (1)$$

The power required, at shaft of trolley motor, to drive the trolley at speed ... is

$$P_T = \frac{(C + W_T)\, R_T S_T}{33{,}000} \text{ horse-power.} \qquad (2)$$

Digitized by Google

The power required, at shaft of hoist motor, to drive the hoist at speed assuming 60 per cent efficiency of gearing and hoisting tackle, is

$$P_H = \frac{CS_H}{10} \text{ horse-power.}$$

For *constant-speed running*, Wales gives the following values for R_B and the former varying with L and the latter with C.

L	R_B	C	R_T
25	30	1–25	30
50	35	25–75	35
75	40	75–150	40
100	45	.....	....

If the moving member is *accelerating* at the rate of a ft. per sec. per to the value of R given in the above table should be added an amount

$$R_a = 64\,a.$$

The power as calculated by the above formulas is the power *output* of motors; to obtain the power input divide by the motor efficiency, which ra from 80 to 90 per cent.

Motor Equipment. — (*See also Motors, Industrial Applications of*). bridge motor should have a 30 minute rating, 1.8 times the calculated po for constant full-load speed, the trolley motor 1.5 times the calculated po for full-load speed, whereas the rating of the hoist motor should be t equal to the calculated power for constant full-load speed. This is a g approximation, but for accurate work the torque capacity of the bridge m should be checked against the rate of acceleration required. A full discus of the motor equipment of cranes is given by McLain and Jackson in the *Elec. Rev. 19, p. 506, June, 1016.*

Both direct-current and alternating-current motors are successfully used crane work. The series direct-current motor has speed-torque characteris especially well adapted for crane service. At light loads the speed incre and at heavier loads the lifting is slower and the raising effect consequer stronger. This characteristic of the series motor often results in consider saving of time, due to the fact that the majority of loads in factories are li so that the increased speed of lift enables work to be performed in a sho time. For a-c. motors a normal operating speed about 25 to 50 per cent hig than for d-c. motors is therefore generally selected and the slowing down for he work is accomplished by inserting resistance in the phase-wound rotor circ

Example. — Crane of 50-ton capacity, span 70 feet, bridge speed feet per minute with full load, trolley speed 100 feet per minute with full lo hoist speed 15 feet per minute with full load. Then $C = 50$, $W_B = 4$ $W_T = 20$, $R_B = 40$, $R_T = 35$, and

$$P_B = \frac{115.5 \times 40 \times 200}{33{,}000} = 28 \text{ horse-power,}$$

and the motor required for the bridge would be $28 \times 1.5 = 42$ horse-power, the nearest commercial size over 42, say 50 horse-power.

$$P_T = \frac{70 \times 35 \times 100}{33{,}000} = 7.43 \text{ horse-power,}$$

Digitized by Google

l the size motor required for the trolley would be $7.43 \times 1.25 = 9.28$ horse-wer, or say 10 horse-power.

$$P_H = \frac{50 \times 15}{10} = 75 \text{ horse-power,}$$

d a motor of this rating would be used for the hoist.

Control of Crane Motors. — The control equipments for crane motors ould be of the regulating and reversible type. The starting and speed regu-tion of series motors is generally accomplished by inserting resistance in ies with the armature and field, and with induction motors, resistance is erted in the phase-wound secondary or rotor circuit. For cranes which do ge amount of lowering, dynamic control is becoming very generally used, d is very readily accomplished with direct-current motors. This also occa-nally is used with a-c. motors of 200 h.p. and above, when direct current is ilable for excitation. On smaller a-c. motors a system of regenerative ering in combination with solenoid load brakes is used.

Drum Versus Magnetic Controllers. — Both hand- and magnetic-con-l equipments are in general use. The former are satisfactory for small and ium-size motors, and consist simply of a drum-type controller with a set of arate resistances. For large-size motors too much physical effort would be uired to move a controller of the necessary size and the magnetic control ld then be selected. A magnetic-control equipment consists of a master troller, a contactor panel and the resistances. The contactor panel contains contactors for cutting in or out the resistances, the interlocks and the current-it relays for automatically controlling the sequence and rapidity with which contactors operate. The master-controller handle can be thrown to the full-ed position quickly without causing an overload on the motor, since the cur-t-limit relays automatically prevent the contactors from cutting out the istances too rapidly.

Dynamic Control. — With dynamic control of d-c. motors the field is arately excited and the armature is connected to the line voltage with one tion of a rheostat in series with it, and another section of the rheostat in allel with it. This is accomplished by means of the controller, whose duty to make each step on the lowering side keep the speed of the motor under trol no matter whether the motor has to drive a light hook downward or ld back against a heavy load. In the former case the current which passes ough the series rheostat also passes through the armature and produces the ired torque. The speed is controlled by varying the value of this rheostat e as in hoisting. If the motor has to act as a brake, the power generated in armature is expended in the parallel rheostat and the speed is controlled by ying this rheostat. In actual practice the two rheostats are varied simul-neously so that if a certain point on the controller tends to cause the motor to ve a load at a high speed it will also cause the motor to hold back at a high ed. The practical result is that an operator always has his load under con-l, and does not have to worry about dropping his load. On the lowering side the controller, a motor holds back against its load even when power fails, ause the motor then acts as a self-excited series generator, and consequently solenoid brake alone is not depended on to prevent the load from falling.

In the case of a phase-wound induction motor it is necessary to excite one rtion of the primary winding with direct current in order to generate a voltage the secondary winding. A rheostat is then connected to the secondary wind-s of the motor and the speed can be controlled as with d-c. motors. As direct rent is necessary for excitation dynamic braking is not very often used with crane motors.

Digitized by Google

Solenoid brakes are also provided for holding the load when the hoist mo is stopped. If dynamic braking is not provided, mechanical brakes must provided in addition to the solenoid brakes to assist in holding the load when motor is stopped and for regulating the speed when lowering.

Solenoid brakes are, as a rule, applied by gravity when the armature curren shut off and released by the solenoid which is energized when the controlle thrown on the first notch. The solenoids of direct-current motors are gener connected in series with the motor circuit, although with polyphase induct motors they are connected directly across one phase thus receiving the full voltage.

All crane motors should also be protected by safety-limit switches arran to cut off the supply current when the limit of motion is reached and thus au matically provide against accidents from over-travel.

SPECIFICATION FOR ELECTRIC CRANE. — The following me randa are intended to assist in writing specifications. See also *Specification*

Principal Characteristics and Conditions of Service. — Span betw crane rails and load to be lifted on main hoist and on auxiliary hoists, if a Characteristics of current, a-c. or d-c. (phases, cycles and voltage).

Style and Description of Apparatus. — Structural work of open-hea steel according to some standard steel specifications. Maximum stresses allo able. Whether hand operation is to be provided for. Distance of hook fr crane rails, vertically and horizontally, when at extreme limits of its mot Details of brake. Description and characteristics of motors to be suppli Whether or not a foot-walk is to be supplied. Whether trolley is to be ab bridge or submerged. Hoisting drum to have bronze bearings. Track wh shall have chilled treads, ground true, with double flanges, and shall be ke to their axles. Axle bearings shall be bronze. Details of lubrication bearings. Location of carriage. Details of control. All gearing (exc when shrouded) shall be cut, etc. Wiring details. Controller details.

Dimensions. — Supply a diagram of clearances.

Work Done by Other Contractors. — Track rail and weight thereof.

Performance and Tests. — Speeds of main travel, lateral travel and hoi Time to get up speed or acceleration rates.

COST OF CRANES (Pre-war figures). — The cost of cranes depends so great an extent upon the design, motor equipment, etc., that no relia average figures can be given. As a rough approximation the cost of a ha operated traveling crane may be taken as from about 5 to 7 cents per pound total crane weight and the cost of an electric traveling crane as from ab 10 to 13 cents per pound of total crane weight.

ROSS ARMS. — (*See also Poles for Overhead Lines; Insulator Pins; nsulators.*) Cross arms are usually of wood though sometimes of iron. ack arms" or "reverse arms" are cross arms attached to a pole at right gles to the principal arms, and are used for taking off wires at right angles the line, either at the junction of intersecting lines or at services. "Double ms" are pairs of cross arms attached to opposite sides of a pole so as to act one compound arm. Double arms are used to increase the strength of an m and to permit the use of two pins and two insulators for supporting a ge wire where additional strength is required.

Cross arms are used principally for supporting pins, insulators and wires, ough lightning arresters, transformers, switches and other miscellaneous pliances are often mounted on them, usually for the purpose of keeping the e free of incumbrances so that it will be more easy to climb.

Alley Arms. — When city distribution lines are located in alleys it is common locate poles next to the property line. Where it is not permissible to let ms overhang private property special arms may be used which extend on one le of the pole only. These must be well braced and should not be used for d ending wires. A better construction is obtained by locating two poles on posite sides of the alley and putting special cross arms across the alley be- en them.

ORCES ON AND STRESSES IN CROSS ARMS. — The forces which ss arm resists are:

(a) Vertical forces due to weight of pins, insulators, wires (with sleet) and idental loads due to linemen standing on arms, etc.

(b) Transverse horizontal forces due to wind pressure on the wires (with at right angles to the line.

(c) Longitudinal horizontal forces due to the pull of the wires where the pull unbalanced. Unbalanced pull is usually due to an angle in the line, the end- of the wire at the arm, a change in the size of wire at arm and an unequal sion in the spans on the two sides of the arm.

The principal internal stresses produced in an arm from these forces are:

(1) A bending force in a vertical plane due to vertical forces (a).

(2) A bending force in a horizontal plane due to horizontal forces (c).

(3) A twisting force about the longest axis of the arm due to the "pin lever- e" of the horizontal forces (c). The pin leverage is the distance from the ter of the wire to the axis of the arm.

Of these stresses the most destructive is probably the twisting stress which ds to split the arm in a vertical plane through the pin holes and along the in of the wood. On this account the pin and insulator should be no taller an necessary, the pin should extend completely through the arm to give the st distribution of bearing pressure and, where stress is heavy, the arm may strengthened by two "strengthening bolts" (machine bolts with nut and shers) put horizontally through the arm one on each side of the pin, one being ar the top and the other near the bottom of the arm.

The vertical and horizontal bending stresses are of some importance and may computed by the usual beam formula (*see Structures, Simple*). Data of tests strength of cross arms for these stresses are given below.

Strength Tests of Cross Arms. — (*Forest Service, Cir. No. 204.*) Tests made 3¾ in. by 4¼ in. by 6 ft., 6-pin air-dried cross arms with vertical load distributed ually at each pin hole gave the results at top of next page.

The tests showed that for ordinary use the strength, for vertical loads of 6-pin ms, need not be considered in calculations of line construction, except in the re case of abrupt change of the grade of the line.

Longleaf pine, 50 per cent heart	8,980
Shortleaf pine, creosoted	7,650
Douglas fir	7,590
White cedar	5,200

DIMENSIONS AND RATING. — Cross arms are rated in terms of number of pins they are designed to carry, 2-pin arms being the minimum 10-pin arms the maximum ordinarily used.

Cross-section. — When arms are made directly from the original logs t are sometimes dimensioned in even inches, i.e., 4 in. by 5 in., 5 in. by 7 in., In most cases they are made from lumber in stock and when finished are a quarter of an inch or more under the even sizes. Several "standard" dimensions have been adopted for distribution arms. In the accompanying table Standard I is that given by Miller (*American Telephone Practice*) and found in various catalogues of dealers in electrical supplies. It is the standard of the American Elec Railway Engineering Association for light service cross arms. Standar is that given in Report of Committee on Overhead Line Construct of the National Electric Light Association, and Standard III is that of American Electric Railway Engineering Association for heavy service cross a

Size of arms	Width, inches	Dept inch
Standard I....	3¼	4½
Standard II....	3½	4½
Standard III....	3¾	4½

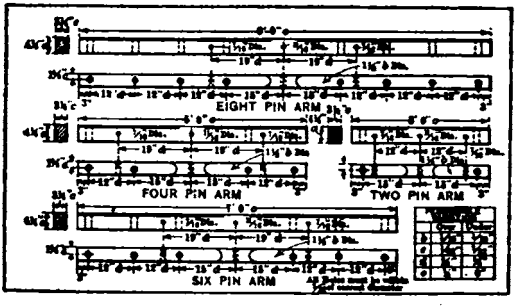

Fig. 1. Standard I Cross-Arms

Distance between Pole Pins. — It is desirable to have the space betw pole pins (i.e., the two pins on opposite sides of the pole) as large as poss to give a clear space for climbing the pole. It usually varies from 16 in 30 in.

Digitized by Google

Distance between Other Pins. — This usually ranges from 10 in. to 21 Under ordinary circumstances 12 in. has been found sufficient to prevent s on adjacent pins swinging in contact in the middle of the span. Where ll wires (such as No. 10 telephone wires) are used on long spans (150 ft. ore) contact is to be expected occasionally where 12 in. spacing is used.

Distance from End Pin to End of Arm. — This is usually 3 or 4 in., ich is about the minimum that can be used without the arm splitting due to leverage.

h order that a line may have a neat systematic appearance it is desirable that pin spacing be the same for all arms, whether 2 pin, 4 pin, etc. In the tabula- s below the arms included in each standard (defined above under *Dimensions Ratings*) have been grouped on this principle which shows that Standard I ly consists of one regular group and 5 odd arms while Standard II consists 2 regular and 1 odd arm. Referring to Standards I and III it will be noted t the length of arm is always a multiple of one foot.

STANDARD DISTANCES BETWEEN PINS

Standard	Group	Number of pins	Length of arm	End pin to end of arm	Between pole pins	Between other pins
			Ft. In.	In.	In.	In.
	Regular	4	4 0	4	16	12
	Regular	6	6 0	4	16	12
	Regular	8	8 0	4	16	12
	Regular	10	10 0	4	16	12
I	Odd	2	3 0	4	28	..
	Odd	4	5 0	4	18	17
	Odd	4	6 0	4	22	21
	Odd	4	6 0	4	24	20*
	Odd	6	8 0	4	18	17½
	Odd	8	10 0	4	17½	15⅝
	Regular	4	5 7	4	30	14½
II	Regular	6	8 0	4	30	14½
	Odd	8	9 2	4	30	12
	Regular	2	3 0	4	28	..
	Regular	4	5 0	4	28	12
III	Regular	6	7 0	4	28	12
	Regular	8	9 0	4	28	12
	Regular	10	11 0	4	28	12

* Alternative found in some catalogues.

Pin Holes. — 1½ in. diameter is standard for wood pins. N.E.L.A. specifications require that holes shall be tested with steel gauges taking one of the nominal size without forcing but not taking one 1/32 in. larger.

Bolt Holes. — For fastening the arm to the pole there is usually one 1 1/16 or 1-in. bolt hole at the middle of the arm. For fastening cross-arm braces there are two 5/8 or ¾-in. bolt holes located 38 in. apart (Standard II) or 40–42 in. apart (Standard III).

High-tension Wooden Cross Arms.—These are not standardized but are specially designed and made as required. They differ from distribution arms in being wider and deeper with larger pin holes and wider pin spacing. The

following tabulation will give data on some arms that have been used for diffe voltages.

Voltage	Number of pins	Width of arm	Depth of arm	Length of arm	Spacing of pins	Pin ho diamet
		Inches	Inches	Inches	Inches	Inches
25,000	2	6	6	64	48	2¼
55,000	2	5	7	88	72	2½

Special high-tension arms are usually unnecessary for circuits of 5500, 6 11,000 and 13,200 volts. Standard 2200-volt distribution arms may be u the wire spacing being increased by not using certain pins. Thus a stand 2200-volt 6-pin arm may be used for a 11,000-volt 4-pin arm by leaving middle pin holes vacant. For higher voltages the strength of arm and siz pin hole is usually insufficient.

SPECIFICATIONS. — (*See article on Specifications.*) The points to covered in a set of specifications are:

Material. — Usually pine or fir, sometimes western hemlock. (*See Poles Overhead Lines.*)

Quality of Material. — Usually should be "straight grained, free from kr (or free from large, loose or unsound knots), sapwood, pitch pockets, shal checks, loose heart, rot, worm holes or other defects." The strictness of specifications, or of the inspection, must, however, be governed in these respe by local conditions. In some localities a quality of material can be obtai cheaply, and should be required, which would be unreasonable to expect wh wood is expensive.

Wood should be dried before manufacture. (When arms are dried af drilling, the pin holes become elliptical, i.e., smaller across the grain, due shrinkage of the wood and the pins do not fit well.)

Dimensions, Pin holes, etc., as noted in preceding section.

COST. — The cost of cross arms is subject to considerable variation a depends largely upon the locality in which they are purchased. The follow figures are rough approximations and are exclusive of freight.

APPROXIMATE COST OF CROSS ARMS

DAMS. — (*See also Hydraulics; Hydrology; Power Stations; Structures, Simple*). A dam is a structure built to interrupt a stream's flow and raise the level of the water, thereby impounding water which may be used for power development, water supply, navigation, irrigation or numerous other purposes.

Coffer-dam. — A dam built for the purpose of holding back water from an area, which would otherwise be flooded, and making it accessible for construction purposes, is called a coffer-dam. It is generally a temporary affair.

Diversion Dam. — This name has been applied to dams built for the purpose of diverting the whole or a portion of a stream into a side channel or pipe line by which it is conducted to one or more places where it is used for power or other purposes.

Storage Dam. — A storage dam is built for the purpose of storing flood waters for use during periods of low stream flow. In many power developments a storage dam is essential to continuous output. Storage dams are sometimes used as diversion dams.

Wing Dam. — In swiftly flowing streams having steep slopes, a diversion dam is sometimes built out from one shore diagonally upstream toward the other, but not to it. This special form of diversion dam is known as a wing dam.

Classification with respect to Materials and Design. — According to the materials used and the design, dams may be classified as:

Wooden dams	Masonry dams
Earth dams	Solid gravity
Rock dams	Hollow gravity
	Arched

By a **gravity dam** is meant one in which the force of gravity is relied upon for resisting the thrust and overturning moment of the water. Earth and loose rock dams, timber cribs and most masonry dams are of this type.

By an **arched dam** is meant one which in plan forms an arch, convex to the up-stream side. The ends of the arch terminate in the valley walls, which thus act as abutments to the arch so formed.

Often a gravity dam has been built in the form of an arch, using the possible arch action as a factor of safety, and depending wholly on the gravity action to resist the thrust of the water. Many of the highest dams in existence are so constructed and are generally in localities where the stream's valley is relatively narrow and deep.

LOCATION AND HEIGHT OF DAMS. — For power developments the location of the dam depends largely on the topography and geological formation of the site. The total fall in a stream to be utilized for power may be developed in whole by a dam or in part by a dam and in part by a canal, flume or pipe to the power-house. Thus the location and height of the dam is fixed by economic considerations to develop the whole head at the least cost, consistent with safety and reasonable operation and maintenance expense. The cost of lands to be overflowed has considerable influence.

WOODEN DAMS. — Wooden dams are made in a variety of forms. The most common form of wooden dams consists of a crib of timbers filled with broken rock and covered on the top and up-stream face with wooden sheeting.

EARTH DAMS. — A typical earth dam is indicated in Fig. 1. No dam is absolutely watertight. The successful construction of a dam of any type embodies the condition that leakage or seepage will not be sufficient to endanger

Digitized by Google

the structure or its foundation and that an excessive amount of impound water will not be wasted.

An earth dam and its foundation must be made sufficiently tight that seepage of water through it will not be great enough to move the minute partic of which it is composed.

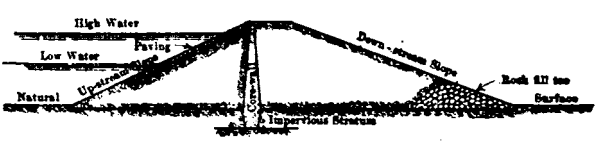

Fig. 1. Typical Earth Section

Materials and Details. — The materials used in the construction of ea dams are loam, sand, gravel and clay of various proportions. The dam is appr imately trapezoidal in section, having a top width and side slopes which determined by the materials used. The best of the available materials used to provide a selected impervious part. The impervious part or core m be placed near the upstream face; but, as impervious materials are relative unstable when saturated, the core is usually placed in the center of the da and supported on each side by the more stable pervious materials. The dow stream toe is often built of loose rock or otherwise well drained to preve slipping when saturated by water seeping through the dam.

Cores of masonry, clay puddle or other materials are sometimes built in t center of the dam, extending into the foundation to an impervious stratu Timber cores above the water gradient are not sufficiently durable for a perm nent structure. Masonry core walls usually have a top width of from 2 to 4 fe with side batters of ½ to ¾ inch per foot down to the foundation, but, if w reinforced may be much thinner. There is a divergence of opinion amo engineers regarding the practical use of masonry corewalls for earth dam However, it has not been shown that they impair the safety of the dam and th are often imperative to guard against burrowing animals.

The downstream slope of the dam should be protected from rain scour b sodding or seeding it. For long slopes, provision is often made for draining the rain water by building berms, a few feet wide every 30 feet or so on the slop containing gutters for lateral drainage.

Riprap, hand laid paving or masonry is used on the upstream face to prote it from the action of waves and ice. Solid paving should be laid on a layer well-drained broken stone or gravel to prevent internal pressure on the pavi when the pond is drawn down rapidly.

Dimensions. — The top width of the dam is often determined by requir ments for a roadway. Where not so fixed it may be made approximatel equal to one-fifth the height of the dam plus five feet. The top of the da must be built sufficiently high to prevent overtopping by waves during extrem high water.

Simple rules cannot be given governing the side slopes of earth dams. Fro the nature of the materials available, this angle of repose when placed in th dam must be determined by tests or practical experience. The upstream fac is continually saturated and the downstream face is more or less damp, render ing the materials less stable than when in a dry embankment. High dams ar usually given flatter slopes than low dams and often the lower part has flatte slopes than the upper part. Low dams often have up and downstream slope

Digitized by Google

to 1. The Ticitus Dam (New York State) is 110 feet high, has an upstream pe of 2.4 to 1 and a downstream slope of 2.5 to 1 with a 30 foot top width. Gatun Dam (Panama) is 115 feet high, has an upstream slope of 4 to 1 a downstream slope of 16 to 1 with a top width of 100 feet. It is thus seen the variation in practice is very great, depending upon the nature of the erials and the methods of placing them in the dam.

Foundations. — In preparing the foundation for earth dams the surface is stripped to a depth sufficient to reach sound material, and all loose stones, mps, roots, etc., removed. If the foundation is rock, the surface is cleaned and in making a good bond with the earth. The foundation should be mined for perviousness. If deemed necessary, one or more trenches should ng to an impervious stratum and refilled with impervious material. Between earth dam and a rock foundation is a plane of weakness which is usually rded against, in the absence of a masonry corewall, by building several low ls of masonry across the site to resist seepage of water along the rock surface.

Construction of Rolled Earth Dams. — The material for rolled earth ms is placed in layers 6 inches to 12 inches thick and well rolled with a rowed roller or otherwise compacted while damp. Sprinkling may be essary during the compacting process. It is often provided that each shed layer shall be harrowed and dampened to provide a bond with the t layer above.

Hydraulic Fill Earth Dams. — Hydraulic fill earth dams are constructed sluicing the materials into place. If available material is found at an ele- ion higher than the crest of the dam and other conditions at the site are orable, the materials are washed out of the borrow pits by a stream of water der heavy pressure, collected by the flow of the water and transported by ity through sluices to the site. The materials are discharged from the ices near the edges of the dam where the coarser particles, possessing the atest angle of repose, remain. The balance of the material is washed by e water towards the center of the dam, the particles depositing automatically d progressively according to size until only the finest particles reach the center the dam. Here a pond of water is allowed to remain through which the fine terials settle to form an impervious core.

When the materials are not located at an elevation sufficiently high to permit sluicing to the site, they are transported by cars, carts or other means to e edges of the dam and sluiced into place as above described by streams of ter.

The greatest difficulty in the construction of hydraulic fill dams is to obtain core which is composed of sufficiently fine materials to make a tight dam and ll possess adequate stability for a firm structure. If the material in the core too fine to drain properly as the construction progresses, it will exert virtually liquid pressure on the outside embankments which may be sufficient to cause em to slip. The degree of fineness in the core can be regulated by adjusting e elevation of the pool at the center of the dam, the deeper the pool the finer e size of particles deposited in the core.

ROCK DAMS. — In localities where earth is not available, broken rock as been used in the construction of dams. The rock fragments are of a size hat can be most conviently quarried and handled. Such dams are made tight by masonry corewall at the middle of the dam or on the upstream face. The atural angle of repose of loose rock is about 1 to 1 but the side slopes of rock lams should not be steeper than 1½ to 1 unless the face is hand laid to a con- iderable thickness and in any case not steeper than 1¼ to 1.

Digitized by Google

MASONRY CONCRETE DAMS. — During the latter part o the century, rubble masonry was used extensively for the construction f d but in recent years this type has been practically superseded by plain nd forced concrete. In massive structures cyclopean concrete is gener: ly consisting of plain concrete containing a liberal percentage of large ton "plums." The usual mix for masonry dams consists of 1 : 3 : 6 (cle concrete for solid gravity and large arch dams; 1 : 2 : 4 to 1 : 2½ : 5 f inf concrete for thin arch dams; 1 : 2 : 4 reinforced concrete for decks a d s of hollow dams and 1 : 2½ : 5 to 1 : 3 : 6 reinforced concrete for butt ess hollow dams. Special provision for water tightness must be made, par icul for solid gravity dams where water pressure in horizontal joints incr ases overturning moment to be resisted.

Foundations for Masonry Dams. — Most masonry dams over 30 high require solid rock foundations. From this all soil and disintegra ed is removed and the surface scrubbed clean. All cracks and fissures at the and for some distance above it must be located and grouted. Often, in rock, a longitudinal trench is taken out and refilled with masonry to form impervious barrier to the passage of water. This is placed at the upstr face or heel of the dam (see Fig. 3).

For dams on earth foundations, a masonry or sheet piling cut-off is bu into the foundation at the heel of the dam extending down to a stratum impervious material. Where this is impractical, undermining by seepage m be prevented by providing a path of enforced percolation of sufficient leng This varies from 5 to 18 times the head on the dam according to the materia of the foundations. The proper length of path may be obtained by one or mo cut-offs, by a downstream apron, by an upstream apron or by a combinati of these. The length of the path of percolation, as affecting uplift and ero force is the length of the actual plane of contact between the structure and t earth including aprons and both sides of all cut-offs, providing the cut-offs a not closer together than twice their depth. The foundations below the da must be adequately protected from wash by proper paving.

Dimensions and Cross-sections of Solid Gravity Dams. — Typical hi solid gravity non-overflow and spillway dams are indicated in Figs. 2 and

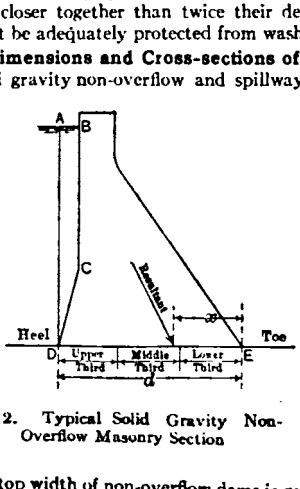

Fig. 2. Typical Solid Gravity Non-Overflow Masonry Section

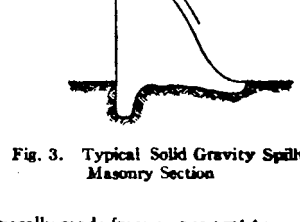

Fig. 3. Typical Solid Gravity Spillwa Masonry Section

top width of non-overflow dams is generally made from 10 per cent to 14 pe of the height of the dam and is placed at or a few feet above high water su

Digitized by Google

. For spillway dams the top is made approximately parabolic to conform the natural path of the water as it leaves the crest. If the descending sheet free of the face of the dam, a partial vacuum will occur behind it and the spheric pressure on the upstream side will become effective as an overturning . The curve or "bucket" at the downstream side of the base is for the pose of deflecting the water and protecting the foundation. This may be ted for low dams on hard rock.

he proportions of the section below the top are possible of mathematical rmination once the forces acting on it are known. A common method is "cut and try" by which a profile is first assumed and then investigated h regard to the conditions of stability previously given. It is then adjusted l again tested until it results in a satisfactory section. It is customary to rt at the top and design the dam progressively towards the base.

l series of imaginary horizontal joints are arbitarily assumed. When the on has been tested for stability at the highest joint and has been properly sted to conform to the conditions of stability, the section of the dam is d and is not influenced by the design of the lower part of the dam. The on above the next lower joint is then tested and adjusted by changing slope of the up- or down-stream faces or both between that and the ning joint. The section to this joint is then fixed and other joints treated ke manner. This method of design applies to all types of gravity dams. ction below on *Forces Acting on Dams.*

llow Concrete Dams. — A hollow concrete dam consists of an inclined ing of reinforced slabs or arches resting on a series of parallel buttresses

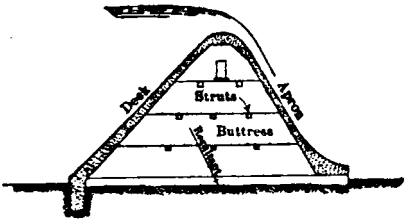

Fig. 4. Typical Hollow Gravity Spillway Section

ch have their footings on the foundations. Fig. 4 shows a section of such m designed for a spillway. With a low dam and rock foundation, the down-am decking or apron may be omitted and the face made vertical.

ability against overturning and sliding is obtained by providing a con-rable batter to the upstream face, thereby obtaining a large vertical com-ent of head water pressure to add to the weight of the structure.

rched Concrete Dams. — A typical arch dam is indicated in Fig. 5. A e of this type consists of a single masonry arch spanning the valley and is pplicable to narrow sites having steep rocky sides.

rch dams are usually treated as sections of simple cylinders and the thick-s at any elevation determined by the equation

$$t = \frac{pr}{s},$$

Digitized by Google

where t = the required thickness in feet,
p = the horizontal load on the dam in pounds per square foot,
r = the radius of the dam in feet,
s = the allowed unit stress in pounds per square foot.

As the arch is fixed at the base and at each end, the actual stresses are in enced by expansion and contraction due to changes in temperature and mois

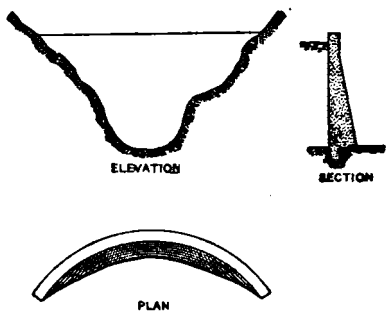

Fig. 5. Typical Arch Dam

contents, contraction due to setting of the concrete and the application of loading, variations in span and radius at different elevations and other consid tions. Theoretical analysis of these influences are considered by most engin to be impractical and allowances for deviation of stress from that indicated the foregoing equation is made in the adoption of low working stresses. T stresses should not exceed ⅛ to ¹⁄₁₂ the ultimate stress of the masonry or f about 30,000 to 40,000 pounds per square foot.

FORCES ACTING ON DAMS. — The forces usually considered in design of dams are water pressure, earth or silt pressure, ice pressure, weigh the dam and the reaction of the foundation. One linear foot is usually con ered in the design of solid dams and the distance center to center of buttre in hollow dams.

Water Pressure. — The weight of water per cubic foot is usually ta equal to 62.5 pounds.

It facilitates computations if the horizontal and vertical components of water pressure are considered separately instead of the resultant pressure.

When the water surface is at or above the top of the dam, the total horizo pressure, in pounds is,

$$P = 62.5\frac{(h_2^2 - h_1^2)l}{2},$$

where h_2 and h_1 are the vertical distances in feet of the bottom and the top the dam respectively below water surface, and l is the length in feet of d considered in the design. The location of the resultant horizontal press above the base of the dam is

$$x = \frac{3h_1h + h^2}{6h_1 + 3h},$$

where h is the height of the dam.

Digitized by Google

the water surface is below the top of the dam, the total horizontal pressure is

$$P = 62.5\frac{h_3^2 l}{2},$$

e h_3 is the depth of water in feet. The location of the resultant above the of the dam is

$$x = \frac{h_3}{3}.$$

vertical faces the vertical component of water pressure is zero; but for ned faces the vertical component is the actual weight of water $A\,B\,C\,D$ 2), directly above the face. The resultant vertical water pressure passes ugh the center of gravity of $A\,B\,C\,D$.

he uplift pressure per square foot of the base of solid dams, due to water ing through the dam, is,

$$p = 62.5\,ch_c,$$

re c is the percentage of the area assumed to be subjected to uplift. The d. h_c, is considered to vary uniformly from headwater pressure at the heel to l water pressure at the toe. The value of c cannot be unity unless the dam re earth foundations. For rock it has been assumed variously from zero to % according to the nature of the foundation.

Total uplift pressure is,

$$P = 62.5cdl\frac{h'_2 + h''_2}{2},$$

ere h'_2 and h''_2 are head and tail water pressures respectively, d is the width d l the length of the base.

The distance of the resultant uplift pressure from the heel of the dam is,

$$x = \frac{2h'' + h'}{3(h'' + h')}d.$$

ift is also considered as existing in any horizontal building joint as well as at base. Drains are sometimes placed in dams to reduce possible head water ft pressure. Head water uplift pressure is never considered to exist to an preciable extent in hollow dams. Uplift from tail water is always present.

Earth Pressure. — Submerged earth or silt deposited against dams exerts a ssure on the structure in addition to the water pressure. The amount and ution of this pressure can be determined by the ordinary methods for retain- walls if the weight and angle of repose when submerged are used. An approx- te method for determining silt pressure is to assume it a liquid weighing 5 pounds. It will then exert a pressure equivalent to additional water pres- e of the same depth.

Ice Pressure. — Much uncertainty exists in the determination of ice pres- e on dams. Pressures amounting to 47,000 pounds per lineal foot of dam e been used in the design of important dams in cold climates. The con- uction of the gorge above the dam has considerable influence on the possible thrust. The reader is referred to the late C. L. Harrison's paper on this ject (*see Bibliography*).

Weight of the Dam. — The weight of masonry varies from 130 to 165 nds per cubic foot. The weight most commonly adopted for concrete is 140 to 150 pounds per cubic foot.

Digitized by Google

Reaction of the Foundation. — The resultant of all forces acting on dam, including the weight of the dam, must be balanced by an equal and oppo reaction of the foundation.

Requirements for Stability. — A dam may fail by sliding, by overtur or by crushing of the materials in the dam or the foundations. This may o at the base or at any horizontal plane above the base. Sliding has been kn to occur on clay-filled seams below the base after the foundation near the has become eroded by the flowing water. A dam must therefore be inv gated for stability at various elevations, considering for each elevation those forces acting above it as though the base of the dam or a horizontal b ing joint actually existed at that elevation. The following are the fundame conditions for the design of gravity dams.

(*a*) At any elevation the resistance to sliding shall be greater than the h zontal component of all forces acting on the dam above that elevation. A sion of the dam at any horizontal joint or at the base is not considered exce an additional factor of safety. The angle that the resultant of all forces m with a vertical line must therefore not exceed the angle of repose of mas on masonry or masonry on the material composing the foundation, as indic by laboratory tests of smooth specimens. The natural or artificial rough of rock foundations and projecting plums in horizontal joints provide the ne sary margin of safety. For dams on good rock the tangent of the angle of inc tion of the resultant force with the vertical should not exceed 0.75. For d on earth foundations the tangent should not exceed 0.1 to 0.2, depending the materials, or the dam should be well anchored to deep cut-off walls piling.

(*b*) To prevent overturning, the resultant of all forces above any joint pass inside the extremity of the joint. To provide a margin of safety an prevent the existence of tension the resultant must intersect the joint at a tance from the extremity equal to at least one-third the width of the joint. other words, the resultant must fall within the "middle third" of the j and this applies to the condition of full or empty reservoirs, as tension is al objectionable. It can be shown that, if the resultant falls within either out third of the joint, tension will exist at the opposite side of the dam.

(*c*) The compressive stresses in any part of the dam must not exceed working values. The unit stress on any joint is assumed to vary as a stra line from the heel to the toe. If the resultant force intersects the joint a exact center, the unit stress will be uniform over the joint. If the resul intersects at any other point, the stress will be a maximum at the edge of base nearest the point of intersection and a minimum at the other end.

In Fig. 2, let

p' = the unit *vertical* stress at E;
p'' = the unit *vertical* stress at D;
x = the distance from the resultant to point E;
d = the width, DE, of the joint;
l = the breadth of the joint;
w = the vertical component of all forces on the dam above the joint inc ing uplift at the joint;
p'_u = the unit uplift at point E;
p''_u = the unit uplift at point D.

Let these quantities be expressed in feet or pounds per square foot. T if the resultant intersects the joint within the middle third and the joi rectangular,

$$p' = \frac{2w}{ld}\left(2 - \frac{3x}{d}\right) + p_s',$$

$$p'' = \frac{2w}{ld}\left(\frac{3x}{d} - 1\right) + p_s''.$$

he maximum *inclined* stress in the dam may be twice the value given by e equations for *vertical* stresses. Therefore due allowance must be made in selection of working *vertical* stresses or the maximum inclined stresses mined by extended calculations.

ertical pressures should not exceed ½1 of the ultimate strength of the masonry, om about 16,000 to 22,000 pounds per square foot.

PPENDAGES TO DAMS. — The more common appendages to dams the following:

hice Gates. — As their name implies, these are large gates placed in the l for the control of the water level, or for relieving the dam in times of flood. mmon type of gate is the so-called Tainter gate, which is slightly curved revolves about its axis of curvature. A later improvement on this is the ll gate, which permits of finer regulation.

Flash Boards. — These are light boards, or their equivalent, placed on the p of the spillway held in position by light rods or frames. Their object o temporarily increase the height of the dam during the dry season so as to serve the water which would otherwise be wasted over the spillway at times en the wheels were not running. They are made light not only to facilitate idling, but also that they may give way quickly in emergency before a dan- ous head could be created by sudden flood.

Log Runs. — On any stream where the driving of logs is practiced, it is gen- lly a requirement that provision be made in a dam for the sluicing of logs. is is accomplished by a chute or trough placed generally near the spillway, th its upper end slightly below the pond level and closed by a sluice gate. this the logs are guided by log booms fastened to the dam and cribs along shore.

Fish-ways. — A fish-way is a gradual incline connecting the water below dam with the pond above. A constant stream of water passes through it th a velocity against which the fish may readily swim. This is sometimes tained by using baffles across a portion of the stream, leaving a passageway the side. The slope of a fish-way should not be greater than 1 in 4 and its ds should be well beneath low water level. Fish-ways are generally more or s covered in order to protect the fish from interference, but should never be ole dark, as they would not be used by the fish. Fish-ways are generally quired by State law on all natural water ways.

COST OF DAMS (Pre-war figures). — It is difficult to give items of cost r dam construction, due to the great influence of local conditions. As earth bankments should not be attempted in places where material is not available ar the site, the figures for unit cost may be fairly well approximated. Exca- tion in earth will cost from 20 to 30 cents per cubic yard; embankment 25 to cents; puddle cores 45 to 70 cents; hand-laid paving $2.00 to $3.00; rip-rap .50 to $2.00; sodding 20 to 30 cents per square yard. Figures for masonry sts depend largely on the ease with which the materials may be brought to e site. The following figures serve to show approximately the unit costs der conditions normally favorable. Rock excavation $1.00 to $2.00; rubble

DEMAND METERS. — (*See also Ammeters; Ampere-hour Meters; W hour Meters; Wattmeters.*) For some time past various attempts have b made to inaugurate systems of charging for electric energy which would more equitable to both the consumer and the central station than a flat kilo or kilowatt-hour rate. The so-called "maximum demand system" has fo favor with many, and may find a much more general application.

The system is based on the fundamental assumption that the charge to consumer should be made up of two parts; one part fixed by the maxim power in watts demanded by the consumer at any time during a certain defi period, and another part fixed by the total energy in kilowatt-hours used du the same period. The object of the demand system of charging is the impro ment of the load factor of the station and the more equitable distribution o fixed charges among its customers.

Demand metering cannot be regarded as an exact science, because of large number of variables involved and the various ways in which they e the problem. These include the capacity of generators, lines and transform and the diversity factor, load factor, and power factor of the system. No p tical meter can be devised to take care of all these variables, consequently char based on the use of demand meters in addition to the usual energy meters m necessarily be somewhat arbitrary.

Requirements of a Demand Meter. — The kilowatt-hours supplied the consumer are readily measured by a watthour meter (q.v.); to record maximum power (kilowatts) taken by the consumer, various forms of "maxim demand meters," usually called simply "demand meters," have been devis In the case of a practically constant d-c. voltage at the consumer's premise device which measures the maximum current is as satisfactory as one wh measures maximum power, but when the voltage or power factor (in case of a-c. system) varies, the maximum current indicator is not suitable.

In any case the device should be one in which the demand measured is the instantaneous peak of the load demanded by the consumer, but is the av age of the power demanded over an appreciable time interval, for the maxim demand recorded should not be influenced by short-circuits, excessive curr flow in starting motors, or by any abnormal consumption of energy that cov too short a time to have any real effect on the capacity which must be provi by the central station to take care of the demand.

The time interval over which the demand should be taken should theor cally differ with the character of the installation and the relation of the maxim power demanded to the maximum capacity of the central station. In relativ large consumers' installations the time should be carefully chosen with ref ence to the time that the central station can endure an overload successfu Hydroelectric plants have a very definite power limit which is reached w maximum gate opening, while steam-power plants have considerable ther inertia and their boilers and generating apparatus can usually carry relativ large overloads for a considerable time. These considerations require m shorter time intervals for large users of hydroelectric power than would necessary in steam plants of corresponding magnitude.

Demand intervals of 15 minutes, 30 minutes, and 1 hour are those in gen use at the present time. For very special installations, intervals as short 1 minute and as long as 3 hours have been used. The general tendency is to the use of a single interval for a given system, and toward the use of inter larger than those formerly used.

On account of the desirability of improving the load factor, the off-p system has been developed, which gives a preferential rate to customers u

current during the times of low load on the central station. Demand meters ng time of day as well as demand are used for this class of metering.

he general subject of demand meters has received considerable attention ng the past five years and many devices have been developed and placed he market. The whole question of charging for electric service, including ecessary devices to be used, is still in a transition state, and is complicated the inclusion of the power factor and balance of the customer's load as ele- ts in determining the cost of supply.

lassification of Demand Meters. — Demand meters may be classified) (1) curve-drawing instruments, giving the load-time curve of the installation; integrated-demand meters, consisting of an integrating meter combined h a device which registers the energy consumption from time to time in such ay as to indicate or record the maximum demand; (3) lagged-demand ters, which require a certain time interval for the indication to reach the value responding to the load. Under each of these types there are a number of ther distinctions, such as length of demand interval, whether the demand rvals begin at specified times of the day or may be so chosen as to include the ximum average load during any time interval of the given length, and whether maximum demand is simply indicated without reference to time or is recorded hat the time of its occurrence may be determined. Some of the types of meters in commercial use are briefly described below.

Curve-drawing Instruments as Demand Indicators. — (*See also Watt-ter*.) The most complete knowledge of the conditions attending the con- er's use of energy may theoretically be obtained by using a curve-drawing ttmeter, with which the average demand for any time interval may be found d also the time at which it occurred. This statement, however, requires siderable modification in practice. Unless the paper speed is fairly high, e lines will run together so as to make it difficult or impossible to determine e demand with any approach to accuracy. Curve-drawing wattmeters are expensive in first cost for any but comparatively large installations, and e of the simpler and cheaper devices described below is ordinarily used. The fications of a curve-drawing wattmeter are difficult of comprehension for the inary customer who knows nothing of integration. Such wattmeters are d largely by central stations to accumulate demand data. Curve-drawing meters may be used on the assumption of constant voltage and power factor, t do not give as accurate information as wattmeters.

Integrated-Demand Meters Indicating Maximum Demand Only. — he Type M-4 demand meter of the General Electric Company consists essen- lly of a demand-registering and a timing mechanism mechanically connected d mounted within the same case. The demand-registering element is electric- ly operated by means of a contact in the register of the watthour meter in con- ction with which the demand meter is used. The registering element consists a train of gears which drive a demand pointer forward over a dial. This ain is actuated by a ratchet and pawl mechanism operated by an electromag- t which receives an impulse every time a certain amount of energy is regis- red by the watthour meter. The speed of advance of this pointer is therefore portional to the power. In order that the meter may show the demand for iven time interval, it is necessary that the pointer-driving mechanism shall reset to zero position at the end of each time interval, leaving the pointer lf in the highest position reached. This resetting is accomplished by a e hanism controlled by a constant-speed motor similar in construction and peration to the motor element of an induction watthour meter. This demand ter is for use on a-c. circuits, and is arranged for intervals of 15, 30, or 60 inutes. The Type M-5 demand meter for d-c. circuits is similar to the pre-

ceding, but has an 8-day keywind clock to give the time interval. The T
M–6 demand meter differs from the M–5 in having a small d-c. motor to k
the clock movement wound. The latest development of this series is the I
demand meter register, Fig. 1. This replaces the standard register of either

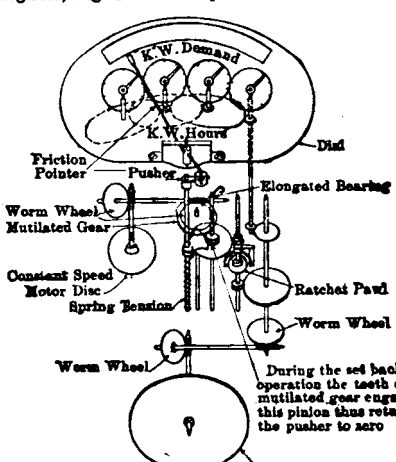

Fig. 1. Type M–7 Demand Meter Register.

I–14 or D–6 watthour meter. In addition to the usual four kilowatt-h
dials, it contains a demand dial. The principle of operation is the same
that of the other demand meters of the Type M series, but the timing devic
a small disk-type constant speed induction motor built into the register.
the M–7 the demand registering mechanism is thus mechanically connec
to the watthour meter, instead of electrically as in the preceding Type M dema
meters. When new I–14 or D–6 watthour meters are supplied with this fu
of demand register they are called respectively Type IM–14 or DM–6 wa
hour demand meters.

The Type RO watthour demand meter of the Westinghouse Company i
combination of induction watthour meter, induction wattmeter, and an esca
ment mechanism. The auxiliary disk of the wattmeter is located in the sa
air gap as the watthour meter disk, and tends to move against the torque o
spring. This tendency is checked by an escapement controlled by the rotati
of the watthour meter disk. The auxiliary disk thus advances step by st
at a speed proportional to the load until the driving torque is equal to the spri
torque. Starting from zero, the time required to reach equilibrium on a
constant load is a constant, since the deflection and the rate of deflection va
in direct proportion. The auxiliary disk drives a demand pointer through a d
and a ratchet holds it in the highest point reached, until released by hand.
second ratchet allows the auxiliary disk to fall back to the position of equilibri
with the spring tension whenever the load drops, but prevents it from advan
ing except as controlled by the escapement.

**Integrated-Demand Meters With Arbitrary Time Interval, Recordi
all Demands and Time of Occurrence.** — The earliest instrument of t

was the printometer, later made by the General Electric Company as the : P demand meter. This instrument is designed to print on a paper tape guiar time intervals the time of record and the consumption of energy up nt time, the energy consumption being that registered by a watthour r connected to the circuit. The instrument contains a set of cyclometer wheels which are moved forward at a rate proportional to the rate of energy mption in the circuit. This is accomplished by a solenoid, the energiz- ircuit of which is closed through a contact wheel fixed to one of the spindles e gear train of the watthour meter. The reading of the cyclometer is printed paper tape (see Fig. 2) by a rubber platen and a copying ribbon, the rubber n being actuated by a solenoid which is energized at regular time intervals eans of a contact making clock. The time is also printed opposite each

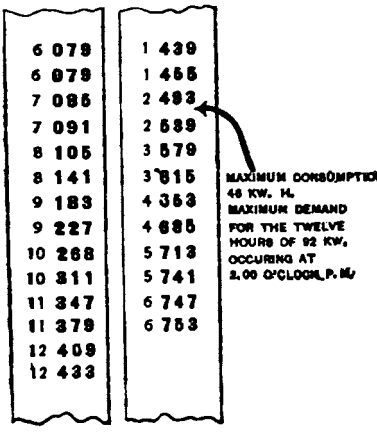

Fig. 2. Record Made by Type P Demand Meter.

ometer reading. Thus, the difference between consecutive records on the pe is proportional to the energy consumption in watt hours in the circuit ring a definite time interval. The average demand over a period of time, responding to the interval between successive operations of the printing lenoid, is obtained by dividing the watthours of energy consumption during time interval by the length of the interval.

The Type RA recording-demand watthour meter of the Westinghouse Com- ny consists of a polyphase watthour meter combined with a mechanism for taining a permanent graphic record of the integrated demand over successive determined time intervals. The total energy consumption is shown in the ual way by the register of the watthour meter. The time interval is con- lled by a clock which requires winding once a month. A separate spring chanism advances the record paper. The pen is moved across the paper by e gear train of the watthour meter, and at the end of each time interval a lease mechanism frees it from the gear train and allows a weight to move it ck to zero where it is again meshed with the gear train to repeat its advance ring the next time interval. Just before the release occurs, the record paper advanced slightly (see Fig. 3) so that the pen makes a distinct record of the aximum travel, which is a measure of the integrated demand. The time of

occurence is shown by the time figures printed on the paper. This met made with time intervals of 15, 30, or 60 minutes. It is a self-contained ture, with the metering and demand-recording mechanisms mechanically nected.

The Piek demand instrument, which was the forerunner of the Type demand meter, is very similar to the latter, but uses the same clock to esta the time intervals and to drive the chart.

The Type G demand meter of the General Electric Company is used in nection with a watthour meter, and gives a graphic record on a circular of the demands integrated over definite time intervals, with the time of and day of week of their occurrence. It consists essentially of a regist element and a timing element. The registering element is electrically conne

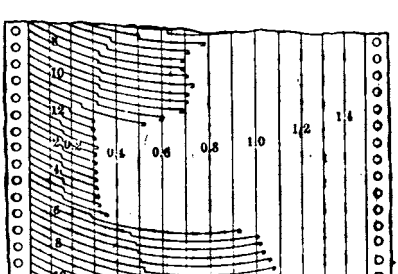

Fig. 3. Record Made by Type RA Recording Demand Watthour Meter.

to the watthour meter, which has a contact device on one of the spindles of register. This contact device alternately makes and breaks the circuit solenoid in the registering element each time that a definite amount of ene is registered by the watthour meter. An armature operates a ratchet and p mechanism to advance the stylus by a small step for each operation of the tacts. At the end of each time interval a cam mechanism operated by the ing device allows the stylus to return to the zero position, where it is re-enga ready to integrate the energy used in the following interval. The timing mech ism rotates the chart continuously, giving a record in the form of a saw-to polar curve. The chart gives a record for one week. The time interval is eit 15, 30, or 60 minutes.

Integrated-Demand Meters Recording Time and Equal Amou of Energy, Non-Arbitrary Time Interval. — The Ingalls demand records operated in connection with a watthour meter. It contains a clock wh uniformly advances a tape upon which a mark is made by a printing sole energized through contact in the meter register. Each mark corresponds t predetermined amount of energy. The number of marks in a given time int val is proportional to the average power.

Thermal-Storage Lagged-Demand Meters. — These meters all al maximum demand only, and the indication depends on the duration of the l as related to the "demand interval" of the meter, as well as on the previ history of the load. The demand interval of this type of meter is usually tal as the time required for the indication to reach 90 per cent of the full value e steady load which is thrown suddenly on it. In principle, all such meters differential thermometers.

Digitized by Google

le **Wright demand** indicator, manufactured by the General Electric Com-, is a **differential** air thermometer having one of the bulbs surrounded by a ing **element.** The expansion of the air in this bulb drives a liquid over into iduated **tube,** giving a measure of the ampere demand. It is suitable for n constant-voltage circuits, either direct current or alternating current nstant power factor. It leaves no record of the duration of the maximum nd nor of the time at which it takes place. After the indicator has been there is no original record of previous maximum demands.

le Type H—2 demand indicator of the General Electric Company is an re-demand instrument also based on the differential thermometer prin-, but using a pair of strips of thermostatic metal. One of these is in prox-y to a heating element traversed by the load current, while the other nomi-y follows the room temperature. The two strips tend to move in opposite ctions, and with no current flowing through the heating device the pointer ains at zero in spite of changes in room temperature. Current flowing ugh the heating device heats the adjoining strip and moves the pointer r the scale. The pointer remains at the highest point reached until manually e.

he Westinghouse Type RH demand meter employs the principle of the hot-r wattmeter, and thus takes account of watt demand. It contains two heat-elements which tend to move a demand pointer in opposite directions. The rical arrangements are such that the difference in the heating is propor-nal to the power in the circuit, and the thermal capacity of the heating ele-nts makes the reading depend also upon the storage of heat in them. The and pointer remains at the highest point reached until manually reset.

Overdamped-Wattmeter Lagged-Demand Meter. — The Type W poly-se demand indicator of the General Electric Company consists essentially a polyphase watthour meter with a system of springs opposing the rotation he disk and thus converting it into a polyphase wattmeter. A large number damping magnets are used, giving heavy overdamping and preventing the er from recording demands of short duration. The rotation of the disk inst the opposing springs moves a demand pointer forward, and this pointer ains at the highest point until manually reset. This type of demand meter ow but little used.

Demand Devices Taking Account of Power Factor. — The increasing reciation of the effect of low power factor on the cost of energy supply is ining to show in the development of demand devices taking power factor account. For example, the Westinghouse Company has made an instru-t consisting of two Type RA watthour demand meters in one case with r charts interlocked and driven by the same clock. One of these meters is nected to record power demand and the other records reactive-component rand. The same object is also attained by the General Electric Co. with Type P demand meter used in connection with a watthour meter and a ctive voltampere-hour meter.

COSTS. — The following figures are approximate and are intended as a gh guide.

RECIATION. — Depreciation is loss of value due to expiration of use-
fe. It is brought about by wear and tear and the action of the elements
l eventually make replacement necessary. *Service value or serviceability*
ar may not suffer diminution as depreciation accrues. Depreciation does
roperly include loss of value due to accidental damage, to obsolescence,
adequacy or to price changes. Replacements due to accidents such as
ay be covered by insurance. If not, they should be charged directly to
ition or amortized over a reasonable period. Replacements due to obso-
ce or inadequacy should be financed from the savings resulting from the
f the more modern or adequate equipment. As for market or price changes,
impossible to show property on the books at its value under constantly
ating prices. The accounting problem involved in making replacements
id at changed price levels is discussed below. Depreciation as specifically
ed * is accrued liability to replace and it involves four problems which may
scribed as follows:

First, *physical*, to determine the amount of the liability at any time and the rate of its accrual.
Second, *financial*, to make provision for meeting the liability.
Third, *accounting*, to keep the proper records.
Fourth, *management or regulation*, to determine the effect of the accrued and accruing liability on the economic position of the enterprise whose assets are under consideration.

HE PHYSICAL ASPECT. — A piece of property whose useful life has
d has suffered depreciation to the extent of the difference between its
e when new and its scrap value. This difference is called the wearing
e. Various assumptions may be made as to the distribution of the depreciа-
over the life of the property, but the usual practice is to assume it uniform.
a the annual depreciation is equal to the wearing value divided by the life
ears. The accrued depreciation at any time is equal to the product of the
al depreciation and the age in years.
ore the extent and rate of depreciation must be known while the property
ll in service, if proper provision is to be made for replacement, the life used
letermining the annual depreciation must be a prediction. Such a predic-
can be made only on the basis of experience, and is a subject for the best
neering judgment, since many factors, such as severity of use, quality of
erial and of workmanship, and climatic conditions, must be considered.
les of lives of various classes of property have been prepared, but should be
l with discretion, since they are unreliable, for the following reasons among
rs. First, many of the renewals considered by the compilers to be due to
reciation were due to obsolescence or inadequacy. Second, improvements
he arts are continually increasing the durability of many classes of equip-
t. Third, replacements are at times postponed past the time when true
omy would dictate replacement because of the financial situation of the
ing company, and as a result, the experience recorded becomes an unreliable
le. In the bibliography appended reference is made to tables of lives which
be used as a guide to judgment.
requently it is desired to create a reserve which will provide for replacing
perty made up of parts having different lives whose independent replace-

* The term "depreciation" has through use by courts and regulatory commissions
e to have the specific and somewhat narrow construction defined above. In gen-
usage, the word "depreciation" denotes decrease in value from any cause, but
mission is here confined to the more technical use of the term.

Digitized by Google

ments are to be charged to depreciation, and it is desired to place a lif piece of property as a whole. This is properly done by dividing the su wearing values of the parts by the sum of their annual depreciations, the being the composite life. The weighted average life of the parts, the v figures being the wearing values of the respective parts, cannot be use of the composite life defined above. To be correct, the average life further weighted by the relative frequencies of renewal of the respecti The test of a composite life is that the wearing value of the property covers shall, when divided by it, give the annual depreciation for t property. This the first method assures, but the second does not.

The scrap, or salvage value of a piece of property is a subject for en estimate. The expense involved in preparing for market and marke scrap is a deduction from the scrap value but the cost of removing th be replaced is a charge to operation.

In certain types of property, life can better be measured in service u in time units. However, in the case of a large and varied property, thi of general application, forms the most satisfactory basis for computing tion.

As the operation of a property continues, the engineers responsible f mining depreciation must constantly check up and revise their opinions lives of various units, basing their conclusions on the frequency of r due to depreciation, as proved in practice. The rate of accrual of dep should be refigured from time to time on the basis of these studies. At an estimate should be made of the depreciation accrued on the prope making this estimate it must be understood that accrued depreciation o liability to replace is a physical fact, independent of the assets accrued the liability as reflected by the balance sheet, and the estimate must b titative statement of that physical fact, as nearly as it can be determine

THE FINANCIAL ASPECT. — As depreciation and the co replacement liability accrues, it is necessary to build up assets to offse this end a portion of the revenue derived from the operation of the should be retained by the corporation for that purpose. Building u to offset the depreciation liability gives assurance that the property will tained in its full usefulness and earning power in so far as these are gov its physical condition. In public utility mortgages, it is frequently that a certain percentage of the gross operating revenue shall be exp reserved for the maintenance of the property. Such provisions ha thought to be particularly necessary where, (*a*) operation cannot be disco (*b*) property cannot be removed to another location, (*c*) scrap or recove of physical property is so small a proportion of original cost as to be of n importance to the creditor. These reasons, while controlling with the do not prove the value of this method of measuring maintenance and tion requirements.

Building up assets offsetting accruing replacement liability serves tain the equity of the stockholders as well as to protect the physical and the earning power of the creditor's security. If the funds required care of replacement are paid out in dividends a partial liquidation tak which may or may not be sound business, but in any event the fact s clearly understood by all concerned, and clearly reflected by the books of

In the case of a property made up of many parts having different liv time, after the initial construction, will all parts be new at once. T the assets reserved to offset depreciation will never all be needed for f replacements. From this it may be argued that it is necessary to rese enough funds to meet such abnormal amounts of replacement expendi

sionally occur. Under this plan no distinction would be made between ntenance and depreciation, so much each month being set aside out of ne, the amount being revised from time to time as found necessary, and all maintaining the property paid out of the reserve. If this plan is followed st be recognized that the company's assets have been allowed to decrease that the depreciated value of the property, plus the reserve, is less than its nal cost. This consideration is particularly pertinent in the case of a lated utility.

reserving funds for effecting replacement due to depreciation various hods are used for determining the amount to be periodically set aside. metimes it is made a fixed percentage of the gross receipts. Sometimes it is nform amount arbitrarily fixed. These methods have only simplicity to mmend them. The correct system is to make the reservations in accord- with the accrual of depreciation as determined by the engineers. Two hods have been generally used. One is the straight line method in which set up for each piece of property is equal to the wearing value of that piece perty divided by its life. The other is the sinking-fund method in which set-up for each piece of property is of such amount that, when the piece of perty has reached the end of its life, the sum of the set-ups made on its unt shall, with the compound interest accumulated on those set-ups, equal wearing value. In the second case the reserve fund must be credited period- ally with interest upon accumulated balances at the rate used in computing set-ups. This interest may be charged either against income or surplus. latter method is well adapted to the case of regulated utilities, as will be ussed later.

The assets set aside or retained to offset depreciation may be handled in ious ways. Specific assets, such as bank deposits and interest-bearing securi- s may be designated as a depreciation reserve fund, and kept equal to the reciation liability as shown on the books, or the offsetting assets may be ed to remain a part of the general assets and used in the business. The ter method is usually preferred, since a going concern can, as a general thing, ve a larger return from capital used in the business than in that invested side. However, care must be exercised that there is always a sufficiency of ck assets to meet any sudden demand. In theory, when expected replace- ts become necessary, they may be financed by borrowing money on the erity of the property in which the reserve against depreciation has been sted. This, however, is not generally practicable due to the provisions of r liens.

The Accounting Aspect. — It is highly important that the accounting atment of depreciation reflect accurately both the lessening of remaining life physical plant and the financial plan by which provision is being made for lacement. The accounting processes involved are primarily: (*a*) Current ges to depreciation reserve either by charges to income or appropriation of plus.* (*b*) The crediting of interest to the reserve where current reservations calculated on the sinking fund basis. (*c*) The segregation of assets against reserve liability or funding. (*d*) The auditing of charges against the reserve the purpose of determining their propriety in the light of the basis on which dits to the reserve have been made.

There is not always a clear distinction between maintenance charges to be ded in current operating expenses, and replacement charges to be made

*In the case of a company which has not from the beginning made provision for lacement of physical property, and in which considerable depreciation has already rued, the initial charge in establishing such a reserve, if it is to cover depreciation rued, must be against surplus.

against the reserve. The final test must always be whether or not th has been built up from credits calculated to cover charges such as th question. In a business where assets are progressively exhausted, as in of a mine, the reserve account may be dispensed with by making the dep credits direct to property. This practice is not proper in the case of a co enterprise.

Expenditures which serve to increase the investment in a prop chargeable to construction. When a piece of property is replaced by which by reason of greater size, superior quality, or higher price level co than the original piece, the procedure is as follows, assuming that an equal to the wearing value of the original property has been accrue depreciation reserve. The amount realized from scrap or salvage is cr the depreciation reserve to bring the amount in the reserve up to the full cost of the item to be replaced. The original cost is then written out of and plant account and depreciation reserve concurrently reduced. Th of the cost of the replacing unit is then added to property and plant acc result being to increase property and plant account by the excess cost of property. In case the new property costs less than the old, there will credit to property and plant. This is sound accounting, since the account should represent the actual cost of the existing property at all

In case the piece of property is replaced for reasons other than depr the depreciation accrued should be charged against the reserve, and the re of the cost of replacement cared for in other ways. For example, if a mated to last 30 years is accidentally destroyed at the end of 10 years, on of its cost will have been accumulated in the reserve. The balance of the at which the car is carried in the property account must either be appr from surplus, charged to operation, or set up as a suspense item, and a over an appropriate period. The latter method would be used ordina in cases where large amounts are involved. The proper division of ch such cases involves engineering judgment.

Reference has been made to periodic engineering estimates of the accrued depreciation. These estimates should be used to check the ba

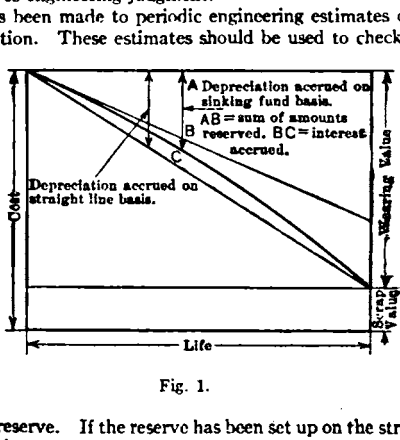

Fig. 1.

the depreciation reserve. If the reserve has been set up on the straight li and the accrued depreciation estimated on the same basis, the two shou general agreement. If the reserve has been set up on the sinking fund should be somewhat smaller than the depreciation estimated to be acc the straight line basis since in the case of any given piece of property, the

als including interest will be more rapid in the latter part of its life than in
arlier part. (See Fig. 1.) If the reserve is found to be too large or too
l by a substantial amount, the amounts currently reserved should be
ased or increased with the object of bringing the balance in the reserve
into line. Usual practice does not provide for accumulating an amount
e reserve in excess of original cost less salvage, therefore cost of removing
nit to be replaced must be charged to operation.
he foregoing comments on the accounting aspects of depreciation further
e the engineering problems involved, rather than accounting procedure.

The Management or Regulatory Aspect. — In the case of property
in unregulated competitive business, the value at any time is the cost at
nt prices of a property which can be used for the same purpose, less the
ued depreciation, the latter being computed as the product of present cost
salvage, and the percentage of expired life. It is necessary to deduct the
eciation in order to obtain a measure of the service which can still be
ained from the property. It is necessary to know the rate of accrual of
eciation in order that the management may know whether or not the busi-
is presently profitable and to know the accrued depreciation in order that
balance sheet may show the true condition of the property.
In the case of regulated utilities, frequently, though inaccurately, described
non-competitive, value is fixed by a regulatory body subject to judicial
view. No final rule of general application has been enunciated, though vari-
elements of value have been specified and defined. It is generally agreed,
ever, that, in any event, the rates allowed must provide for current operat-
expenses and reserve for depreciation, before they can provide for return on
value fixed. Since the function of the depreciation reserve is to provide for
acement at original cost, (increases or decreases in cost being cared for
ugh capital account) "original cost," not "present value," is considered here.
the depreciation reserve accumulates and is invested either in extensions to
utility's plant, or independent thereof, it furnishes a source of income aside
n that earned by the original property.
f the reserve has been set up on a straight line basis, the original cost of the
erty, plus the assets which offset the reserve, less depreciation accrued,
s the original investment. If the offsetting assets are invested so as to
a return equal to that allowed on utility property, it is fair to fix the earn-
from utility operation so as to yield a return on the property at its
ciated value, but if this is done the earnings of the reserve are a part of the
porate revenues and should go to the owners. But it is seldom possible to
vest so advantageously and still fulfill the essential requirement of having
assets readily available for financing replacements. If a return is allowed
the undepreciated cost of the property, then the income from the invested
ve should be considered part of that return and the balance collected in
n. If, however, the depreciation reserve is set up on a sinking fund basis,
earnings of the reserve are needed as a part of the reserve, and are not
ilable as return. Then the company must be allowed in rates a return on
undepreciated cost of its property. As the income from the reserve appears
porate income, the interest payments to the reserve should be made out
rporate income. Since normally a part of the reserve will be invested in
ity property, and part in quick assets, the interest rate used in calculating
its to the reserve must be a compromise between the return allowed on
ity property and that obtainable from quick assets.
In cases where the depreciation reserve is less than the accrued replacement
ity, to the extent that returns to investors have been excessive, it may
rly be considered that partial liquidation has occurred. Where returns

have not been excessive and rates have been insufficient to permit full rese tion to cover replacement liability, equitable consideration must be give that fact.

Calculations. — The following notes are illustrative of the calculations ne sary to determine the proper amounts to be currently reserved for the pur of financing replacements.

Let C = cost of property,
S = scrap value,
n = life in years,
r = annual interest rate,
A = annual reserve credit,
M = monthly reserve credit.

Then, on the *straight-line* basis:

$$A = \frac{C-S}{n},$$

$$M = \frac{A}{12} = \frac{C-S}{12n}.$$

On the *sinking fund* basis:

Assume first that the reserve credit is made annually and interest is cred annually, then:

Case I.—If interest *is* allowed each year on that year's reserve credit, set-up made at beginning of year:

$$A = (C-S)\frac{r}{(1+r)^{(n+1)}-(1+r)}.$$

Case II.—If interest *is not* allowed each year on that year's reserve credit, set-up made at end of year:

$$A = (C-S)\frac{r}{(1+r)^{n}-1}.$$

Assume next that the reserve credit is made monthly and interest is cred monthly, then:

Case III.—If interest *is* allowed each month on that month's reserve cre *i.e.*, set-up made at beginning of month:

$$M = (C-S)\frac{\frac{r}{12}}{\left(1+\frac{r}{12}\right)^{(12n+1)}-\left(1+\frac{r}{12}\right)}.$$

Case IV.—If interest *is not* allowed each month on that month's rese credit, *i.e.*, set-up made at end of month:

$$M = (C-S)\frac{\frac{r}{12}}{\left(1+\frac{r}{12}\right)^{12n}-1}.$$

Illustrative Example: Cost of property $1000. Net scrap value $200. I 10 years. Interest rate on depreciation reserve 4%.

On the straight-line basis:

$$A = \frac{1000-200}{10} = \$80,$$

$$M = \frac{80}{12} = \$6.67.$$

Digitized by Google

On the *sinking fund* basis:

Case I.

$$A = (1000 - 200)\frac{.04}{(1.04)^{11} - 1.04} = \$64.07.$$

Case II.

$$A = (1000 - 200)\frac{.04}{(1.04)^{10} - 1} = \$66.63.$$

Case III.

$$M = (1000 - 200)\frac{.00\frac{1}{2}}{(1.00\frac{1}{2})^{121} - 1.00\frac{1}{2}} = \$5.41.$$

Case IV.

$$M = (1000 - 200)\frac{.00\frac{1}{2}}{(1.00\frac{1}{2})^{120} - 1} = \$5.43.$$

In large enterprises it is the usual accounting practice to make credits to the reserve each month. It will be seen that the difference between the monthly reserve credits determined under Case III and Case IV are less, in proportion, than the probable error in the life assigned to the property.

Composite Life. — A piece of property is made up of two parts. The first part has a wearing value of $2000 and lasts 20 years; the second part has a wearing value of $1000 and lasts 10 years. Depreciation reserve is credited on the straight-line basis:

W. V.	Life	Annual Set-up
2,000	20	100
1,000	10	100
3,000		200

The composite life is 3000 divided by 200 = 15 years. If life is weighted by wearing value, it averages as follows:

W. V.	Life	Product
2,000	20	40,000
1,000	10	10,000
3,000		50,000

The weighted average is 50,000 ÷ 3000 = 16⅔ years. Dividing the wearing value by this gives 300 ÷ 16⅔ = $180 for the annual reserve credit which is sufficient by $20. If frequency of rewewal is introduced we have the following:

W. V.	Relative Frequency of Renewal	Product	Life	Product
2,000	1	2,000	20	40,000
1,000	2	2,000	10	20,000
		4,000		60,000

The weighted average is 60,000 ÷ 4000 = 15 years, which is correct.

RIVATIVES. — (*See also Equations, Differential; Integrals; Maxima and ima; Series, Mathematical*).

ifferentials. — Let y be a function of x, i.e., a quantity which varies tinuously with variations of x. If x be increased or decreased by the smallest ant conceivable, y will change by a correspondingly small amount. Such ll variations are called "differentials," and are symbolized thus: dy and dx, ere d is not a quantity but a symbol meaning "the smallest conceivable ue of" y or x.

Derivative or Differential Coefficient. — The ratio $\frac{dy}{dx}$ is the rate of nge of y with regard to x and is called the "derivative" or "differential fficient" of y with respect to x.

Geometrical Meaning of a Derivative. — If a curve be plotted between nd y for any equation $y = f(x)$, and a tangent drawn to the curve at any nt, Fig. 1, then the tangent of the angle θ between

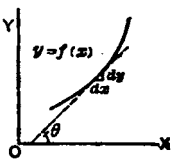

Fig. 1

s tangent and the axis of x is equal to $\frac{dy}{dx}$.

Differentiation. — Differentiation is the process of taining the derivative of a function. If $y = f(x)$

$$\frac{dy}{dx} = \frac{df(x)}{dx}$$

$$= \frac{f(x+dx) - f(x)}{dx}.$$

Example. — If $y = ax^2$

$$\frac{dy}{dx} = \frac{a(x+dx)^2 - ax^2}{dx}$$

$$= \frac{a\,dx\,(2x+dx)}{dx}$$

$$= a\,(2x+dx).$$

dx is the smallest conceivable value of x, it is so small compared to x that it y, with the smallest conceivable error, be neglected. Hence,

$$\frac{dy}{dx} = 2ax.$$

Formulas for Differentiation. — (u, v, x and z are variables; a is a constant.)

$$\frac{d}{dx}(u+v) = \frac{du}{dx} + \frac{dv}{dx}$$

$$\frac{d}{dx}(au) = a\frac{du}{dx}$$

$$\frac{d}{dx}(uv) = v\frac{du}{dx} + u\frac{dv}{dx}$$

$$\frac{d}{dx}\left(\frac{u}{v}\right) = \frac{v\frac{du}{dx} - u\frac{dv}{dx}}{v^2}.$$

Digitized by Google

When x is itself a function of some other variable s,

$$\frac{du}{dx} = \frac{du}{ds} \cdot \frac{ds}{dx}.$$

TABLE OF DERIVATIVES

Function $f(x)$	Derivative $\frac{d}{dx} f(x)$	Function $f(x)$	Derivative $\frac{d}{dx} f(x)$
x^n	nx^{n-1}	$\tan^{-1} ax$	$\frac{a}{1+(ax)^2}$
$\sin ax$	$a \cos ax$	$\sinh^{-1} ax$	$\frac{a}{\sqrt{1+(ax)^2}}$
$\cos ax$	$-a \sin ax$	$\cosh^{-1} ax$	$\frac{a}{\sqrt{(ax)^2-1}}$
$\tan ax$	$\frac{a}{\cos^2 ax}$	$\tanh^{-1} ax$	$\frac{a}{1-(ax)^2}$
$\sinh ax$	$a \cosh ax$	$\log_a x$	$\frac{1}{x} \log_a e$
$\cosh ax$	$a \sinh ax$	$\log_e x$	$\frac{1}{x}$
$\tanh ax$	$\frac{a}{\cosh^2 ax}$	$\log_{10} x$	$\frac{0.4342944819}{x}$
$\sin^{-1} ax$	$\frac{a}{\sqrt{1-(ax)^2}}$	a^x	$a^x \log_e a$
$\cos^{-1} ax$	$-\frac{a}{\sqrt{1-(ax)^2}}$	e^x	e^x

Note: See also Table of Integrals in article on *Integrals* noting that the col there headed "Function" is the derivative of the column headed "Integral."

Second Derivative. — The derivative of a derivative, i.e., $\frac{d}{dx}\left(\frac{dy}{dx}\right)$, is ally written $\frac{d^2y}{dx^2}$. Similarly $\frac{d}{dx}\left(\frac{d^2y}{dx^2}\right)$ is called the third derivative and is wri $\frac{d^3y}{dx^3}$, and so on.

SPATCHING OF TRAINS BY TELEPHONE. — (*See also articles Telephony.*) Up to 1907 train dispatching was done almost entirely by the graph. In that year the telephone began to replace the telegraph for purpose. At the beginning of 1920, 83 railroads in the United States, rating 120,000 miles of line, had abandoned telegraphic train dispatching in r of the telephonic method.

Telephone train dispatching has many advantages over the former method. dispatcher's work consists in the main of gathering information and issuing rs for train movements. These operations are much quicker by the use of telephone and are no less accurate. Special training in the use of the apparas not as necessary as when telegraphy is employed. All the agencies are ught into closer personal relations, with the result that there is better coation and better discipline. The dispatcher can call and speak at the same e, which is impossible by telegraph.

It now is possible to operate dispatching lines as long and with as many stations railway conditions may permit. The length of line and number of stations not limited by the nature of the electrical equipment. Lines of 300 miles gth are in operation, and 65 stations on one line are in successful use. More n 65 stations could be operated successfully if desired.

Dispatching circuits are multi-station lines, like the telegraph-dispatching es they displace. Broadly speaking, they are selective party lines, but are pped with systems of apparatus which allow the placing of many more staons on a line than is possible with any other party-line system so far developed. Several train-dispatching systems are on the market, the principal ones being own as the Gill System, the Western Electric System, the Cummings-Wray tem, and the Kellogg System. These are in general similar in that the dister has means of calling any station selectively. In some systems he can l several stations at once by setting keys for them in advance and operating ommon calling key.

Each way station is equipped with a device called a selector. These selectors n be operated only by the dispatcher. They work on the step-by-step principle d the whole object of the device is to close a contact at the station called and s to ring a bell. No provision is made for cutting the way-station telephone on and off the line, as secrecy is not aimed at. Any way station may comnicate with the dispatcher at will by lifting the telephone receiver. The patcher wears a head telephone constantly and so listens upon the line at all es.

Train orders are written as given and received and are read back to the disher by each station, the dispatcher underscoring each word once for each rect repetition from a way station.

DISTRIBUTION LINES. — (*See also Conduits and Conduit Lines; L tribution and Transmission Systems; Transmission Lines; Wires and Cabl Wiring of Buildings.*) Two types of construction are employed, overhead a underground. Overhead construction has the following advantages (1) lo first cost, (2) easier to repair, (3) easier to change, (4) adaptability to hig voltages; while underground construction has the advantages (5) less unsight (6) less dangerous to the public, (7) less subject to damage by external agenci The majority of circuits in use are overhead. Underground circuits are pri pally used in the central portions of the larger cities. When undergrou circuits are used a large part of the construction consists of a composite of und ground and overhead construction.

MATERIALS FOR LINE CONSTRUCTION. — The principal eleme for wood-pole construction are the conducting wires, insulation on the wi insulators, tie wires, pins, cross arms, cross-arm braces, bolts, poles, guy wi guy anchors. For underground construction, see *Wires and Cables, Insulat* and *Conduits and Conduit Lines.*

Wires for Overhead Construction. — The conducting wires are usua of copper, sometimes of aluminum. Iron is not used as it costs more th copper for equal conductivity. Aluminum is used to a much less extent th copper; see articles on *Aluminum* and on *Copper*. Soft-annealed copper is u ally employed for ordinary distribution work, as it has the greatest conductiv and is the easiest to work with. Medium hard-drawn and hard-drawn wi are used in lines where great mechanical strength is necessary.

For overhead city distribution copper wires ranging in size from No. 6 B. & (or A. W. G.) to 500,000 circular mils are used; see *Wires and Cables*. Si larger than No. 0000 B. & S. are usually stranded. Conductors as small No. 14 B. & S. have been used for overhead work but are too small, as they frequently broken by wind and sleet.

Standard Sizes of Wire. — Of the gage numbers between No. 6 B. & and 500,000 circular mils (*see Gages, Wire*), some are but little used beca (1) the difference between consecutive sizes is less than is found necessary usual practice and (2) the difference is too small to be readily detected by ordinary lineman or stock keeper. In practice the number of sizes to be u and carried in stock has usually been reduced by omitting certain sizes: No. and 1 are nearly always omitted; practice regarding the omission of larger s varies. The most commonly used are No. 6, 4, 2, 0, 0000 B & S. and 500, circular mils.

Wires for Underground Lines. — See *Wires and Cables, Insulated.*

Covering on Overhead Wires. — Overhead conductors for city distri tion are covered with weatherproof braid. Two grades are recogni "double braid" and "triple braid," according to the number of coveri though the actual thicknesses are not the same for different makes. Do braid is considered suitable for use on voltages of 600 or less, and triple b for voltages up to 2500 constant potential and on series-arc circuits of voltages. To prevent the possibility of double-braid wire being used voltages over 600 and to reduce the number of kinds of wire used, it is g practice to have all No. 0000 wires and smaller covered with triple br Ordinarily cables larger than No. 0000 are not used on voltages above 600 may therefore be double braided.

Object of Covering on Overhead Wires. — The covering on o head conductors is solely for the purpose of limiting the short-circuit cur due to an accidental cross or grounding. The normal insulation of the lin

intained by the insulators alone (*see below*); any reinforcement obtained
m the insulation on the conductors is neglected in practice. While weather-
of braid is an imperfect insulator, it serves to eliminate the greater propor-
n of the short-circuits and arcs which would occur, due to momentary contact,
re bare wires used. Rubber and other more perfect insulators are not used
ause of expense and the impossibility of maintaining perfect insulation,
e to weakness, against mechanical injury and deterioration.

Bare wire is usually used on circuits operating at 10,000 volts and over to
oid giving a false sense of security. For voltages between 2500 and 10,000
atherproof wire is often used, though the protection afforded against short-
uits is doubtful.

Extra Cost and Weight due to Weatherproof Braids. — In estimating
e cost of a distribution line, the additional weight and cost of the weather-
of braids should be taken into account. The following is a rough comparison
bare, double-braided and triple-braided copper wire, the cost being based on
pper at 15 cents per pound.

OMPARISON OF BARE AND WEATHERPROOF COPPER WIRES

Conductor	Relative weights			Relative Costs		
	Bare	Double braid	Triple Braid	Bare	Double Braid	Triple Braid
No. 6 B. & S., solid	100	123	137	100	127	141
500,000 cir. mil cable	100	112	117	100	115	121

he cost and weight of weatherproof insulation for aluminum wires are greater
an for copper of the same conductance on account of the larger cross-section
conductor required.

Insulators for Overhead Lines. — City distribution circuits are ordinarily
arried on double-petticoat deep-groove glass (D.P.D.G.) insulators; see article
n *Insulators for Overhead Lines*.

Tie Wire. — The conductor is attached to the insulator by a tie wire of
e same material as the conductor, though soft wire is usually employed even
r hard-drawn conductors; the tie wire is either bare or insulated to corre-
pond to the conductor. The size of tie wire is often the same as that of the
nductor; for small wires it is merely a piece of conductor. With large
nductors it may be as much as three sizes smaller. See also the section on
stallation in the article on *Wires and Cables, Bare*.

Pins. — See article on *Insulator Pins*.

Cross Arms. — See article on *Cross Arms*.

Poles. — See article on *Poles for Overhead Lines*.

DESIGN OF CITY DISTRIBUTION LINES. — City distributing sys-
ms should be designed so that service may be given to any building in the
ty and ultimately to every building present and future. On certain streets
de lines may be omitted without defeating this object. The arrangement of
es which will serve scattered customers with the least number of poles will
nally contain many poles which should not be used if the ultimate arrange-

ment were immediately constructed. Preliminary studies and designs sho made, first, of arrangements suitable for servicing the initial expected cu ers, second, of arrangements for ultimately servicing customers on every the city, third, of a plan of extension by which the initial arrangement extended to the ultimate with the minimum expense in changing line services.

The Pole Line. — The pole lines perform two functions: (1) of ca feeders from the station to the mains and (2) of carrying the mains sup services to buildings immediately adjacent. In the old cities of the e part of the United States where the streets are crooked general rules fo tematic line work cannot be followed far. In the newer cities of the We South the streets are laid out at regular intervals and at right angles, di the city into rectangular blocks of equal size. In such cases the foll rules should be followed:

(1) A pole line should continue on the same side of the street throu its entire length and disconnected lines built in the same street should the same side, so that they may be connected when desired without cr the street.

(2) The spacing between poles should be an exact divisor of the lengt block (including cross street), giving a uniform number of poles per bloc

(3) Whenever the line crosses a street where there is, or may be, an secting line there should be a corner pole on the proper side of the inters street for making a junction.

These rules logically lead to the use of corresponding sides of all p streets.

When each block contains lots fronting on all four surrounding stree servicing of every lot in the city would require poles on all streets, thou the streets in at least one direction the lines may be discontinuous. Oft lots all front on the streets in one direction, which are laid out to be pri streets, in which case no service lines are necessary in cross streets, thou intervals connecting lines are necessary.

Trunk Lines. — Where the location of power house or subs is fixed, trunk lines must be laid out from such point, but often a study sible trunk-line arrangements made before the location of the power is fixed will show that other locations are more advantageous. If distril station (power house or substation) is centrally located, there should least four main trunk lines (of poles) from it, say north, east, south and A short distance from the station they should be divided into branches subdivided into smaller branches and finally merge into the service The trunk lines should be laid out: (1) on back streets where the large numerous and heavy wires and heavy guying will not be conspicuous, side streets or streets little built up so that interruption to service due in adjacent buildings will be infrequent, (3) on streets where there ar trees, (4) on streets where there are no jogs or offsets to weaken the lin require heavy guys, (5) on streets which lead directly to the section sup penetrate its center and intersect the maximum number of service lines. when the station location is excellently chosen these desirable conditio have to be compromised to a serious degree.

Street and Alley Service Lines. —With the symmetrical ar ment of lots described above there is often an alley through each block p with the principal streets. Under these conditions there is therefore a of two methods of laying out the lines: (1) run the lines on the principal servicing the houses from the front and (2) run the lines in the alleys ser

houses from the rear. The disadvantages of the first are unsightliness he poles and wires, difficulty of avoiding or of trimming shade trees; the dvantages of the second are discontinuity of alleys, proximity of buildings lammable barns and out buildings in residence districts and of windows and escapes in business districts) and lack of established grade.

omposite Distribution. — The most expensive and difficult part of an erground system is that for taking the current from the conduit to the cus-er's building. This includes underground secondary mains, transformers, tholes, service pipes and wires. Where it is necessary to remove poles n streets but not to remove overhead wires from private property the pole s are replaced by conduits which contain primary feeders and mains only. m the conduit in the street a small branch runs into the interior of each ck where the ducts (usually iron pipes) come to the surface at the foot of a minal pole up which the cables run. At the top the cables connect to over-d wires. The interior of each block contains a complete overhead dis-ution system of poles, transformers, secondary mains and services. Some-es the servicing is done from a single centrally located pole and at others re may be a pole line of several spans length running longitudinally through block. The most serious disadvantage of this method is that the poles and es frequently have to be on private property, where no permanent rights may obtained. Being dependent on concessions from one or more customers, the mpany does not have the independent position that a public service company ould in order to serve all equally and fairly. The poles and circuits are erefore often put up of insufficient size without proper guying.

The composite system has the advantage of the overhead system in less sightliness, less accessibility of public to high-voltage wires and less trouble om trees. In thickly built-up blocks its use results in a tangle of wires over ofs and along walls which may be as dangerous in case of fires or high winds an overhead system. The composite system is used (1) in small cities where e load density is small and (2) in large cities in an annular district between verhead and underground construction; in either case it is usually an inter-ediate step from overhead to underground construction.

Crossing of Waterways; Submarine Cables. — Where a distributing stem is divided by a navigable waterway the connection is usually made y submarine cables laid on the surface of the bottom, or better, below the rface in trenches dredged for the purpose. Cables may be single or multi-le conductors, the latter being usually used for alternating currents to avoid ductance due to wire armor of cable. Two conductor cables may conveniently e of concentric type to give a true circular exterior. In laying cables it is sirable to keep them approximately parallel. Where one crosses under an-ther it may be impossible to remove it. Each cable should be in a single length ithout joints, and the length should be made as short as possible, as repairs are ery difficult and often impossible. At ends unimportant cables may be brought p a pole and connected to overhead wires; important cables should land in a able house with suitable provision for disconnecting the cable or for transfer-ing the overhead circuit to a spare cable in case of trouble, and also with ghtning arresters. Submarine cables are weak links in a distribution system ut may sometimes be avoided by crossing channels at sufficient height to lear the masts of ships.

Calculation of Size of Wires. — The size to be used depends upon the oltage drop which should be permitted, considering the probable growth of he load. The following table of per cent voltage drop in the various lines is epresentative of ordinary practice.

Digitized by Google

	For light
	Per cent
House wiring	2
Service wires	2
Secondary mains	5
Transformers	2
Primary mains	5
Primary feeders	10

The drop in the feeders is usually compensated for by raising the volt the substation or power station or by using voltage regulators; see *Distr and Transmission Systems.*

Formulas for calculating the size of wire for a given length of line load and given distribution of load are given in the articles on *Trans Lines* and *Wiring of Buildings.* Due to the uncertainty regarding the p increase of load, a close calculation of the size of wire is seldom made, gineer relying largely on his experience and judgment, making only a calculation as a check. For overhead lines 500,000 circular mils is the largest size used on account of the difficulty of supporting a large greater conductance is obtained by installing parallel circuits. For ground lines No. 0000 B. & S. three-conductor cable is the largest si can be conveniently drawn into the ducts; 1,000,000 c.m. is the usual ma size of single-conductor cable used.

Effect of Diversity Factor. — It should be noted that in a distr circuit the maximum load on a feeder is less than the sum of the ma loads on the mains which it feeds, these in turn are less than the sum maximum loads on the transformers connected to these mains, and Therefore, whenever a circuit divides or subdivides, the aggregate s areas should ordinarily be greater after division than before. The tot in voltage from power house or feeding point to a customer's lamp or is also usually less than the sum of the maximum drops in the parts circuit which are in series (such as house wiring, services, secondary mai because these component drops do not have their maximum value s neously.

Stresses on Poles. — An overhead line is a framed structure. Th are struts resisting the weight of wires, including sleet on the conducto insulators, cross arms and transformers and the downward pull of t wires. The horizontal pull of the line wires is balanced by the hor component of the pull of the guy wires, which transmit it to the grou addition to being struts the poles resist certain bending stresses, bu should be but a small part of the normal horizontal tension of the The principal normal bending stresses are of two classes: (1) constant s due to the unbalanced pull of service and other wires which do no sufficient force to require guys, and (2) variable stresses, due to the the wind at right angles to the line on both the poles and the wires. also resist a twisting force where the tension on one side of an arm is than on the other, due to a difference in the number or weight of ending on the two sides. The poles, wires and guys should be so d that the bending and twisting forces on the poles are insignificant calculation of the strains produced in a pole is given in the article o *for Overhead Lines.*

rrangement of Wires on Poles.— The arrangement of wires is governed nechanical, electrical and practical considerations. For mechanical reasons desirable that:

The largest wires be on the lowest cross arm, in order to reduce the bend- itress on the pole to a minimum.

The largest wires be on the pins nearest the pole, in order to reduce the ting stress on the cross arm to a minimum.

The wires be arranged symmetrically on the two sides of the pole, espe- ly those which end at the pole, in order to reduce the twisting stress on pole to a minimum

or electrical reasons (which, however, are of minor importance) it is de- ble that:

. The wires of any one circuit be as close together as practicable (on adja- t pins), in order to reduce the self-inductance of the circuit.

. The wires of a three-phase circuit be arranged to form the edges of an ilateral prism and the wires of a two-phase circuit be arranged to form edges of a square prism, in order to render the inductances and capacities the wires respectively equal.

. The wires of different circuits be placed as far apart as practicable, in der to reduce their mutual inductance.

For practical reasons it is desirable that:

. The highest voltage wires be on the top cross arms and on the pins farthest m the pole, in order to reduce the danger of accident to linemen.

. The mains, which have the greatest number of taps, be on the lowest ss arms, in order to avoid danger of accidental crossing (with contact) of e wires.

. The arrangement be systematic throughout; this is absolutely essential r safe and economical operation.

As it is impossible to meet all of these conditions the actual arrangements ed are compromises and are governed by the relative importance attached the several desirable conditions. In some cases the electrical requirements 1 to (6) have been considered of most importance, resulting, for example, n arrangement subordinated to the idea that the three wires of a three- ase circuit must be arranged exactly in an equilateral triangle. It appears, owever, that these electrical requirements are really the least important of he considerations and that in most practical cases can be entirely neglected.

Transpositions. — Due to the effect of mutual electromagnetic induction *see Inductance*) an alternating or varying current flowing in one circuit will nduce a voltage, and therefore a current, in any parallel circuit; and due to the effect of mutual electrostatic induction (*see Capacity*) an alternating r varying voltage in one circuit will induce currents in a parallel circuit, even hough there is no metallic connection between the two circuits. It is possible, however, by properly transposing equal alternate lengths of the wires forming the two sides of each of the parallel circuits, to neutralize these effects. Fig. 1 shows diagrammatically a scheme of transposition whereby a two-wire circuit can be protected from both electromagnetic and electrostatic induction from a parallel circuit and vice versa, provided neither circuit is grounded. The more frequent the transpositions the more thoroughly are the effects due to inequality in the spacing of wires and poles eliminated. Transpositions cannot be made effective in eliminating inductive effects when either circuit is grounded, otherwise than at the neutral point. See also *Transmission Lines*.

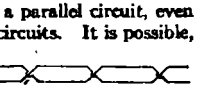

Fig. 1. Transposition of Two Two-wire Circuits

Digitized by Google

Methods of calculating the induced voltage and induced currents line due to currents and voltage in a neighboring line are indicated articles on *Inductance* and *Capacity*.

Disturbances in Telephone Circuits due to neighboring power are the most common results of electromagnetic and electrostatic ind When the power circuit is grounded and carries either (1) fluctuating currents (e.g., a d-c. railway) or (2) alternating currents it may pro noise in the telephone receiver, even though both the power circuit an phone line are transposed. See also *Telephone Lines*.

Trees. — Trees constitute the most serious obstacle to the proper pla construction and operation of overhead lines. The principal methods of ing this difficulty are (1) avoiding them, (2) going over them, (3) going them, (4) going through them. In most cases a combination of these m is used. Where trees are a serious factor it is necessary to examine the of every line in detail and the size and location of the trees may becom determining feature of the whole design. In such cases nearly all r good construction and systematic arrangements are violated in the in of expediency.

The methods by which trees may be avoided are: using alleys inst streets, or vice versa, choosing streets without trees for important lines, side of street with fewest trees, and finally the very bad arrangement of c the street back and forth to avoid the trees either individually or in group

The plan of going over the trees is the proper one in the case of all trees and is perfectly satisfactory until the trees grow up and touch the It is therefore only a temporary method, especially where the trees are quick growing varieties. In going over small trees it is well to have tall enough to allow for wires clearing after several years growth. It is u impracticable to go over large full-grown trees because of cost of pole sightliness of very tall poles, and the difficulty of properly guying th resist wind and the unbalanced pull of wires, which is magnified by the leverage. It is also difficult or impracticable to take off service wire the tops of tall trees.

In the case of very large trees it is sometimes practicable to take the under the trees on short poles. Where the wires pass the trunks it m necessary to spread them or necessary to pass between large branches, insulators fastened to the trees to maintain clearance. While such a lin be kept fairly clear under normal conditions, there is apt to be trouble storms from branches falling on the wires or from limbs bent by wind or touching them.

With trees of moderate size it is usually necessary to take the wires th the trees among the leaves and small branches. Such wires are a co source of trouble and expense. The branches and leaves should be tri from around the wires as much as possible, including not only those in c with the wires but such as will be brought into contact by wind or whic grow into contact during the season. In addition it is usual to protec wires in the worse places by tree insulation consisting of split tubes of or bamboo.

Pole Transformers. — The primary (1100- or 2200-volt) mains are u run to transformers mounted on poles and the voltage there stepped do the lamp or motor voltage (110 or 220 volts), and secondary mains run the transformer to the buildings in the immediate vicinity. These transfo usually range in size from ½ to 50 kw., but transformers of ¼ kw. were erly common and transformers larger than 50 kw. are sometimes used in fa districts where the unsightliness of the supporting structure (several poles fr

Digitized by Google

ther) does not have to be considered. Very small transformers are ob-
onable because of their poor regulation, lower reliability and the cost of
ently changing them as the load increases.

Use of Single and Polyphase Transformers. — Transformers are
ly of the single-phase type, two being used for motors on two-phase cir-
and two for small motors and three for large motors on three-phase circuits.
e-phase transformers are also used for motors on three-phase circuits, and
the advantage of reducing the amount of wiring on the poles. Single-
e transformers have the advantage of being interchangeable between the
le-phase lighting and polyphase power circuits where the same voltage is
[illegible]

Voltage Ratios of Pole Transformers. — Lighting transformers were
r standardized with voltage ratios based on multiples or submultiples of
1, that is, 1000 and 2000 volts primary to 50, 100 or 200 volts secondary,
040 and 2080 primary to 52, 104 and 208 volts secondary. It was found
on account of the voltage drop in the transformers and secondary mains,
ers wound for this voltage did not operate well. Instead of remedying
difficulty by winding the motors for a lower voltage or by raising the volt-
in the generators and lamps, power transformers were introduced with
ings based on a ratio of 9 : 1 thus giving with $^{1040}/_{2080}$ volts primary a
ndary voltage of approximately $^{115}/_{230}$. It was soon found that many com-
ions followed from the use of transformers of the two ratios, so that
anies dropped one or the other ratio and made their transformers inter-
angeable. Of the two ratios the 10 : 1 ratio is preferable, because it is the
e extensively used, gives a higher voltage for primary distribution and
es better with the general principles according to which voltages have
n standardized.

ervice Wires. — The service wires are those which connect the house
ing with the main on the street. Usually these wires extend in a single
n from the nearest pole to the house. At the house they are fastened to
ators similar to those used on the line and mounted on brackets attached
the house. These brackets are often the ordinary wooden bracket used
ise work, though the special iron brackets made for the purpose are neater
more secure. The bracket should take the strain off the service span,
that where the service passes through the wall it will not be under the strain
the span. The wires should pass through the wall in porcelain bushings
should have a drip loop between the bracket and bushing so that water
not follow the wire into the building. Where service wires do not conven-
ly reach the house at point of entrance, they are carried along the wall
such point, being supported at intervals by insulators on brackets. See
Wiring of Buildings.

At the pole the service wires are sometimes attached directly to the mains
supply them; while this is the easiest method it has the disadvantage
the strain in the service wire will come on the mains, which may also be
ired by the attaching and detaching of numerous service wires. When the
ice wires do not slope upward or downward at a considerable angle they
liable to become crossed with the main of opposite polarity. Since the
eral direction of the service wire is at right angles to the main, the service
should naturally originate on a cross arm at right angles to the arm carry-
the mains. In good service work consequently a cross arm is attached to
pole below the main, and all the service wires to both sides of the street
from this. One tap to each of the wires constituting the main can then
used for a number of service wires.

Digitized by Google

Front and Rear Servicing. — When houses are serviced from line on the street the service wires usually enter the front of the hou if serviced from alley they enter the rear. Service wires can be run detached houses from front to rear on brackets on the wall, but this is ur expensive and increases the service wire drop. Service entrances can be by changing the inside wiring, but the expense is usually heavy and the to decoration of rooms sometimes makes it prohibitive. In the wiri building the error is frequently made of bringing out services withou to location of supply lines.

Attic and Basement Servicing. — The service-wire entrance center of distribution in the house is generally in the attic for houses overhead and in basement for those serviced underground. Build ranged for underground service are sometimes supplied from overhe by taking service wires down poles and under sidewalks in iron pipes.

In changing an existing system from a street to an alley distribu from overhead to underground service, the center of distribution in th must be correspondingly changed, or a connection run from the new entrance to old center of distribution large enough to carry the current unduly increasing the drop.

Sectionalizing of Distribution Circuits, Fuses and Cut-Outs. — head alternating-current system supplied from a single bus is sectic (1) at the switchboard in power station or substation into circuits ha external interconnection by knife switches or oil switches with fuses matic trip; (2) at the poles where long branches leave, by transfor outs, either fused or solid, or by pole-type oil switches; (3) at tra primaries by fused cut-outs. Switches and fuses are used but spar the primary mains, and in a small compact circuit none are necessa switches or fuses are ordinarily used on the secondary side of tran or on secondary mains. Occasionally transformers have been provid switches in secondary side so that part of the transformers on a netwo be cut out during times of light load to save core-loss. Such sectic has been little used, as the small savings have not justified the comp care and hazard to service due to mistakes.

When several transformers feed the same secondary main, the op a primary cut-out, either by blowing of fuse or by hand, does not m transformer primary dead, as it is still alive from the secondary side. the fuse of one transformer on a secondary network blows the additio thrown on an adjacent transformer may cause the fuse of that to blow transformers to go out in succession. Under these conditions the fuse be replaced in one transformer at a time. To avoid the interruption t involved in leaving the fuses out until a time of day when one tra can carry the whole load temporarily, or in having the whole primar out while the fuses are replaced, it is sometimes possible to have all th formers on a single secondary network on the same branch of the main, this branch being sectionalized from the rest of the primary ci a switch.

Lightning Protection. — (*See also article on Lightning Protectors.* tically all disturbances from lightning enter a system through the distributing circuits. The most serious effects are not to the dist circuit itself but to the switchboard and machinery in the station. Th on the circuit consist of splitting of poles, puncturing of insulators, pu of transformers, blowing of transformer fuses. There may also be to meters or appliances on the premises of consumers. The protecti cipally used includes (1) lightning arresters and choke coils in the static

tus), (2) lightning arresters at intervals on he lines, (4) lightning rods on poles and (5)

design and construction of pole lines and underground circuits are treated tail in the articles on *Distribution Lines, Conduits and Conduit Lines, Transsion Lines, and Wiring of Buildings.* Requirements regarding the grounding circuits and methods of making ground connections are treated in the articles *Grounding of Electric Circuits* and *Ground Connections.*

Circuits designed for transmitting relatively large amounts of power from ated point to another are called transmission lines, while those for delivering small amounts at numerous points are called distribution circuits. Transsion lines usually have no or few branches, while it is characteristic of tribution circuits to have many branches. The various systems of transmitand distributing electric energy for light and power may be classified under general heads, viz., constant current or series and constant potential or ltiple systems, and each of these may be subdivided into direct-current sys- and alternating-current systems.

CONSTANT CURRENT OR SERIES SYSTEM. — The lamps or other vices are connected in series and the current through them is kept constant, voltages varying automatically to increase or decrease the energy delivered. is the principal system used in the United States for street lighting, but is little used for any other purpose. At one time such circuits were extenly used for commercial arc lighting in stores, but the series arc became olete for commercial use when the arc lamp was perfected for use in multiple uits. The value of the current used for street lighting ranges from 1.75 to amp., depending upon the type of lamp used.

Source of Current. — Direct current for series circuits is usually obned from d-c. series generators (*see Generators, Direct-Current*) or from an c circuit by rectifying the alternating current from a constant-current transmer (*see Rectifiers*); adjustable resistance in series in a constant potential d-c. uit is sometimes used. Alternating current is usually obtained from a constantrent transformer on a constant potential a-c. circuit; other methods sometimes used are an adjustable resistance or reactance in series on constant potenal a-c. circuits and by automatic regulating reactance coil on a constant tential a-c. circuit.

Digitized by Google

Cut-Outs, By-Passes and Transformers. — Switching out of la series circuits is accomplished by short-circuiting them; this leaves the charged to the potential of that point in the circuit. To make them handle "absolute cut-outs" are used which also disconnect both conduc the lamp, leaving the circuit closed.

To avoid the excessively high voltage which would occur when the opened, due to series incandescent lamps burning out, an automatic is provided in multiple with the lamps, sometimes consisting of a piece o which punctures on a moderate rise of voltage, or of a choke coil whic but little current at normal lamp voltage. Sockets for series incan lamps are arranged to automatically close the circuit when the lamp i drawn.

Transformers, one at each lamp, are sometimes used to insulate the sec circuit containing the lamp from the primary or for reducing the curr low-current lamps used in series with lamps taking higher current.

Advantages and Disadvantages of Series Lighting. — Constant or series systems have the advantage that low-voltage lamps may be high-voltage circuits without the expense, losses or complication of tran tion. They have the disadvantage that the lamps are dangerous to the efficiency is low at light loads and it is impracticable to distribute a amount of power on a single circuit. In the series system the curre consequently the loss in the conductor is the same irrespective of th while in the multiple system, the current is proportional to the load, watts lost in the line therefore vary as the square of the load and the loss directly as the load. For this reason the series system is not an eco one where the load varies and averages much below full load, which is with most commercial loads. For street lighting where all the lamps are on and off at once the efficiency at partial loads is of no importance. In c current systems the resistance of the circuit does not affect the unifor the voltage on the lamps at different parts of the circuit, while with c potential systems it does. For a scattering load of lamps, such as street a uniform light can therefore be obtained from the several lamps, with smaller weight of copper and fewer wires by using the series than by us multiple system.

Thury System. — In Europe the constant-current or series syste direct current of extra high voltage, has been used for long-distance transmission under the name "Thury System." The current is obta connecting several generators in series, and is utilized by a number of mot in series. The advantages are simple switchboards, no transformers an mum strain on line insulators, the latter due first to the fact that i current the effective voltage is as high as the maximum voltage, and that in a constant-current system the working voltage only remains at i imum value during the short period when the load is also a maximum. the disadvantages are the necessity for insulating frames of generat motors, need of speed governors on motors, necessity of converting the by moving machinery in every case where it is used for lighting and cases for power. The Thury System is not used in the United States.

CONSTANT-POTENTIAL OR MULTIPLE SYSTEM. — In this which is the one principally used for electrical distribution, the voltage conductors is kept as constant as practicable and the current varies as t changes. The degree to which the voltage approximates constancy t out the system is called the "regulation" of the system.

Use of Direct or Alternating Current. — Either direct or alternating can be used equally well for certain purposes, principally those for wh

ed, including the lighting of carbon and tung-
g and heating. For certain purposes, where
hysical changes, such as charging storage bat-
current is essential; for other purposes, such
lum incandescent lamps, it is better; whereas
Nernst lamps, the alternating current is better.
urrent is most favorable where acceleration,

nected Networks.— The simplest method of
to run one set of wires through the middle of

Digitized by Google

the district to be served, running branch wires from them wherever conve for reaching loads at the sides. At the beginning, the single set of wi large enough to carry the whole current, but the size is diminished as the cu branches off. In this system adjacent branches will often have widely diff voltages, due to unequal drop because of varying loads. If wires are run necting the out-lying ends, currents will flow and partially equalize the d ences in voltage. This plan, if carried out systematically, develops in network, usually composed of two sets of parallel mains crossing at right a and connected at each point of crossing.

Feeder and Main System. — It is practicable to keep the voltag the customers' electric lamps within 2 to 5 per cent of being constant, when it is necessary to raise the voltage of the generators from 10 to 20 per from no load to full load, by arranging the distribution circuits on the f and main plan. The area to be served is first divided into compact sect each small enough to be fed from a central point with a voltage drop w the desired percentage. A system of wires called "mains" are run from central point, called the "feeding point," or "distribution center," to customers. The mains form a little circuit originating at the feeding instead of at the power house; they may be arranged on either the tree or i connected network plan. A set of wires called "feeders" is run from the p house to the feeding point. As no current is taken off at intermediate p these wires are not tapered and any desired drop of voltage may occur i feeders without affecting the lamps, provided the power-house voltage is r proportionally.

Two-wire System. — The simplest multiple system is the two-wire sy where all devices are connected directly in multiple. This system is used extensively for direct-current light and power, from isolated plants, for p circuits (usually 500 volts) and railway circuits from central stations. also used for single-phase alternating-current distribution for both pri and secondary circuits.

Edison Three-wire System. — The three-wire system, Fig. 1, is obtain replacing the out-going wire of one two-wire system and the return wire second two-wire system by a single wire, called the "neutral." The voltage between the outside wires is then double the voltage between the neutral and either outside wire. For example, 110-volt lamps may be connected between the neutral and either outside wire, and 220-volt motors may be conn between the two outside wires, and both the lamps and motors be sup with their rated voltage. The neutral wire carries a current which de only upon the *difference* in the loads on the two sides of the system and distribution. As a rule the neutral of a three-wire main is made equal in c section to each outside wire. With perfectly balanced load the three-wire tem with all three wires of the same size results in a saving in copper of per cent as compared with a two-wire system supplying the same load a same regulation.

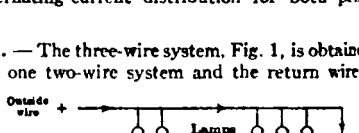

Fig. 1. Three-wire System

The three-wire system is used very extensively for direct-current light power distribution from central stations, also for large isolated plants an alternating current for lighting on the secondary circuit. Three-wire sys are usually 110 volts on each side of neutral, or 220 volts between outs

Digitized by Google

gh there are several systems using 220 volts on each side and 440 volts
een outsides.

he Edison three-wire distribution system, as used in the business sections
rge cities, consists of a set of interconnected three-wire mains supplied by
wire or three-wire feeders from one or more power houses or substations.
different feeders feed into the same set of mains at different points. At
power house or substation end the feeders are often all supplied from a
mon bus, though where there is a great difference in the length of the feeders
re are sometimes two busses which are run in multiple when the load is light
separated when it is heavy, the short feeders on one called the "low bus,"
the long feeders on the other called the "high bus," because of the relative
tages. As the feeders from the several substations connect to interconnected mains, the bus voltage in each is raised or lowered in accordance with the
p in its own feeders. All mains which connect feeding points supplied from
ven bus are made large enough to allow large equalizing currents to flow
ough them, without requiring any great drop in the mains, in order to equalize
voltages at these points.

ALTERNATING-CURRENT SYSTEMS. — The simplest form of alternating-current system is the single-phase system, for which the connections are
only the same as for the direct-current systems. Both two-wire and three-
circuits are used, the former for primary circuits and small secondary
and branches, and the latter for large secondary circuits. The principal use of single-phase circuits is for electric lighting and auxiliary uses, such as
heating or cooking, and fan motors. For delivering large amounts of power
two-phase or three-phase system is generally used.

Two-phase Systems. — In this system there are two single-phase currents
having a difference in phase of 90°, or a quarter of a cycle. These currents
may be distributed on the three-wire, four-wire or five-wire system; see also
the *Transformer Connections* in the article on *Transformers*.

Three-wire Two-phase Systems. — Each single-phase current has a
separate outgoing wire but unites in a common return wire. Each two-phase
circuit has two circuits, each connected between an outside wire and the return
wire. The voltage between the two outside wires is 41 per cent greater than
between outside wire and return wire and the current in the return wire is 41
per cent greater than in each outside wire. This is an unsymmetrical system
and has the disadvantage that even a balanced load will cause a distortion and
unbalancing of the delivered voltage of the two phases because of the unsymmetrical drop in the common return wire.

Four-wire Two-phase System. — Each of the two single-phase circuits
is a complete, independent two-wire circuit. There are two variations, first
where the circuits are insulated from each other, in which case a cross between
either wire of one circuit with either wire of the other will change the voltage
from to ground, but will not affect the delivered voltage or cause a short circuit;
second, when the neutrals of the two circuits are connected. In the latter case,
from each wire of one circuit to either wire of the other circuit, the voltage is
71 per cent of the voltage between wires of the same phase. The four-wire
system with insulated phases is probably the most extensively used of the two-
phase systems.

Five-wire Two-phase System. — This is a modification of the four-
wire system, with interconnected neutral in which the common neutral is ex-
tended as a fifth wire. Lamps may be connected from each of the four wires
to the neutral. The five-wire system may be considered as two three-wire
single-phase systems, one for each phase, with a common neutral wire.

Digitized by Google

Three-phase Systems. — In this system there are three single-phase nating currents with a phase difference of 120°, or of one-third of a cycle. currents may be distributed on the three-, four- or six-wire systems.

Three-wire Three-phase System. — Each single-phase current separate outgoing wire; the three return currents neutralize so that no retu is required. The three wires are necessarily interconnected, the voltag usually the same between any two and the currents equal in each of the conductors, provided the loads on the three phases are equal, i.e., provid load is balanced. When equally loaded the voltage drops in the three conc are equal and symmetrical. This is the most extensively used of the phase systems.

Four-wire Three-phase System. — This is a modification of the wire system in which a neutral wire is extended as a fourth wire. La transformers may be connected from each of the three wires to the neutral, carries only the unbalanced current, due to the differences in loading three phases. The voltage between the three outside wires is 73 per cent than from each outside wire to neutral.

Six-wire Three-phase System. — If to a three-wire, three-pha tem, three wires are added, one with voltage midway between that of eac of outside wires, lamps may be divided into six groups, between the thre side wires and the three adjacent middle wires. The result is the sa though there were three single-phase three-wire circuits, one for each with the six outside wires combined in pairs giving three common outside in place of the three pairs. When connected in this way, the three middl cease to be neutrals, as between the three there is a three-phase voltage e one-half of that between the three outside wires.

Six-phase System. — This is used for circuits in the interior of subst (q.v.), such as from transformers to rotary converters, but is not used f tribution.

Monocyclic System. — This is a variety of unsymmetrical polyphase s now obsolete. It may be regarded as a species of two-phase system with v on one phase one-fourth of that on the other and with the two wires of the phase acting as a common return for the small phase.

Star or Y, and Mesh or Δ Connections. — See article on *Alter Currents*.

Transformer Connections and Phase Transformations. — See arti *Transformers*.

Transformations of Systems. — Any electric system can be transf to any other electric system by the use of rotating machinery; see *Generators* and *Converters, Synchronous*. This method is used chiefl changing from alternating to direct current and for changing the frequer alternating current. Conversion from alternating to direct current is accomplished by means of mercury arc rectifiers, particularly for serie arc lighting and for charging storage batteries; see *Rectifiers*. Conversion any alternating voltage to any other alternating voltage at the same freq is accomplished by means of transformers (q.v.).

Frequencies in Use in the United States. — At present the two fre cies in most general use and adopted as standards in most new work are

60 cycles per second or 7200 alternations per minute, used by the ma of companies operating alternating-current lighting systems.

25 cycles per second or 3000 alternations, generally used for alterna current railway or power work or where the alternating current is to be conv into direct current before final use.

O WEIGHTS OF COPPER REQUIRED

— The comparison of the various systems pper required, as tabulated below, is based e energy delivered, (2) that the energy loss e strain on insulation between any wire and or all systems.

nt of the system is grounded, then the maxi- ion to ground is the maximum instantaneous outside wire and neutral. In the case of an he maximum instantaneous value is equal to mined by a voltmeter. When the neutral is ground on any leg will throw full line voltage other leg and ground.

Digitized by Google

On this basis of comparison, assuming a sine wave of voltage and 100 p
power factor for the alternating-current systems, the relative voltages b
outside wires and the relative weights of copper are as follows:

RELATIVE VOLTAGES AND RELATIVE WEIGHTS OF COPI

System*	Relative voltages between outers		Relative wei of copper*	
	Grounded neutral	Insulated neutral	Grounded neutral	Ins ne
	Per cent	Per cent	Per cent	Pe
Direct-current (2-wire)	100	50	100	
Single-phase (2-wire)	71	35.5	200	
Two-phase (4-wire)	71	35.5	200	
Three-phase (3 wire)	61	35.5	200	

* Neutral wire not included; when neutral is added increase the figures giv
ratio of weight of neutral to combined weight of the outside wires for the sy
question. For example, the addition of a neutral wire equal in size to either
wire to a d-c. 2-wire system with grounded neutral gives a relative weight of
$100 \times 1.5 = 150$ per cent.

Effect of Power Factor. — To correct the above tabulation for alter
current systems in cases where the power factor is less than unity div
relative weight of copper given by the square of the power factor (i.e
single-phase two-wire system with insulated neutral and 70 per cent
factor the weight of copper will be $800/0.70^2 = 1630$).

VOLTAGES FOR D-C. AND A-C. SYSTEMS. — Unless otherwi
fied the "voltage" of a polyphase system refers to the potential differe
tween adjacent outside wires; see *Alternating Currents* for the relations b
the various voltages.

A considerable number of voltages are standard or semi-standard. In
they may be considered as derived from a lamp voltage of 50 or 100 m
by the factors 2, 3, 5 and 10, and increased by 4, 5, 10, 15 and 20 per
various reasons, principally to allow for line loss. In addition to this
of voltages there is another system which arises from the use of Y and
nections on the three-phase system; these voltages are related to the al
the factor $\sqrt{3} = 1.73$, either as a multiplier or a divisor. For exam
voltage between the outside wires of a four-wire three-phase system su
115-volt lamps connected between each outside wire and neutral is $\sqrt{}$
= 198 volts.

Voltages Commonly Used. — The voltages most used are:

Direct current:

100 to 120 volts	Lighting, small power and field excitation.
200 to 240 volts	Power, lighting and field excitation.
500 to 600 volts	Power, electric urban railways.
1200 to 1500 volts	Interurban electric railways.
2400 to 3000 volts	Electric trunk lines.

UTION. — The ratio of the energy registered ch would be so registered if all customers had the generator to the bus-bar in the generating efficiency of distribution. The losses may be loss, transformer loss, converter loss, meter ounted for. For some purposes it is useful to ts of view: (1) as a loss of energy, and (2) as st may be called the energy loss and the second onding efficiencies are usually designated as he full-load or capacity efficiency respectively.

— The total energy loss consists of two com- dent of load, including the core-loss of trans- , friction and windage of rotating converting

Digitized by Google

apparatus, the loss in the shunt coils of meters, the copper loss in c current circuits, and the loss in the arc of mercury arc rectifiers for c current circuits; (2) a variable loss proportional to the square of the including the copper loss of constant potential circuits and of transf the armature copper loss of rotating converting apparatus. The effect fixed loss on the per cent efficiency depends on the load factor of the loa that of the variable loss depends both on the load factor and the shap load curve.

Representative Losses. — For a lighting system, the full-load losse mary feeders, primary mains, transformers, secondary mains, services and may be expected to be as much as 17.5 per cent of the power generated daily energy loss 33.3 per cent of the energy generated, giving 82.5 p capacity efficiency and 66.7 per cent energy efficiency respectively.

Effect of Nature of Load. — In making estimates of the efficie particular systems, the effect of the following items should be con (1) relation of transformer capacity to maximum loads, (2) load (3) shape of load curve, (4) power factor, (5) diversity factor.

REGULATION. — An ideal constant potential distribution woul one uniform, unvarying voltage, and would be said to have perfect reg The greater the variation from such constancy the poorer the reg The regulation is usually specified in per cent variation, either "above or a standard mentioned. The standard is usually either the nominal desired or the actual average voltage obtained.

Evil Effects of Poor Regulation. — The evil effects of high volt short life of electric lamps, excessive speed of direct-current motors, e exciting current of induction motors and burning out of motors and other on the other hand, low voltage greatly diminishes both the candle-pow efficiency of electric lamps, decreases the maximum power of motors creases the current which a motor will take for a fixed horse-power As electric lamps are much more sensitive to change of voltage than separate circuits are often used for lighting and power, the former having for regulation which are omitted from the latter.

The following figures give roughly the quantitative effect of voltage va between 5 per cent below and 5 per cent above normal:

Each per cent decrease in voltage decreases candle-power of carbon incandescent lamps ..... 5 Pe
decreases torque of induction motor ..... 2 Pe
Each per cent increase in voltage decreases the life of carbon incandescent lamps* ..... 13 Pe
increases the magnetizing current of induction motors ..... 2 Pe

Ordinary Limits of Regulation. — Roughly, the maximum voltage tion at the lamps on a lighting system should never exceed 5 per cent, i regulation above or below normal should never be greater than 2.5 pe and should be as much less as is economically feasible; the voltage va on power systems is usually 10 per cent (5 per cent above or below norma is sometimes considerably more.

Calculation of Regulation. — In order to calculate the variation in v at any receiving device or group of such devices from no load to full loa voltage at the generating or substation or feeding point being assumed co the impedance drops in all parts of the distribution system must be calc

* Average for 5 per cent increase in voltage; the first per cent increase in decreases the life 18 per cent, the fifth per cent 8 per cent.

properly combined. The various parts of the system to be considered are house wiring, service wires (or leads from street mains to the house), secondary mains, transformers, primary mains, primary feeders. See *Distribution in Transmission Lines; Wiring of Buildings.*

In making such calculations account should be taken of the fact that the maximum currents in the several parts of the system seldom have their maximum values at the same time. The maximum drop in house wiring will not occur simultaneously in all houses nor will the maximum service drop occur together with the services, etc. Furthermore, the maximum house wiring drop for a given house may not occur at the same time as the maximum drop on the secondary mains, transformer or primary mains to which it is connected.

Effect of Line Reactance. — The regulation of an alternating-current system of unity power factor will be poorer than that of a direct-current system of the same copper efficiency (see tabulation above) because of additional drop due to line reactance.

Effect of Lagging Power Factor. — A lagging power factor usually makes the regulation of an alternating-current system worse than it would be for unity power factor and therefore much worse than for a direct-current system of the same copper efficiency.

Effect of Leading Power Factor. — A leading power factor usually makes the regulation better than it would be for unity power factor and may give even better regulation than can be obtained from a direct-current system of the same copper efficiency.

Effect of Currents in Neutral. — Any current in the neutral wire of a balanced system produces a drop which tends to unbalance the voltage of the two sides. In the case of a three-wire direct-current or single-phase system *one per cent drop in neutral produces two per cent difference in the voltages on the two sides.* The drop in the neutral therefore affects more seriously the regulation than an equal amount in the outside wires. If the currents in the neutral all have the same direction, say toward the station, the voltage drops in the various sections of it will be cumulative, and though the drop in each section may be small the total current may actually reach the station, the aggregate effect may be serious. The individual loads on the two sides of the neutral should be connected so that the unavoidable neutral currents flow alternately in each direction, thus causing drops in alternate directions thereby neutralizing each other over the total length of the circuit.

Feeder Neutral in Three-wire Systems. — When the "feeder and main" system is used with a three-wire system, two-wire feeders should be used only for the outside wires, and only a single "feeder" neutral be used. That is, with respect to the neutral, the "tree" system gives better regulation for the same weight of copper than the "feeder and main" system, but with respect to the outside wires the latter system gives the better results. This is a point which has not always been recognized in laying out three-wire systems.

VOLTAGE CONTROL. — (*See also Controlers.*) The more common methods of controlling the voltage at feeding points when the feeder and main system of distribution is used (*see above*) are the single bus system, the high and low bus system, and feeder regulators.

Single Bus System. — (*See also article on Bus-Bars.*) All the feeders may be connected to a single bus and the bus voltage be raised as load increases so as to compensate for average drop of all the feeders on it. This method gives excessive voltage on such feeders as are comparatively short and low voltage for those that are long. Usually maximum voltage is carried in the evening

Digitized by Google

during the lighting peak and lower voltage during day giving very p
lation on power circuits having maximum load during the day and
at night. This method is used on most small direct- and alternatin
distribution systems.

High and Low Bus System. — The bus may consist of two pa
may be separated, and operated at different voltages, feeders of greate
drop connected to the "high" (voltage) bus and the others to t
(voltage) bus. The voltage of each bus is raised or lowered in accord
average drop of feeders on it as in the single bus system. This metho
extensively on the Edison three-wire direct-current systems, as note
The unequal drop of the several feeders on same bus are equalized
interconnection through mains.

Feeder Regulators. — A feeder may have a separate regulator a
to compensate for its own drop. This method is sometimes used c
current railway feeders and very extensively on alternating-current
feeders. See article on *Regulators*. A feeder or other distribution circ
contains a voltage regulator is frequently referred to as a "boosted
Boosted circuits are not usually interconnected but may be if the b
of the same nature in each.

Control of Polyphase Systems. — In a polyphase system the l
be as equally divided among the phases as possible and the voltage
with respect to any one phase taken as representing the average of a
lighting load may be connected on a single phase and the voltage regu
this phase alone. The former method is more common, as it permits o
put of all the phases of the generator being used and gives a more equa
on the several phases of polyphase motors.

Transformers as Outside Boosters. — An auto-transformer or an
transformer may be connected to a feeder at any point and used as a "
to raise or lower the voltage. In the case of an ordinary transformer the
and secondary are connected in series thus converting the transforme
auto-transformer; see article on *Auto-Transformers*. Such boosters
adjustable and have a bad effect on the regulation as they give excessiv
on the boosted part of line at light load.

To cut such a booster out of service without taking it off the circuit the
coil must be open circuited and the secondary short circuited. *Caut*
main circuit must be opened before cutting out booster, because if the
is opened while current is flowing in the secondary the booster become
up transformer and may give a dangerously high voltage on the prim
on the other hand the secondary is short circuited first, a destructiv
circuit current may flow through it and the primary, and when the pr
opened a dangerous arc will form.

Use of Lamps of Different Voltage. — Attempts have been made
pensate for the difference in voltage at the various points of a network
lamps of different rated voltage, high-voltage lamps being used near the
supply and low-voltage lamps at the ends of line. This plan has not b
cessful because the difference in voltage between any two points is not c
Frequently some of the high-voltage lamps are used by mistake wh
voltage lamps are intended; the results are then poorer than when no d
is made in lamp voltage. While lamps of two or more voltages may
temporarily as an expedient when regulation is very bad, it is better
to have all lamps on a system of a single uniform voltage.

Use of Transformers of Different Ratio. — Transformers are als
with taps so that a uniform secondary voltage can be obtained with a
primary voltage. The plan is not a good one, because if the difference

correct for uniform voltage at full load it gives unequal voltages at light ad. It also has the very serious disadvantage that the haphazard changing transformer ratios by ignorant linemen to compensate for dim light, due haps to lamps already blackened by excessive voltage, makes it impossible carry out any systematic plan for securing the best average regulation for e system as a whole.

BALANCING OF LOAD. — In three-wire direct-current or single-phase stems and in all polyphase systems supplying single-phase load it is necessary approximately balance the load between the two sides or the several phases the case may be. Unbalanced load has two bad effects: (1) it loads the o sides or phases of the system unequally, making it impossible to get full tput out of the lightly loaded side or phase without overloading the other;) it makes the regulation of the system worse by causing high voltage on the htly loaded side or phase and low voltage on the other.

The first difficulty is not serious, because through the conduction of heat from e loaded to the unloaded coils of transformers and generators the machine pacity is not reduced in proportion to the unbalance; for moderate unbalance, say up to 10 per cent greater load on one side or phase than on the other, is doubtful if any appreciable effect could be discovered. As the total load ually consists of a great number of small parts, a very little foresight in dividing e load in the first place between the sides or phases, and in suitably distributing subsequently connected load, will give a balance good enough for all practical rposes. When polyphase alternators were first installed for supplying existing ngle-phase lighting circuits, it was supposed to be important to have a close alance of load between the phases, and early switchboards were therefore ovided with transfer switches for throwing single-phase feeders from phase phase. It was later found that instead of being necessary to transfer the load om phase to phase, following the diurnal or annual variations of load, that e circuits could stay on the same phase indefinitely and that transfer switches ere unnecessary and undesirable. The time when rebalancing of this kind necessary is usually when new circuits are established, at which time the anges of connections are best made by changing the taps to the bus-bars.

Motor-generator Balancer. — On direct-current three-wire systems the fference in current on the two sides may be balanced without taking the neutral rrent to the generator by a balancer consisting of two similar machines echanically coupled and electrically connected in series. Each machine is ound for the voltage of one side f the system (110 volts for a hree-volt system); the common nnection between the machines connected to the neutral and e other two terminals to the o outsides, see Fig. 2 (the field indings are omitted for clear-ss). The unit acts as a motor nerator (q.v.), whichever ma-ine happens to be on the light de being the motor for the time being and the other the generator. By engthening the field of the one on the side where the voltage is low and akening that of the other, so as to keep the same total voltage, the voltages the two sides as well as the currents may be balanced if necessary.

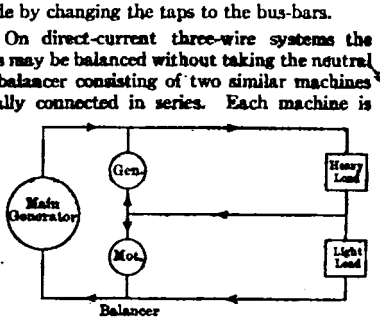

Fig. 2. Motor-generator Balancer

The output of the balancer generator and the input of the balancer motor re practically equal to each other, neglecting the losses in the machines, and ch is equal to

Digitized by Google

$$\frac{P_1 - P_2}{2},$$

where P_1 is the load on the heavily loaded side of the system and P_2 the the lightly loaded side. For example, if the load on one side is 110 kw. the other side 90 kw., the load on each unit of the balancer is 10 kw.

It would, however, be unsafe to use a balancer as small as such calcu for the normal unbalancing would indicate as correct, because in case of a circuit on one side of the system, or of loss of a large amount of load on o due say to the blowing of fuses, the balancer would be dangerously over This may not only destroy the balancer, but may burn out many lam motors on one side due to excessive voltage. In small systems, say up t kw. total capacity, the balancer should be able to operate momentaril any loading up to the capacity of the main generator, and in large s should have capacity sufficient to burn off a short-circuit on one side of the without creating an unduly high voltage on the lightly loaded side.

Dynamotor as a Balancer. — A smaller and cheaper balancer is ob by using a dynamotor (q.v.), which is a single machine with two windi one armature and two commutators. The armatures are connected in seri balance the currents, but as there is only one field the voltages can balanced.

Alternating-current Balancing Coil. — On alternating-current single three-wire systems it is usual to obtain the neutral from the middle of the coil of the transformer supplying the current. It can, however, tained at any point of the two-wire circuit without going back to the former by using a balance coil. A balance coil is a transformer with two windings connected in series across the circuit and with the neutral wi nected to the common point between the windings. Whichever coil is lightly loaded side acts as the primary and the other as the secondary, t balancing the circuit by transferring one-half of the difference in load fr heavily loaded side to the lightly loaded side. Such coils, which are esse auto-transformers with a 2:1 ratio, may be used in various ways: to the neutral for an unbalanced three-wire circuit from a two-wire circ supply a 110-volt load from a 220-volt circuit; to supply a large 110-vo from a 110/220-volt circuit without connecting to the neutral. In p balance coils are not much used as the neutral can more cheaply be ob from the transformer.

RAFT, MECHANICAL. — (*See also Blowers and Compressors; Chimneys; as; Pipes and Piping.*) Any system producing draft either by steam jets or r blowers is called a mechanical draft system. The relative advantages of achanical draft as compared with chimney draft are: (1) The supply of air ay be more readily controlled; (2) a fan permits a lower temperature of flue ses, which increases the boiler efficiency; (3) the boiler may be forced to gh overloads in case of emergency; (4) the draft is uninfluenced by climatic nditions; (5) the system is low in first cost. The disadvantages of mechanal draft are: (1) danger of breakdown; (2) cost of maintenance and operaon; (3) a stack or other means must be provided to carry off the flue gases herever their discharge at low levels constitutes a public nuisance. Many lants with tall stacks are provided with mechanical-draft apparatus as a eans of forcing the boilers in case of heavy overloads. Mechanical draft is so frequently used in connection with fuel economizers.

Steam Jets for producing artificial draft are simple, inexpensive and easily plied, but are very uneconomical, since they require from 6 to 11 per cent f the total steam generated (A. J. Whitham, *Trans. A.S.M.E.*, Vol. 17).

Forced Draft. — A blower system creating an excess of pressure beneath the te is known as a forced-draft system. A single fan is commonly employed to pply a number of boilers through a system of ducts beneath the floor. The ir is sometimes taken from a chamber built around the breeching, thus utilizng a part of the heat energy in the exhaust gases.

Induced Draft. — In the induced-draft system the fan is placed between the eeching and the stack. All leakage of air is inward, avoiding inconvenience hen the doors are opened. This system is frequently used in plants which ave high peak loads, being ordinarily installed in connection with fuel econoizers. A by-pass directly from breeching to stack is usually provided for use hen mechanical draft is not required or in case of accident. A double system f fans is also sometimes provided as a further insurance against accidental terruption.

POWER REQUIRED — SIZE OF FANS. — The power and size of fans equired to operate either a forced-draft or induced-draft system may be roughly alculated by the method given in the article on fans. The static pressure may e roughly approximated from the data given in the article on chimneys, the gures there given for loss of draft being taken as the static pressure to be overcome. The quantity of air required per boiler horse power depends upon the uality of the coal, upon the care taken in firing and upon the efficiency of the oiler and grate (*see Boilers*).

Let R be the number of pounds of coal required per boiler-horse-power hour, W the pounds of air required per pound of coal, P the boiler horse power and $w = \frac{1.33\,B}{460 + t}$ = pounds per cubic foot of gas passing through the fan, where B is the barometric pressure in inches of mercury and t the temperature of the gas in degrees Fahrenheit; then the volume of gas passing through the fan per minute is $Q = \frac{RWP}{60\,w}$. This formula and the formula for w are strictly applicable only to the case of a forced-draft fan, but the two formulas may also be used with but a small error for an induced-draft fan, taking for t in the latter case the temperature of the discharged products of combustion (about 500° F., when no economizer is used and about 300° F. with an economizer). The size of fan and the power required to operate it will be greater for induced draft than for forced draft, since in the former case the volume of gas passing through

the fan is greater. According to Gebhardt the power required to operate forced-draft system for a plant of 1000 boiler horse power or more, will ran from 1 to 5 per cent of the plant capacity.

COSTS (Pre-war figures). — According to Gebhardt the cost of a force draft fan, engine and stub stack for a plant of 1000 boiler horse power or more w approximate 20 to 30 per cent of the cost of an equivalent brick chimney. Th cost of a single induced fan, engine, stack, etc., will approximate 40 to 50 p cent of the cost of an equivalent brick chimney, and the double-fan outfit w be 50 to 60 per cent of that of an equivalent brick chimney. Two per cent is liberal allowance for maintenance and depreciation of a brick or concrete chim ney, while for a mechanical-draft system an allowance of from 4 to 10 per cen should be made. It costs nothing to operate a chimney, while from 1 to 5 p cent of the cost of operation of a boiler plant is chargeable to a mechanical-dra system.

REDGES, ELECTRICALLY OPERATED. — (*See also Motors, Industrial Applications of.*) Electrically operated dredges are now used very generally, especially in connection with gold mining. This drive has indisputably owed its advantages over steam drive from the standpoint of both operation nd economy, as individual motors can be applied to the various units of the redging machinery, and a larger percentage of the power input can thereby be rectly applied in useful work.

The standard form of dredge is of the continuous-chain, close-connected cket type, ranging in capacity from 3 to 16 cubic feet and with a digging depth from 40 to 60 feet. As the power is mostly obtained by transmission from ne hydroelectric power system or central generating station, alternating rrent is generally used for driving the dredge machinery. For a modern ld-mining dredge this consists of the digger or bucket line, the winch, e high- and low-pressure pumps, the priming pump, the screen and the acker.

Bucket Line. — The bucket line is supported on a sheet-steel or girder struc- re of massive construction, so as to resist the heavy strains while in operation, pecially when striking rock. The speed varies from 50 feet (with from 16 to 25 ckets) to 75 feet (with from 35 to 50 buckets) per minute, depending upon e condition of the ground.

The operation and control of the digger a variable-speed induction motor is ed. This is located on the lower deck and belted to the driving pulley, which enerally situated in the rear of the pilot house on the upper deck. The duty posed upon this motor is severe, as it must operate under conditions calling r power varying from 75 per cent overload down to 25 per cent of its rated pacity. A drum-type controller for forward and reverse operation is pro- ided, including the necessary resistance for continuous operation on any notch f the controller from one-half to full speed. The maximum starting torque is quired and obtained at about the fourth point of the controller, thus leaving ree points on which to bring the motor up to half speed, at which time nearly ll rated torque is required. As a result of these conditions the ordinary motor signed for intermittent service cannot be successfully applied.

The raising and lowering of the bucket-line ladder is generally accomplished y a friction clutch which can be connected to the digger motor. For the larger ne dredges, however, a separate motor is often provided to perform this nty.

Winch. — To keep the dredge in place and to move it about or hold it against e bank when digging, head lines are used, which are controlled from the for- ard end and operated by a six- or eight-drum winch driven by a variable-speed otor. The winch motor, though of smaller capacity, is of the same staunch nstruction as the digger motor and is equipped with a suitable controller and sistance to permit its continuous operation from one-half to full speed. It as been found advisable to equip the motors for this service with solenoid brakes, y means of which the motor can be brought to a standstill almost instantly. t is then ready for the reverse operation without the usual reversing of the motor hrough the controller, which is not only bad practice but may result in a burn- ut due to the heavy strain on the windings.

Pumps. — The high- and low-pressure pumps for supplying water to the screens nd sluices are generally connected to individual motors. Constant-speed quirrel-cage motors of compact construction and large overload capacity, with speed of from 600 to 900 r.p.m., are usually installed for this work.

To prevent the filling up of the basin, in which the dredge floats, when dig- ing in shallow water, it is sometimes found necessary to install a sand pump,

which carries the fine tailings from the sluice boxes to the top of the rock way of the stacker.

Priming Pump. — A priming pump is required for priming the large or for supplying water on the tables during the "clean-up." It genera sists of a small centrifugal pump driven by a high-speed direct-connected s cage induction motor.

Screen. — Either a shaking or revolving screen is used to separate th from the clay and permit the fine particles containing the gold to pass t on to the gold tables and sluices below. For this service a constant-spee is recommended, which can be placed on the upper deck and belted dow driving pulley of the screen.

Stacker. — After screening the large rocks are carried on a belt conv the end of the stacker and deposited on the spoil in the rear of the dredg operating this conveyor a constant speed motor is installed at the extre of the stacker, where it can be readily housed.

Monitor. — When a dredge is working in a high bank of hard materia experience has demonstrated that it is advisable to lower the water leve pit and cut the bank down with a "Giant," water being furnished by a t four-stage, high-pressure centrifugal pump driven by a phase-wound in motor. The Giant is mounted on the bow of the boat, and as the dredge from one side of the cut to the other, the stream of water is thrown agai bank about two feet above the water level. This undermines the bank, the material to cave into the pond where it is brought up by the buck The Giant is also used in localities where the water in the pond cannot b high enough to bring the bucket line near the top when the dredge is s ahead.

Power Required. — The sizes of motors required for driving the ma of some dredges of different capacities are given in the following table proper speeds will depend on whether the motors are to be belted or dire nected to the machines which they are to drive.

SIZES OF MOTORS FOR DREDGES

Machinery to be driven	3 cu. ft. dredge, 40-ft. digging depth		5 cu. ft. dredge, 40-ft. digging depth		7 cu. ft. dredge, 40-ft. digging depth		13½ cu. ft. dredge, 40-50 ft. digging depth		16 c dred ft. d de

oltage of Motors. — The power for operating a dredge is generally trans-
ed from some existing power system, and the connection between the line
the dredge is, as a rule, made by means of armored cable carried on floats.
n this transmission can be economically carried out at a voltage of 2200,
customary to provide the motors for this voltage, thus eliminating the ex-
e of installing step-down transformers. When the transmission voltage is
re 2200 volts, it is desirable to step it down to 440 volts and use motors for
voltage. When step-down transformers are required, their capacity is
lly taken as two-thirds of the total horse-power load, allowing one kilowatt
ach horse-power.

DYNAMOTORS. — (*See also Converters, Synchronous; Motor Gen Transformers.*) A dynamotor is a direct-current device combining both mo generator action in one magnetic field. It has an armature having two s windings and two separate commutators, one at each end of the ar Either winding may be used as the motor winding, and the other as the ator winding. Such a machine performs the same function in a direct- circuit that a power transformer does in an alternating-current circu serves as a means of transforming high-voltage direct current into low- direct current, or vice versa.

Performance Characteristics. — The device corresponds to two mad which there is only one core-loss, one friction loss, one excitation loss, l losses due to RI^2 in the two armature circuits. It is therefore more than a motor-generator set, but less efficient than one machine. Si currents in the two windings flow in opposite directions their resultar netic effect is zero. The machine has therefore no armature reaction for the slight amount due to the current to overcome the losses in the m It is not subject to the troubles of field distortion and bad commutati occur in either motors or generators. It is impossible to compound a motor, since any increase in field strength intended to increase the vo the generator would decrease the speed of the motor by the same amo no change would result. The ratio of the two voltages is therefore fixed number of turns, and only varies from this by the loss due to RI drop windings. These two drops are additive, and therefore the regulation a machine is not very good.

Applications. — Dynamotors are used largely to give large currents other motors, or to give low voltages or a fractional voltage in a multi- system for speed control. The motor of the combination may be wo the line voltage and the generator for any fraction of the line voltage. the combination supplies a large current at a low voltage, which will good starting torque in motors connected to it with a reasonable const of power. They are used as equalizers or "balancers" in three or m circuits, but are not as desirable for this work as motor-generator se compound-wound machines, on account of their poor regulation. T also used to supply a low voltage for such purposes as telephone and te systems and the low voltage and large currents for electrolytic work.

Dynamotors are also used in radio work in connection with vacu detectors and amplifiers, in order to obtain from a battery of 4 to 10 voltage of 300 for operating the tube.

ECTRICITY AND MAGNETISM, PRINCIPLES OF. — In
article are given definitions of the various electric and magnetic quantities,
ther with a brief statement of the fundamental principles in accord with
ch all electric and magnetic phenomena take place.
he following is a brief table of contents of this article:

Units and Working Hypothesis	p. 393
Electric Fields of Force	394
Electromotive Force	395
Flow of Electricity	397
Electric Energy and Power	404
Dielectric Flux and Electric Charge	405
Electrostatic Capacity and Condensers	408
Electrostatic Energy and Forces	412
Magnetic Fields of Force	414
Electromagnetic Induction	416
Self and Mutual Induction	424
Energy of the Magnetic Field	428
Forces in the Magnetic Field	430

NITS AND QUANTITATIVE LAWS. — Three different systems of
rs are in use in terms of which electric and magnetic quantities are expressed.
ese systems are known as the c.g.s. electrostatic system, the c.g.s. electro-
gnetic system and the practical system (*see also Units, Practical Electric*).
e various units in the practical system have been given short names which
e in common use, e.g., ampere, volt, coulomb, etc. For the sake of brevity
corresponding units of the electrostatic system will be designated by these
e names with the prefix "stat," and the corresponding units in the c.g.s.
ctromagnetic system will be designated by these same names with the prefix
b," the latter prefix arising from the term "absolute" sometimes applied to
system.

The use of the electrostatic and electromagnetic systems of units arises from
manner in which certain of the fundamental quantitative relations, or
ws," were originally formulated. The practical system is related to the
ctromagnetic system, by even multiples of ten times the units in the latter,
- 1 volt = 10^8 abvolts, 1 ampere = 10^{-1} abamperes, 1 ohm = 10^9 abohms.

The quantitative relations given below between *electric* quantities are in-
endent of the system of units employed provided *all the quantities involved
expressed in the same system of units.* (*See Units and Conversion Factors.*)
r some of the *magnetic* quantities, certain additional practical units have
n introduced which are not related to the c.g.s. electromagnetic units by
ltiples of 10; consequently, to avoid confusion it is best to reduce all quanti-
s to electromagnetic units before applying any of the formulas given.

**WORKING HYPOTHESIS REGARDING THE NATURE OF
CTRICITY.** — The various facts of experience described as electric and
gnetic phenomena can best be coördinated by assuming at the outset the
stence of electricity as an actual entity, possessing the following properties:

1. Electricity exists in two forms, which for convenience may be called
sitive" and "negative" electricity. These names arise from the fact that
two kinds of electricity produce certain effects which are just the opposite
each other, and, therefore, under certain conditions the external effect of one
d of electricity may completely neutralize the effect of the other kind.
A given quantity of electricity is called an "electric charge."

2. All matter contains electricity of both kinds, even when in the neutral or
uncharged" state. An uncharged body contains in every elementary portion
molecule) equal quantities of positive and negative electricity, so thoroughly

"mixed" that no external effects are produced, unless the two kinds of electri ity are constrained to take up a definite position or to move in a definite manne

3. A body or portion of a body can be charged with electricity of either kin either by adding to it electricity of that kind or by taking away from it electri ity of the other kind. In general only the *surface* of a body can be charged, i. the excess or deficit of charge exists only at the surface of separation between th body and some other body, the interior elements of the body containing, as the neutral state, equal amounts of electricity of opposite kinds.

4. It is impossible to charge a body with electricity of one sign without pr ducing on the same or on some other body an equal charge of the opposi sign.

5. Forces can be produced on the electricity in a body by various extern agents, without necessarily producing a force on the body as a whole. Wh such forces are produced the two kinds of electricity are either displaced rel tively to each other or are constrained to move through the body in opposi directions. This displacement or motion is always opposed by forces set within the body itself. The opposing forces are of two kinds, (1) a for analogous to the opposing force set up in an elastic body when it is stretched compressed, and (2) a force analogous to the resisting force due to mechanic friction produced when one body moves over another.

6. When the electricity in a body is acted upon by an external force, bu cannot escape from that body to another, this force is transmitted to the bo itself.

7. Electricity possesses inertia, just as ordinary matter possesses inertia; i.e., force is required to change the motion of a charge of electricity just as a force required to change the motion of a portion of matter. The "effective" inert of a given quantity of electricity depends upon the path over which it caused to move and upon the nature of the surrounding bodies (*see Electr Theory*).

Unit of Charge or Quantity of Electricity. — The unit of electr charge or quantity of electricity in the practical system of units is called t coulomb. For the relation between the coulomb, statcoulomb, abcoulom and other units of quantity see *Units and Conversion Factors*.

ELECTRIC FIELDS OF FORCE. — In any portion of a substance which the electricity is acted upon by a force tending to move it, there is sa to be an "electric field of force," or briefly an "electric field." An electric fie is also said to exist in any region of free space where a charge, if placed the would have a force exerted upon it tending to move it.

Intensity of an Electric Field (F). — The "intensity" of an electric fie at any point is defined as the force per unit positive charge exerted on a char at this point by the agent or agents producing the field i.e., by the agent agents tending to move the charge. The direction of the field intensity, or t direction of the field, is defined as the direction of the force acting on a *positi* charge at this point. A positive charge then moves or tends to move in t direction of the field and a negative charge moves or tends to move in t opposite direction.

Units of Electric Field Intensity. — The unit of electric field intens has not been given any special name, but since it is of the same nature electromotive force per unit distance, the intensity at any point may be co veniently expressed as so many volts, abvolts or statvolts *per centimeter* or *inch;* see *Units and Conversion Factors*. Hence electric field intensity is f quently called the potential, or voltage, "gradient."

Lines of Electric Force. — Lines of Electric Intensity. — A line dra in an electric field in such a manner that its direction at each point coinci

ith the direction of the field at that point is called a "line of electric force." line of force is usually a curved line, though in certain special cases it may straight. Any number of such lines may be drawn in an electric field, but two of these lines can intersect. The density of these lines, i.e., the num- drawn through unit area perpendicular to their direction, may be chosen rbitrarily to represent the value of the field intensity at this area, and when drawn are preferably called "lines of electric intensity," as distinguished om flux lines and stream lines defined below. The term "lines of force," owever, is frequently used to designate any one of these three sets of lines, but s loose use of the term is liable at times to lead to much confusion. The rm "line of electric force" will be used in this article to designate merely the irection of the field at any point; in any statement involving the *density* of ese lines the proper one of the other terms will be employed.

Electric Equipotential Surfaces. — A surface drawn in an electric field in uch a manner that it is perpendicular at each point to the line of force through ch point is called an "electric equipotential surface." The electric in- nsity has no component along such a surface, and therefore no work is re- ired to move a charge from one point to another over any path in such a rface.

ELECTROMOTIVE FORCE (E). — The work done by the field intensity moving unit positive charge around any *closed* path or circuit (Fig. 1) in electric field is defined as the "electromotive force," breviated "e.m.f.," acting around this path. Elec- motive force is not a force in the mechanical sense t is *work per unit charge*. The relation between elec- motive force E and field intensity F is analogous to at between work and mechanical force viz.,

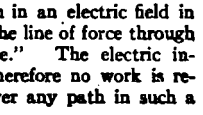

Fig. 1.

$$E = \int (F \cos \theta)\, dl, \qquad (1)$$

here dl represents an elementary length of the path, $(F \cos \theta)$ the *component* the field intensity along dl and $\int$ represents the integral around this closed th. When the field intensity has the same value F at every point of a path d coincides in direction with the path at every point, the electromotive force ting around the closed loop is

$$E = Fl \qquad (1a)$$

here l is the total length of the path.

Units of Electromotive Force. — The practical unit of electromotive rce is the volt; see *Units, Practical Electrical*. See also *Units and Con- rsion Factors* for the other units and their interrelations.

Sources of Electromotive Force. — The primary sources of e.m.f. are (1) two dissimilar bodies in contact (*see Batteries; Electrochemistry, Principles* f) and (2) a varying magnetic flux linking the circuit (*see the articles on nerators; Transformers, etc.*). The e.m.f. is said to be "located" at the rface of contact in the case of a "contact" e.m.f., or in that portion of the rcuit which is linked by the varying magnetic flux in the case of an "induced" m.f., for experience shows that the value of the work integral, equation (1), ound any circuit passing through a given surface of contact or linking a given rying flux is always the same, irrespective of the shape of the circuit and of e nature of substance through which the path passes, provided there are no her sources of e.m.f. in this path. Contact e.m.f.'s are usually extremely

small (of the order of 0.001 volt) except in the case of metallic subst contact with electrolytes, in which case they may amount to several v *Batteries; Electrochemistry, Principles of.* E.m.f.'s of 500,000 volts or n be produced by a varying magnetic flux.

Direction of an Electromotive Force. — The direction of the e.m.f portion of a circuit is taken as the direction in which a positive charg be forced *around* a circuit containing only this one source of e.m.f. A circuit may contain several sources of e.m.f.; in this case the resultan acting around in the circuit is the *algebraic* sum of all these e.m.f's, the acting around the circuit in one direction being taken as positive and th ing around the circuit in the opposite direction being taken as negative. e.m.f.'s which act in the opposite direction to the resultant e.m.f. ar "back" or "counter" e.m.f.'s.

A convenient symbol for a source of constant e.m.f. is shown in Fig. long light line represents the positive terminal and the short heavy

Fig. 2.

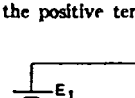

Fig. 3.

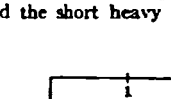

Fig. 4.

negative terminal. Fig. 3 shows two e.m.f.'s acting around a circuit in t direction, and Fig. 4 shows two e.m.f.'s acting around the circuit in directions. In the first case the resultant e.m.f. is $E_1 + E_2$ and the two are said to be "in series," and in the second case the resultant e.m.f. actin right-handed direction around the circuit is $E_1 - E_2$ and the two e.m said to be "in opposition." When E_2 is less than E_1 then E_2 is a counter e.m.f.

DIFFERENCE OF ELECTRIC POTENTIAL (V). — Consider tion of a path A between any two points 1 and 2 in an electric field (The total work done on unit charge, *by the e.m.f.'s external to this portio path* when unit charge moves from 1 to 2, is called the "drop of electri tial" from 1 to 2. The term "difference" of electric potential is also co used to designate this quantity; the term "drop" is preferable since it the direction of the difference. Electric potential drop is of the same na electromotive force and is expressed in the same units. It is frequently viated "p.d." Potential drop may be due either (1) to a "back" electr force, analogous to the back pressure of a pump, or (2) to an opposin analogous to that due to the resistance of a pipe to the flow of water.

Let the path from 1 to 2 be in the direction of the line of force from let E_{12} be an e.m.f. whose source is between 1 and 2 and whose direction 1 to 2, then the general expression for the potential drop from 1 to 2 is

$$V_{12} = \int_1^2 F\,dl - E_{12}.$$

The first term represents the "resistance" drop and $-E_{12} = E_{21}$ represe "back" pressure. If the field intensity along the path from 1 to 2 is neg then $V_{12} = -E_{12}$; hence an e.m.f. in a given direction is equivalent to a n drop of potential, i.e., is equivalent to an actual *rise* of potential. Con

) with equation (1) it is evident that the total drop of potential around a *closed* rcuit is always zero. This relation is conveniently expressed by the formula

$$\Sigma V = 0 \qquad (3)$$

hich holds for every closed path or circuit. This is one way of stating Kirchoff's second "law."

Voltage and Voltage Gradient. — The term "voltage" is commonly used r either an e.m.f. or a potential difference, particularly when these quantities re expressed in volts. Since from equation (2) the field intensity F is equal in ids to the drop in voltage per unit length, the electric field intensity is also requently called the voltage "gradient."

Positive and Negative Terminals. — That terminal of a device which is at he higher potential is called the positive terminal, the other terminal being alled the negative terminal. The drop of potential is *always* from the positive o the negative terminal, irrespective of the direction of flow of electricity hrough the device.

FLOW OF ELECTRICITY. — Whenever an electric field is set up in a ubstance by any means whatever a displacement of the electricity in that ubstance always takes place, the nature of the displacement depending upon he nature of the substance. In every case the positive electricity within the ubstance is displaced in the direction of the field intensity and the negative lectricity in the opposite direction, until an opposing force of some kind is set up which just balances the forces due to the impressed field.

Conductors and Insulators or Dielectrics. — A substance in which a onstant electric field is always accompanied by a *continuous* displacement or *low* of electricity through the substance is called an "electric conductor;" hen there is no flow of electricity through a conductor the field within the conuctor is *always* zero. Every substance is a conductor of electricity, at least to a slight extent, but some substances are far better conductors than others. A ubstance in which a constant electric field produces only a relatively small ontinuous flow of electricity is called an "electric insulator" or "dielectric." A *perfect* dielectric may be defined as a substance through which it is impossible to set up a continuous flow of electricity; no such substance exists, but very poor onductors are approximately such. Free space may be considered a perfect dielectric, but free space differs from a substance in that it does not contain electricity.

Metals are the best conductors, carbon and most moist substances are fair onductors; dry non-metallic bodies such as air and other gases (at normal pressure), porcelain, glass, rubber, and dry paper are very good insulators.

A wire covered with an insulating substance or supported on insulating substances is said to be "insulated," even though its ends are connected to a source of e.m.f.

Electric Current (I). — The displacement of the electricity within a substance cannot be measured directly, but only in terms of some effect produced thereby. Two effects which always occur when a displacement of electricity is produced are (1) a magnetic field is established around the path along which the displacement takes place (but disappears when the electricity comes to rest) and (2) heat is developed in the path of the displacement. The magnetic field produced by a displacement or flow of electricity is usually taken as the measure of the *rate* of flow, i.e., of the quantity of electricity displaced per unit time through a surface perpendicular to the direction of the displacement. This rate of flow is called the "intensity" of the electric current, or simply the "electric current," and is usually represented by the symbol I.

Google

Direction of the Electric Current. — A flow of positive electric one direction is equivalent magnetically to a flow of an equal amount of ne electricity in the opposite direction; hence the total flow along a given p the sum of the positive electricity displaced per unit time in one direction point in this path plus the negative electricity displaced per unit time pas point in the opposite direction. The "direction" of the electric current is as the direction in which the positive electricity is displaced, and is, the the same as the direction of the field intensity.

Current due to Varying Electric Field. — When the electric fi any substance is *varying*, the total magnetic effect produced is found to d not only upon the rate of displacement of the electricity within the subs but also upon the *rate of change* of the electric field. In fact, a magneti is produced around a path in *free space* along which the intensity of the el field is varying, see *Waves, Electromagnetic*. In dealing with varying el fields it is found convenient to consider the variation of the field intens equivalent to an actual flow of electricity, and to take as the total *equ* electric current the flow of electricity which would produce the same ma field as that actually observed; the *actual* flow of electricity is then in g less than this equivalent current, but the difference is negligible except i stances which are good insulators.

Units of Electric Current. — The practical unit of electric current ampere; see *Units, Practical Electrical*. For the relation between this un the statampere and abampere see *Units and Conversion Factors*.

Continuity of an Electric Current. — When a varying electric fi considered as equivalent to an electric current, it is found that the total e lent current coming up to any point or surface in any network of circuits, no matter how complicated, is *always* equal to the total current leaving that point or surface, irrespective of the nature of the substances through which the currents are established and irrespective of whether the currents are constant or are varying. For example, in Fig. 5,

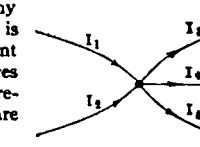

Fig. 5.

$$I_1 + I_2 = I_3 + I_4 + I_5. \qquad (4)$$

Or, calling the currents coming up to any point positive, and the currents le that point negative, the *algebraic* sum of all the currents at any point in work of circuits is always zero. This fundamental principle is conven expressed by the formula

$$\Sigma I = 0$$

which holds at every junction point both for variable and for continuous cur This is Kirchhoff's first "law."

Stream Lines of Electric Current. — Current Density (σ). — consequence of the continuity of an electric current, the total current i substance of any size or shape may be looked upon as made up of a numb small streams of electricity flowing side by side, the strength (quanti electricity per second) of each stream being constant throughout its length the cross-section of each stream at any point is so chosen that each st represents unit current (unit quantity per second), then the number of streams crossing unit area of a surface perpendicular to their direction w equal to the current per unit area of this surface, or to the "current density this surface. Each such stream may be represented graphically by a line ciding with its axis; such lines are called "stream lines." When the st lines are drawn as described their direction at any point gives the directi

current at this point and the number of these lines per unit area perpendicu- to their direction is equal to the current density at this point.

In the case of an insulated wire the stream lines are parallel to the axis of the e, except in the immediate vicinity of its ends; this non-uniformity at the ls in the case of a long wire is negligible. The stream lines in an ordinary e may also, in most practical cases, be considered as all coinciding, and the e may, therefore, be treated as a geometrical line as regards *external* effects. wever, in the case of a short rod or strip (such as an ammeter shunt) con- ted in the circuit by wires attached to its ends, the stream lines are not in eral parallel but diverge from one terminal and converge toward the other.

Continuous, Direct, Pulsating, Alternating and Oscillatory Currents.— "continuous" electric current is defined as a current which does not vary th time. A "direct" current is a current which is always in the same direc- n but may vary or pulsate in value. The term "direct current" is ordi- rily used to designate either a continuous current or a current which varies pulsates only by an inappreciable amount, such as the current from a battery direct-current generator (q.v.). A "pulsating" current is a direct current hich pulsates by an appreciable amount, such as the current from a rectifier (q.v.). An "alternating" current is a current which reverses in direction, being st positive and then negative, but alternates between *constant* maximum sitive and negative values; see article on *Alternating Currents*. An "oscilla- ry" current is a current which reverses in direction, oscillating between positive d negative values which either decrease or increase with time.

Conduction Current and Displacement Current. — Experience shows at when an electric field is established in any substance, the total equivalent lectric current set up depends (1) upon the value of the field intensity, (2) upon le rate of change of the field intensity, and (3) upon the nature of the substance which the field is established. The current density σ at any point at any stant may in general be expressed by the relation

$$\sigma = \gamma F + \frac{1}{4\pi}\frac{d}{dt}(kF), \tag{6}$$

here F is the field intensity, γ and k are coefficients depending upon the chemi- l nature and physical condition of the substance at the point in question, and

$\frac{d}{dt}$ means the rate of change with respect to time, the factor 4π arising from the

istorical definition of the quantity k, see below. The total current may then e considered as the sum of two components having respectively the densities

$$\sigma_1 = \gamma F \qquad \text{and} \qquad \sigma_2 = \frac{1}{4\pi}\frac{d}{dt}(kF). \tag{6a}$$

The first of these components (σ_1) is called the "conduction" current, and the second (σ_2) is commonly called the "displacement" current. The term "displacement" current, however, is somewhat a misnomer, for both com- ponents of the total current are probably due, in part at least, to a displace- ment of electricity; whereas a displacement current is set up by a varying electric field in a *free space*, although there is probably no electricity in free space to be displaced. The conduction current is the only appreciable com- ponent in substances usually classed as conductors, and the displacement cur- rent is appreciable only in substances ordinarily classed as dielectrics. The conduction current in a dielectric is usually small, though measurable; it is frequently called the "leakage" current. When the electric field in a dielectric is rapidly varying the displacement current may be many times greater than the conduction or leakage current through the dielectric.

Digitized by Google

Conductivity (γ) and Resistivity (ρ). — The quotient of the density σ the conduction current by the field intensity F, i.e., the coefficient γ in expression $\sigma_1 = \gamma F$ is called the "conductivity" of the substance at the po in question. Since in an ordinary conductor the displacement current is appreciable, the conductivity of an ordinary conductor is also equal to density of the total current divided by the field intensity, i.e., for a conduc

$$\sigma = \gamma F,$$

where σ represents the density of the total current. Experience shows that a given conductor at constant temperature (and also at constant pressure case of a gas) this coefficient γ is a constant irrespective of the strength, d tribution or time variation of the current. The value of γ for a dielectr however, is not in general a constant but depends upon the time variation the field intensity; see below under *Capacity and Condensers*.

The above relation between σ and F may also be written

$$F = \rho\sigma, \qquad (7$$

where ρ is the reciprocal of the conductivity γ. The constant ρ is called t "resistivity" or "specific resistance" of the substance. Values of γ and ρ f various conductors are given in the article on *Resistance and Conductance*, an also the methods of measuring these quantities. The values of γ and ρ f some of the more common insulating materials are given in the article on *I sulating Materials, Properties of*. For the units of conductivity and resistivi see *Units and Conversion Factors* and also the next two paragraphs.

Conductance (g) and Resistance (r). — To cause a *continuous* current I flow through a given conductor in which there is no source of e.m.f. a differen of potential must be established by some external agent between the ends of th conductor. Let V be the potential drop established through the conducto from any point 1 to any other point 2, then the quotient

$$g = \frac{I}{V} \qquad (8$$

is defined as the "conductance*" from 1 to 2, and the quotient

$$r = \frac{V}{I} \qquad (8a$$

is defined as the "resistance*" from 1 to 2. Conductance is the reciprocal o resistance and vice versa. The practical unit of resistance is called the ohm and the practical unit of conductance is called the mho; see *Units and Con version Factors*.

It should be carefully noted that the definitions expressed by equations (8, and (8a) hold only when there is no e.m.f. in the portion of the circuit unde consideration; this condition is realized only when the current remains con stant in value (i.e., a *continuous* current) and the conductor is of uniform material and at constant temperature throughout. Also, the definition is mean ingless unless the same current flows through each cross-section of the conducto and the drop of potential is the same between all points in the two end surfaces; i.e., the end surfaces must be equipotential surfaces.

Factors Upon Which Conductance and Resistance Depend. — The re sistance or conductance of a given portion of a conductor included between

Digitized by Google

equipotential surfaces and bounded laterally by a surface through which tream line passes, depends upon (*a*) the conductivity of the conductor he dimensions of this portion of the conductor, and (*c*) the distribution e stream lines over each cross-section perpendicular to them. Consider ase of a straight wire or bar over the cross-section of which the current is mly distributed. Let l be the length of the bar, A its cross-section and resistivity. Then from equation (2) the drop of potential along the length $V = Fl$; from equation (7a) $F = \rho\sigma$; therefore $V = \rho\sigma l$. The total current σA; whence the resistance and conductance are

$$r = \rho \frac{l}{A} \quad \text{and} \quad g = \gamma \frac{A}{l}. \tag{9}$$

ence, the conductivity of a substance is equal to the conductance, and the tivity is equal to the resistance, of a unit cube of this substance when the ent through this cube is parallel to four edges of the cube and is uniformly ibuted over the section at right angles to these four edges. Hence conduc- ty is frequently expressed as mhos per centimeter cube or inch cube; see *tance and Conductance; Units and Conversion Factors.*

quation (9) is applicable only to a conductor in which the stream lines are formly distributed and parallel to each other, such as in insulated wires carry- continuous or comparatively slowly varying currents. When the stream es are not parallel to each other, let dl represent an elementary length along stream line and σ the current density at dl; then taking the integral along stream line from one end surface to the other, the resistance is

$$r = \frac{\rho \int \sigma \, dl}{I} \tag{9a}$$

re I is the total current. The calculation of the value of σ at each point g the line from one surface to the other is difficult except in certain special s of symmetry; see however, equation (22) below.

hm's Law and Resistance Drop. — From the relations noted above it is ent that, in a conductor (*a*) which remains at constant temperature, (*b*) in ch there is no internal e.m.f., and (*c*) in which the distribution of stream lines ains unaltered, *the quotient of the voltage by the current is a constant.* This tion is known as Ohm's Law; it holds only when the three conditions specified ve are fulfilled.

he above relation may also be written $V = rI$ which is merely another form equation (2); i.e., if r is the resistance between any two points 1 and 2 n electric circuit in which the current is I, then the integral of the electric l intensity along the path from 1 to 2 is equal to rI. This drop of poten- l due solely to resistance between 1 and 2 is called the "resistance drop" m 1 to 2, and is always in the direction of the current. When there is an f. in the circuit between 1 and 2 and the distribution of current remains same,* the total drop from 1 to 2, from equation (2), is

$$V_{12} = rI_{12} - E_{12}, \tag{10}$$

subscripts indicating the directions of the various quantities. Equation (10) metimes referred to as the "modified" Ohm's law.

In general, the distribution of current depends upon the time variation of the volt- see article on *Skin Effect.*

Terminal and Impressed Voltages. — The application of this eq
best shown by considering a simple circuit containing a generator and
or other receiving device, Fig. 6. Let I be the current in this circuit,
the internal resistance of the generator, R_m the internal resistance of the motor and R_l the total resistance of the "line" or connecting wires, let E_g be the e.m.f. developed by the generator and E_m the back e.m.f. developed by the motor, and let V_g be the terminal voltage of the generator and V_m the terminal voltage of the motor. Through the generator the current flows from the − to the + terminal, the e.m.f. is from the − to the + terminal, and the drop of potential the + to the − terminal. Hence

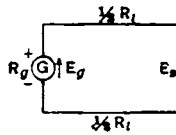

Fig. 6.

$$V_g = E_g - R_g I,$$

i.e., the terminal voltage is less than the generator e.m.f. by an amou
to the resistance drop in the armature. Through the motor the curr
from the + to the − terminal, the e.m.f. is from the − to the + termi
the drop of potential is from the + to the − terminal. Hence

$$V_m = E_m + R_m I,$$

i.e., the terminal voltage is greater than the back e.m.f. of the mot
amount equal to the resistance drop through the motor.

The terminal voltage of the motor is less than that of the generat
amount equal to the resistance drop in the line, i.e.,

$$V_m = V_g - R_l I.$$

The expression "impressed" electromotive force is also used to desig
rise of potential from the negative to the positive terminal of any
device, whether it be a motor, bank of lamps, or any "straight" resistan
resistance containing no source of electromotive force.

Series Circuits. — When several conductors are connected end to
that the *same current* flows through each of them (Fig. 7), they are said to be connected "in series." Let I_{12} be the current in each conductor in the direction from 1 to 2, let R', R'', R''', etc., be the resistances of the various conductors and E'_{12}, E''_{12}, E'''_{12}, etc., be the e.m.f.'s in the circuit between 1 and 2 in the direction from 1 to 2. Then the potential drop from 1 to 2 is

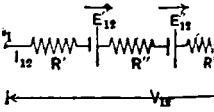

Fig. 7.

$$V_{12} = R'I_{12} - E'_{12} + R''I_{12} - E''_{12} + R'''I_{12} - E'''_{12}, \text{ etc.}$$

Therefore, the resistances between the points 1 and 2 are equivalent to resistance

$$R = R' + R'' + R''', \text{ etc.,}$$

and the e.m.f.'s between the points 1 and 2 are equivalent to a single e

$$E_{12} = E'_{12} + E''_{12} + E'''_{12}, \text{ etc.}$$

Digitized by Google

equivalent conductance of several conductances G', G'', G''', etc., in series *there are no e.m.f.'s in the path*, is G where

$$\frac{1}{G} = \frac{1}{G'} + \frac{1}{G''} + \frac{1}{G'''} + \ldots \qquad (11b)$$

allel Circuits. — When several conductors are connected to two common ints so that the *same potential drop* tablished through each (Fig. 8), they are to be "in parallel." Let the currents, e.m.f.'s resistances be as designated in the figure. n from equation (5)

$$I_{12} = I'_{12} + I''_{12} + I'''_{12} + \text{etc.}$$

Fig. 8.

from equation (10a)

$$V_{12} = R'I'_{12} - E'_{12} = R''I''_{12} - E''_{12} = R'''I'''_{12} - E'''_{12} = \text{etc.},$$

which relations the currents in the individual branches may be calculated. ere *there are no e.m.f.'s* in the various branches, the combined resistance of veral branches from 1 to 2 is R where

$$\frac{1}{R} = \frac{1}{R'} + \frac{1}{R''} + \frac{1}{R'''} + \ldots, \qquad (12a)$$

the combined conductance is

$$G = G' + G'' + G''' + \ldots, \qquad (12a)$$

re G_1, G_2, G_3, etc., are the individual conductances.

wo Parallel Circuits. — In the special case of two conductors in parallel, no e.m.f. in either, the combined resistance is

$$R = \frac{R_1 R_2}{R_1 + R_2}. \qquad (12b)$$

eries-parallel Circuits. — When a circuit is made up of several conductors e of which are in series and some in parallel, it is called a "series-parallel" it. The total resistance or conductance of such a circuit can be calculated the constants of the several branches by applying successively the formulas eries and for parallel circuits.

Kirchhoff's Network Laws. — The relations given above for conductors in es and in parallel are special cases of two general laws already stated, namely:

The algebraic sum of the currents coming up to any junction in a network conductors is always zero (equation 5).

The algebraic sum of the potential drops around any closed loop in a net- k of conductors is always zero (equation 3).

ese two laws are known as Kirchhoff's Laws, from the name of the scien- who first clearly enunciated them. By making use of them one can always termine (*a*) the current in each branch of a network when the resistance ch branch and the e.m.f. in each branch are known, or (*b*) the e.m.f. in each ch when the current in each branch and the resistance of each branch are wn.

should be carefully borne in mind in applying these laws that a current ing a point is equivalent to a negative current *entering* that point, and that

an e.m.f. in any chosen direction is equivalent to a *rise* of potent direction. In working out any problem concerning a network of ci convenient to make a diagram of the network and to place on each this diagram a number or symbol to represent the value of the curr branch and an arrow or subscripts to indicate the direction of the cur sented by this number or symbol, and wherever there is an e.m.f. number or symbol to represent the value of this e.m.f. and an arrow o to indicate its direction. Then at any junction point those currents r by arrows pointing toward the point are to be considered positive (say represented by arrows pointing away from the point are to be consid tive; and for any closed loop those currents and e.m.f.'s represented pointing around the loop in the clockwise direction (say) are to be positive and those pointing around the loop in the counter-clockwis are to be considered negative. With this understanding, these la written

$$\Sigma I = 0 \text{ at every point,}$$

$$\Sigma E = \Sigma rI \text{ for every closed loop,}$$

where I, r and E represent the current, the resistance and the e.m.f. r in each branch of the loop, and the symbol Σ indicates the algebraic quantities following it.

These equations enable one to write down a set of simultaneous eq the given network, but it will be found that at least one of the curren may be derived directly from the other current equations, and that a of the potential equations may be derived from the other potential That is, the number of independent equations of each form will be on the number which it is possible to write down. It should also be no is frequently unnecessary to write down formally all the possible in equations; many of the simpler problems can be solved by writing independent expressions for the potential drop between each pair of equating these two expressions.*

When the currents and e.m.f.'s are *varying*, the first law applies t current (conduction and displacement current), but the second law i given in (13b) applies only to closed loops of conduction current; in the instantaneous values of the currents and e.m.f.'s must be taken quantities are varying.

ELECTRIC ENERGY AND POWER. — From the definition o drop it follows that the total work done by the external agents in forci of electricity from any point 1 in a circuit to any point 2 is $W = V$ the definition of electric current the quantity of electricity carried fr when the current I is established from 1 to 2 is $Q = It$, where t is the ti which the current exists. Hence when a current I is established th device for a time t by an impressed voltage V, the energy input to thi

$$W = VIt$$

and the power input, i.e., energy input per unit time, is

$$P = VI.$$

When V and I are expressed in volts and amperes respectively the po is in watts; if t is in seconds, the energy input is in joules or watt-second V and I are in statvolts and statamperes respectively, or in abvolts a

* The application of these laws to the solution of complicated network p given in detail in Del Mar's *Electric Power Conductors*, New York, 1913.

s respectively, the power input is in ergs per second, if t is in seconds the gy input is in ergs. See *Units and Conversion Factors*.

pplying the above relations to the simple circuit shown in Fig. 6 containing nerator and a motor (armature windings only are considered), the power ut to the motor armature is

$$P_i = E_m I + R_m I^2, \tag{15a}$$

power *output* of the generator armature is

$$P_0 = E_g I - R_g I^2 \tag{15b}$$

l the power lost in the line is

$$P_l = R_l I^2.$$

e term $R_g I^2$ represents the power lost in heating the armature winding of the erator due to its resistance, and the term $R_m I^2$ represents the power dis-ted as heat in the armature winding of the motor. The net electric input the generator armature is $E_g I$ and the gross mechanical output of the motor nature is $E_m I$. The gross mechanical input to the generator is greater than I and the net mechanical output of the motor is less than $E_m I$ by an amount e to the friction and "core-loss" in the respective machines; see *Generators d Motors*.

Joule's Law. — That portion of the power input to any device which is equal the product of the resistance of the conductors forming the winding of the ice by the square of the current through this winding is always converted into t. That is, when a current I flows through a resistance r heat is always ipated" in this resistance, and the rate of dissipation is

$$P_h = rI^2. \tag{15c}$$

is experimental fact is known as "Joule's Law." This law applies directly y to continuous or non-varying currents. The relation $P_h = rI^2$ is, however, o as the basis for defining the "effective" resistance of a conductor to an rnating current (q.v.).

DIELECTRIC FLUX (ψ) AND DIELECTRIC FLUX DENSITY). — As noted above the displacement current through a dielectric at any nt depends upon the rate of change of the electric field intensity and upon the ture of the dielectric, and the density of this displacement current at any point y be expressed by the relation

$$\sigma_2 = \frac{1}{4\pi}\frac{d}{dt}(kF), \tag{16}$$

ere F is the field intensity and k a coefficient depending upon the nature of e dielectric. The coefficient k in this expression is the so-called dielectric co-ient or dielectric constant.

The quantity kF, whose rate of change is equal to 4π times the density of the placement current, is called the "dielectric flux density," and may be repre-ted by the symbol D. Then

$$D = kF. \tag{17}$$

e direction of the dielectric flux density is arbitrarily chosen to be the same that of the electric field intensity F. Through any surface of area A at each nt of which the dielectric flux density has a constant value D and is perpen-ular to that surface, there is said to exist a "dielectric flux" equal to DA. he total dielectric flux through a surface may be represented by the symbol ψ.

In general, the total dielectric flux through any surface perpendicular at point to the direction of the field intensity at that point (i.e., through an potential surface) is

$$\psi = \int D\, ds,$$

where ds represents any elementary area of this surface and D the flux de per unit area at ds, and $\int$ represents the sum of all the products $D\,ds$ for surface. The total displacement current through this surface is then

$$i = \frac{1}{4\pi}\frac{d\psi}{dt}.$$

Lines of Dielectric Flux. — The electrostatic flux through any surface be represented by lines drawn in the same direction as the lines of electric in sity, but of such a density that *their number per unit area* perpendicular to direction at any point *is equal* to the *dielectric flux density* at this point. number of these lines cutting any surface is then equal to the total dielec flux through this surface. The ratio of the number of flux lines through surface to the number of lines of electric intensity through that surface is e to the dielectric coefficient of the substance in which the field exists.

ELECTRIC CHARGE (Q) AND DIELECTRIC FLUX (ψ). — Wi any substance of uniform structure throughout the dielectric flux lines are tinuous lines, i.e., the number of these lines coming up to one side of a sur *within* such a substance is equal to the number of these lines leaving the o side of that surface. Experience shows that it is impossible to produce appreciable dielectric flux in those substances ordinarily classed as conduct *hence dielectric flux lines cannot pass through a good conductor*, but terminat its surface. Every dielectric is a conductor to at least a slight extent, on account of this fact the dielectric flux lines coming up through one di tric to the surface of contact between this dielectric and another do not pass through the second dielectric, but some of them terminate at this surf

Experience shows that to establish an electric field in the dielectric arou conductor, electricity must be *conducted through the conductor* to the surfac contact between the conductor and the dielectric. For example, conside good conductor in contact with a perfect dielectric, Fig. 9; a momentary conduction current must flow through the conductor along the stream lines of the conduction current, represented by the dotted lines. While the field is being established (and therefore varying) a displacement current is set up in the dielectric requiring an equal conduction current in

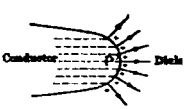

Fig. 9.

the conductor, and consequently $\frac{1}{4\pi}$ times the rate of change of the dielec flux (ψ) established in the dielectric must be equal to the conduction current flowing up to this surface through the conductor, i.e.,

$$\frac{1}{4\pi}\frac{d\psi}{dt} = i,$$

or

$$\psi = 4\pi \int i\, dt = 4\pi Q,$$

Digitized by Google

: Q is the quantity of electricity (current multiplied by time) conducted gh the conductor to this surface.

is relation is a general one, viz., the total dielectric flux from any area A t surface of a *conductor* is equal to 4π times the total charge on this area. e every flux line originates at a positively charged conducting surface and inates at a negatively charged conducting surface, 4π of these lines con- g each unit positive charge to each unit negative charge.

e quantity of electricity conducted through a conductor when a momen- current is established through it can be readily measured by means of a ic galvanometer (*see Galvanometers*) and consequently the dielectric flux al to $4\pi Q$) may be readily determined.

its of Dielectric Flux. — Dielectric flux may be expressed in the same as electric charge, viz., coulombs, statcoulcombs or abcoulombs; see *Units Conversion Factors*.

rface Density of Charge (σ_c) and Dielectric Flux Density (D). — When e is no current in a conductor there can be no electric field within it, see ion (7), and therefore *the surface of a conductor in which no current is flow- is always an equipotential surface.* Hence the lines of electrostatic intensity, e surrounding dielectric, and therefore the dielectric flux lines also, must t at enter this surface in a direction perpendicular to it. The dielectric x density in the dielectric just outside a conducting surface in which there is ectric current is perpendicular to this surface and is

$$D = 4\pi\sigma_c, \tag{20a}$$

re σ_c is the charge per unit area of the surface at this point, or the "surface sity" of the charge.

Dielectric Flux Density Due to a Number of Charged Conductors. — an be shown that when any number of charged conductors are surrounded a *uniform* dielectric, the dielectric flux density at any point in the field may expressed by considering each elementary surface having a charge q as pro- ing at any point P at a distance r from q a flux density equal to q/r^2, in direction of the line from q to P when q is positive and in the direction of line from P to q when q is negative. The total flux density at P due to the charges is then the *vector summation*

$$D = \sum \frac{q}{r^2}. \tag{20b}$$

Dielectric Flux Density at any Point due to a Uniformly Charged ire of Circular Cross Section and Infinite Length. — Let q be the charge r unit length, K the dielectric coefficient of the surrounding dielectric, as- ed uniform, and r the perpendicular distance from the center of the wire any point P, then the dielectric flux density at P due to this wire is

$$D = \frac{2q}{r} \tag{20c}$$

e resultant dielectric flux density at any point due to any number of *uni- ly* charged wires is the vector sum of the flux densities due to each sepa- ely. However, when two or more wires are close together the distribution charge on them is not uniform,* but when the wires are more than 10

* The distribution can be calculated readily in the case of two parallel wires; see nder and Osborne, *Elec. World*, 1910, *Vol.* 56, *p.* 667.

Digitized by Google

diameters apart the error introduced by the assumption of uniform c practically negligible.

ELECTROSTATIC CAPACITY (C) AND CONDENSERS. — T lish a given dielectric flux ψ through a given dielectric a certain diffe electric potential is always required. Consider any portion of an electric field (Fig. 10) between the two equipotential surfaces S and S_1 bounded laterally by a surface tangent at each point to the flux line through that point. Let V be the drop of potential from S to S_1, and let ψ be the dielectric flux through this region. When there is no source of e.m.f. between S and S_1 the quotient

Fig.

$$C = \frac{\psi}{4\pi V} \qquad (21)$$

is defined as the "electrostatic capacity" of this portion of the field. pare with the definition of conductance, equation (8).

When the equipotential surfaces S and S_1 are the surfaces of two con the two conductors and the dielectric between them are said to form a tric condenser." Practical forms of condensers are described in the a *Condensers, Electric*. When all the flux lines from one conductor end second conductor (e.g., when they are given equal and opposite charges necting them respectively to the two terminals of a source of e.m.f.), flux from one to the other is equal to $4\pi Q$ where Q is the numerical valu total charge on either conductor. The capacity of the condenser may written

$$C = \frac{Q}{V}.$$

When there are several charged conductors in the field the total fl one conductor does not in general all end on another single conduct some of the flux lines from No. 1, say, may run to No. 2, some to No Let ψ_{12} be *that portion* of the flux from any conductor 1 which ends other conductor 2, and let V_{12} be the drop of potential from 1 to 2, t capacity between conductor No. 1 and conductor No. 2 is

$$C_{12} = \frac{\psi_{12}}{4\pi V_{12}}.$$

Or, calling Q_{12} that portion of the charge on No. 1 which is balanced by and opposite charge on No. 2, the capacity between 1 and 2 is

$$C_{12} = \frac{Q_{12}}{V_{12}}.$$

Units of Capacity. — The unit of capacity in the practical system is the farad (*see Units, Practical Electric*), but as this is a very large unit equal to one-millionth of a farad, called the microfarad, is usua ployed. The c.g.s. electrostatic unit may be called the statfarad a c.g.s. electromagnetic unit the abfarad. See *Units and Conversion Fact*

Factors Upon Which Capacity Depends. — The capacity of a giv tion of a dielectric depends upon (*a*) the dielectric coefficient k of t lectric, (*b*) the length of the dielectric flux lines through it; (*c*) the cross of the dielectric at right angles to the flux lines, and (*d*) upon the distribu the flux lines over this cross-section. Compare with electric conductan

Digitized by Google

of a dielectric bounded laterally by flux lines surfaces (Fig. 10) can be expressed by the

$$= \frac{k\psi}{4\pi \int D\,dl}, \qquad (21d)$$

ψ the total dielectric flux through the given tary length along one of the flux lines and D oint, the integral being taken along the flux her. When the end surfaces are conductors respectively, then

$$C = \frac{KQ}{\int D\,dl}. \qquad (21e)$$

la the capacity of various practical forms of the article on *Capacity and Charging Cur-* oted that the capacity of a condenser depends ric flux (k being assumed constant), but not ix; i.e., for a given dielectric and given dis- constant. In general, when any conductor inductive capacity is placed in the electric of a condenser, the distribution of the flux, ondenser, is altered.

ce and Capacity. — Comparing equations t when the dielectric flux lines and the cur- distribution in any given region, the ratio o the capacity of this region is $4\pi\gamma/k$ where he conductivity of the material in this region. y and conductance of the dielectric between ondenser differ only by a constant coefficient. condenser, then

$$g = \frac{4\pi\gamma}{k} \cdot C \qquad (22)$$

between its plates. Values of C for various *apacity and Charging Current.*

Condenser. — To charge a condenser a dif- e established between its plates. This may cting the two plates of the condenser respec- source of e.m.f., see Fig. 11. If the dielectric source of e.m.f. t set up in this difference of po- ished across the il a charge equal e "negative" to

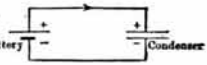

Fig. 11.

nser. The establishment of the electric flux nser may be looked upon as setting up in the analogous to the opposing force set up in a hen the opposing force just balances the im- ned, just as the compressing of a spring ceases

Digitized by Google

when the force producing the compression is just balanced by the
force due to the elasticity of the spring.

When a condenser has thus been charged, the wires connecting it to th
of e.m.f. may be removed and the condenser remains charged for a lengt
depending upon the resistance of the dielectric separating the plates; th
this resistance the longer the time that the condenser remains charge
plates may also be moved apart and they still retain their charges, o
a positive charge and the other a negative charge, but the distribution
charges on the plates will in general become altered. Experience show
mechanical force is required to separate the charged plates irrespe
whether or not they are connected to the source of e.m.f.

When the two charged plates are "short-circuited" by a wire, as s
Fig. 12, a momentary current is established through the wire and the
field between the plates and the charges disappear. The quantity of el
discharged through the wires is equal to the quantity of charge origi
either plate. A charged condenser, therefore, acts like a
source of e.m.f., the direction of this e.m.f. *around* the circuit
containing the condenser being in the direction *through* the
condenser from its negative to its positive plate. A condenser
when it is being charged may also be looked upon as produc-
ing a back e.m.f., that is, an e.m.f. opposing the e.m.f. which
charges it. When a condenser is considered from this point of view
conducting portion of the circuit is to be considered in applying Kirchhof
When the condenser has an appreciable leakage its resistance must be co
to be in *parallel* with its e.m.f.

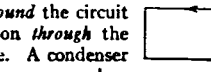

Fig.

Charging or Capacity Current and Leakage Current. — The
ment current through the dielectric of a condenser is frequently ca
"charging" or "capacity" current. The conduction current through
electric is called the "leakage" current. Let C be the capacity of the co
g the conductance of the dielectric, and v the voltage across the condens
the total current through the condenser is

$$i = gv + C\frac{dv}{dt},$$

where $\frac{dv}{dt}$ represents the rate of change of v with time. The compone
this current is the leakage current and the component $C\frac{dv}{dt}$ is the cha
capacity current.

Capacities in Series. — When several capacities* are connected en
so that the *same dielectric flux* passes through each of them, they are sa
"in series." The total capacity of any number of individual capacitie
C_1, etc., connected in series is C where

$$\frac{1}{C} = \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \ \cdots$$

Compare with conductances in series, equation (11b).

Capacities in Parallel. — When several capacities* are connected
the same pair of equipotential surfaces so that the *same potential drop* i
lished through each, they are said to be "in parallel." *When there are no*

an actual increase in the resistance of the dielectric with the speed of of the field, or may be due to a phenomenon analogous to magnetic i.e., to a lag of the dielectric flux density behind the electric field int *Magnetic Materials, Properties of*). Whatever may be the cause of loss of power for rapidly varying fields, it is generally described as th to "dielectric hysteresis." The heat developed is in many cases quit able. See also the article on *Condensers, Electric.*

DIELECTRIC STRENGTH. — ELECTRIC SPARK AND EL CORONA. — Experience shows that when an electric field is esta a dielectric and the intensity of this field is increased, a point is reache the dielectric loses its insulating property and becomes a conduct condition of affairs is usually accompanied by a spark which burns a ho the dielectric, i.e., the dielectric is "punctured." Under other cond breakdown may not be permanent, but may result in the acquisition conductivity by the dielectric only while the voltage gradient is m above the critical value, the dielectric regaining its insulating property field is reduced below this critical value. This latter condition is us scribed as the formation of an electric "corona" in the dielectric; in t air the formation of corona manifests itself by a bluish light in the a the conductors between which the field is established. Whether the b produced by a given voltage is of the nature of a puncture or results i mation of a corona depends chiefly upon the *distribution* of the diel produced in the dielectric (*see Corona, Electric*).

The critical field intensity or voltage gradient at which breakdown called the "dielectric strength" of the dielectric. The dielectric depends upon the nature of the dielectric, its value for the various ordinarily employed in practice depending decidedly upon their che physical nature (*see Insulating Materials, Properties of*). It is also f for a given dielectric the critical voltage *gradient* at which breakdo depends in general upon (*a*) the distribution of the dielectric flux jus breakdown and (*b*) upon the thickness of the dielectric. It is natur expected that the *voltage* (total potential difference) required to produc down would depend upon the distribution of the dielectric flux and the of the dielectric, for the voltage gradient at all voltages depends u factors (*see above under Capacity*), but there is as yet no satisfactory ex of the dependence of the *critical gradient* upon these factors.

In fact, but little is known regarding the nature of an electric breakd even the values of the dielectric strength are known only approximatel instances, for in many of the tests made to determine its value the di of the electric flux was not known. The values of the dielectric stren in the article on *Insulating Materials, Properties of*, must, therefore, be c only as rough approximations except for conditions identical with th which the tests were made.

ELECTROSTATIC ENERGY. — From the general relations by equations (15) and (23) it is evident that when the potential between the plates of a condenser is increased from 0 to V the ene is

$$\int_0^t gv^2\,dt + \int_0^V Cv\,dv.$$

The energy represented by the first term on the right-hand side of this is dissipated as heat in the dielectric, but the energy represented by th term, which, when C is constant, may be written

$$W = \tfrac{1}{2}CV^2,$$

Digitized by Google

heat; this is a fact of experience. More-
ged, by short-circuiting its plates with a
; CV^2 is transferred to the wire. Hence,
said to be stored in the condenser, or pref-
nser, for the electric force F exists only in
s called the "electrostatic" energy. It is

ple, the capacity of a parallel plate condenser

$$C = \frac{kA}{4\pi x},$$

Digitized by Google

where k is the dielectric coefficient, A the area of the smaller plate, an distance between the plates. Hence the force of *attraction* is

$$f = \frac{V^2 kA}{8\pi x^2}.$$

Principle of the Electrometer. — This relation suggests a method of m ing potential difference, for, by transposing,

$$V = x\sqrt{\frac{8\pi f}{kA}}.$$

If the force acting on the upper plate is measured by means of a balance, a and x are also measured, and the dielectric between them is air ($k = 1$ electrostatic system, by definition), then all the data necessary for the c tion of V is at hand. The above formula for V is approximate only, sin capacity formula is approximate, due to the assumption of a uniform flu sity in the dielectric between the plates. As a matter of fact the flux d near the edges of the plate is not uniform, but it is possible to correct f non-uniformity; see article on *Electrometers*.

MAGNETS AND MAGNETIC SUBSTANCES. — A magnet m defined as any body which possesses the property of attracting pieces of i steel * and which when freely suspended takes up a definite position with r to the geographical meridian. A magnetic substance is any body which ac this property when it is placed near a magnet or near a conductor carryi electric current. A body which is given this property is said to be " netized." A magnetic needle is a magnetized needle of iron or steel; the seeking end of such a needle is called its north pole and the south seeking e south pole. When such a needle is freely † suspended near a magnet conductor carrying an electric current a couple is bound to be exerted u which causes it to take up a definite direction. The nee · is said to "p in the direction of a line drawn through it from its south to its north pole.

MAGNETIC FIELD OF FORCE. — Any region in which a magnetic stance (e.g., a piece of soft iron), when placed therein, becomes magneti said to be a "magnetic field." A magnetic field exists in and around magnetized substance and around every stream line of electric current. direction of the magnetic field at any point P is arbitrarily chosen as the tion in which a small magnetic needle point would point when placed at P out disturbing appreciably the existing conditions.

Magnetic Flux (ϕ). — Consider a small closed turn of wire, Fig. 13, placed in a magnetic field with its plane perpendicular to the direction of the field. Experience shows that when such a turn of wire is removed from the field in any manner whatever (the coil remaining short-circuited on itself or forming part of a closed circuit), or when the magnetic field is caused to disappear in any manner whatever, a momentary electromotive force is set up or "induced" in this coil, which in turn causes a momentary electric current to flow th the coil. This e.m.f. exists only while the coil is *moving across* the field or the field through the coil is *varying*.

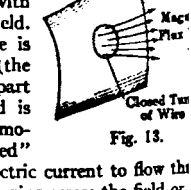

Fig. 13.

* With a force in excess of the gravitational force, which latter is extremely small

† A needle is said to be freely suspended when there is no controlling force exerted it through its suspension tending to make it take up any definite position.

time integral of the induced e.m.f. when the coil is removed entirely the magnetic field is taken as the measure of the "magnetic flux" through the coil when in its original position. That is, calling e the induced in the coil at any instant due to its motion through the field, the time during which the e.m.f. exists in the coil, then the magnetic flux the coil when in its original position is

$$\phi = \int_0^t e\,dt. \tag{28}$$

antity is readily measured by means of a ballistic galvanometer; see *Testing*.

of Magnetic Flux. — The unit of magnetic flux in the c.g.s. electrostatic system is frequently called a "maxwell" or simply a "line." The flux in the practical system of units is sometimes called a "weber"; see *Conversion Factors*.

netic Flux Density (B). — Experience shows that the magnetic flux any closed loop, such as the turn of wire described above, depends upon the inclosed by this loop. The magnetic flux per unit area through any perpendicular to the direction of the field is defined as the "magnetic density" at this surface, and is usually represented by the symbol B. By density at any *point* is meant the flux density at an infinitely small drawn perpendicular to the field at this point. The direction of the flux density at any point is the same as that in which a magnetic would point if placed at this point; i.e., the direction of the flux density the direction of the magnetic field are the same. When the flux density same value B at every point of a surface of area A and is perpendicular surface, then the total flux through this surface is

$$\phi = BA. \tag{29}$$

otal magnetic flux across any surface S may in general be expressed matically by the surface integral

$$\phi = \int (B \cos \alpha)\,ds, \tag{29a}$$

ds represents any elementary area of this surface and $(B \cos \alpha)$ the component of the flux density perpendicular to ds.

its of Magnetic Flux Density. — The unit of magnetic flux density in the c.g.s. electromagnetic system is called the "gauss"; no name has been given the corresponding practical unit.

gnetic Flux Lines. — Continuity of Magnetic Flux. — Magnetic flux is represented by lines drawn in the field in such a direction that their tion coincides at each point with the direction of the field at that point, of such a number that their density at each point (number per unit area perpendicular to their direction) is equal to the magnetic flux density at that t. Such lines are called "magnetic flux lines." Experience shows that lines drawn in a magnetic field always form *closed* loops, i.e., a magnetic flux has no ends. As a consequence of this fact the total magnetic flux coming any surface in a magnetic field is always equal to the total flux leaving surface. (Compare with stream lines of electric current.) When the flux

TE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

leaving a surface is considered as equivalent to a negative flux cou
that surface, this relation may be expressed by the formula

$$\Sigma\phi = 0$$

at every surface, the summation being an algebraic one. This is an
Kirchhoff's first law for electric circuits.

Fig.

Magnetic Fields Due to Electric Currents. — Experience shows that every stream line of electric current is always accompanied by a magnetic field the flux lines of which *link* the stream line of current. That is, the flux lines thread the loops formed by the stream lines and the stream lines thread the loops formed by the flux lines; see Fig. 14.

Right-handed Screw Law. — The direction of the curre
around any electric circuit and the direction in which the flux lines c
current thread this circuit are related to each other in the same man
direction of motion of a point on the edge of the head of a right-han
placed at the center of the circuit and the direction of advance of
Or, if one faces the electric circuit looking in the direction of the flux li
ing it, the current producing these lines is in the clockwise direction
circuit. The relative direction of the current and its magnetic flu
briefly described by saying that the current is in the right-handed scre
with respect to the flux which it produces.

MAGNETICALLY INDUCED ELECTROMOTIVE FORC
measure of magnetic flux is based on the experimental fact that wh
magnetic field threading an electric circuit changes, an electromoti
induced in that circuit. When the circuit is formed by a single tu
this induced e.m.f. is, from the definition above, equal to the rate of
this flux with respect to time, i.e., $e = \frac{d\phi}{dt}$. When the circuit is in t
a coil each turn of which links the flux, the e.m.f. induced in *each* tu
to $\frac{d\phi}{dt}$ where ϕ is the flux which links that particular turn. When
links the *same number of flux lines*, then the total induced e.m.f. in
turns is

$$e = N\frac{d\phi}{dt}.$$

When the change in flux is due to a motion of a circuit or part
through a magnetic field the induced e.m.f. in any conductor is als
the number of flux lines which *cut across* this conductor.

Magnetic Linkages (λ). — The condition that each turn be link
same flux ϕ is seldom the case; some of the flux lines link only p
turns, see Fig. 14. In general, the total e.m.f. is

$$e = \frac{d}{dt}(\phi_1 + \phi_2 + \ldots \phi_n),$$

where ϕ_1, ϕ_2, etc., represent the fluxes linking the various turns.
$(\phi_1 + \phi_2 + \ldots \phi_n)$ may be called the total number of "magnetic
and may be conveniently represented by the symbol λ, viz.,

$$\lambda = \phi_1 + \phi_2 + \ldots \phi_n.$$

erefore, the electric instant is $ei = NI\frac{d\phi}{dt}$. This power is transmitted he varying flux through it; hence the power

$$p = NI\frac{d\phi}{dt} \qquad (32)$$

magnetic power input, this power being converted ower.

Current. — The varying flux established by B pon as the means whereby this energy is trans- ield, just as an electric current may be looked upon y is transferred from one point to another in an

ON THIS PAGE ARE IN C.G.S. ELECTROMAG-

Digitized by Google

electric circuit. Hence the varying flux may be looked upon as a "
displacement current."

Magnetomotive Force ($\mathfrak{F}$). — The above expression for the rate of
of energy by a varying magnetic field may be compared with the rate of
of energy, or power input $P = EI$, corresponding to an electric current
in a circuit in which there is *back* electromotive force E. The strengt
"magnetic displacement current" may be chosen arbitrarily* as

$$\text{Magnetic displacement current} = \frac{1}{4\pi}\frac{d\phi}{dt},$$

just as the strength of the electric displacement current is taken as $\frac{1}{4\pi}\frac{d}{4\pi d}$

ψ is the total electrostatic flux. Then the quantity correspondin
electromotive force must be chosen numerically equal to

$$\mathfrak{F} = 4\pi NI$$

and may be called the "magnetomotive force," abbreviated "m.m.
magnetic power input may then be written

$$p = \mathfrak{F} \times (\text{Magnetic displacement current}).$$

where $\mathfrak{F}$ is the *back* magnetomotive force.

Direction of the Magnetomotive Force. — The closed path of
netic flux lines through a magnetic field is called a "magnetic circuit,
the path of the stream lines of an electric current is called an electri
In general, a magnetomotive force is produced in every magnetic circuit
it is linked by an electric circuit, equal in numerical value to $4\pi NI$,
is the number of times the current I links this circuit. The magne
force is taken as positive when the current links the flux lines in t
handed screw direction, for then an increase in the flux corresponds to a
power output. When the current links the flux lines in the left-hand
direction the magnetomotive force is taken as negative, i.e., a "back"
motive force, for in this case an increase in flux corresponds to a magnet
input; see the special case considered above.

Units of Magnetomotive Force. — Ampere-Turns. — The pro
in the expression for the magnetomotive force, equation (33), is c
"current-turns"; when I is expressed in amperes it is called the "amper
The magnetomotive force as above defined differs from this product o
constant numerical factor; hence the ampere-turns of a coil may be ta
measure of the magnetomotive force produced by it. This unit of
motive force, namely, one ampere-turn, is the unit commonly employe
practical calculation of magnetic circuits. The c.g.s. electromagneti
called the gilbert; 1 ampere-turn = 1.2566 gilberts. See *Units and C
Factors*.

MAGNETIZING FORCE OR MAGNETIC FIELD INTENSI
— Experience shows that the magnetic flux density produced at any
a given magnetomotive force depends (*a*) upon the position of the p
respect to the source of the m.m.f. and (*b*) upon the nature of the su
through which this m.m.f. produces the magnetic flux. Compare
electric current density or dielectric flux density produced at a given

* The factor 4π arises from the manner in which the conceptions of the mag
were originally developed.

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTR
NETIC UNITS.

of electric potential difference per unit length. Hence the c.g.s. electro unit of magnetizing force may be called the "gilbert per centimeter"; with volts per centimeter. When the magnetomotive force is exp ampere-turns, the magnetizing force is expressed in ampere-turns p meter or per inch; see *Units and Conversion Factors*.

Values of the Magnetizing Force in a Uniform Medium. — V medium surrounding the stream lines of an electric current is of a *unif netic nature throughout*, the magnetizing force at any point may be c from the shape and distribution of the stream lines of the current, irr of whether the medium be non-magnetic or highly magnetic, e.g., i *Units and Conversion Factors* for numerical multipliers to change t practical units.

Magnetizing Force at any Point Due to an Element of a Stream Line (Fig. 17). — Consider any closed stream line of electri and let the surrounding *medium be uniform* in its magnetic properties throughout the region in which the magnetic field produced by this stream line exists. It can be shown that each elementary length dl of this stream line may be considered as contributing to the magnetizing force H at any point P in this region an amount

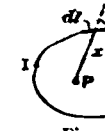

Fig.

$$dH = \frac{(I \sin\theta)\, dl}{x^2}, \qquad (35)$$

where I is the current flowing along this stream line, x the distance fr dx, and θ the angle between x and dl. The direction of dH is perpend the plane determined by x and dl. The total magnetizing force at P the *vector sum* or *vector integral* of dH for all the elementary lengths in the stream line is divided.

Magnetizing Force Due to a Straight Wire (Fig. 18). — A equation (35) to the case of a straight wire of circular cross-section carrying a current I, the magnetizing force at any point P due to a length l of this wire is

Fi

$$H = \frac{I}{x}(\sin\theta_1 + \sin\theta_2), \qquad (35a)$$

where x is the perpendicular distance from P to the wire and θ_1 and θ_2 the angles designated in Fig. 18.

When the wire is very long compared with x, this becomes

$$H = \frac{2I}{x}.$$

This formula also holds approximately for any point outside a wire shaped cross-section, provided x is large compared with the maximum d of this section. For a point *inside a long wire of circular cross-section* o *a* the magnetizing force is also given by (35b) when I is taken to repres *part of the current inside the circle through P* concentric with the axis of t When the current density is uniform over the cross-section, as is usually (*see, however, the article on Skin Effect*), the magnetizing force inside the

$$H_i = \frac{2xI}{a^2}.$$

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTR NETIC UNITS.

Digitized by Google

Magnetizing Force on the Axis of a Circular Coil of N Turns. — t I be the current, r the mean radius of the coil, and x the distance of the ict from the center of the circle; then

$$H = \frac{2\pi NIr^2}{(r^2 + x^2)^{3/2}} \tag{35d}$$

Magnetizing Force due to a Solenoid. — A solenoid is a helical coil f wire, each turn having the same radius. Let N = total number of turns, = current in abamperes, r = mean radius of the helix in centimeters, l = length helix in centimeters. Then at any point on the axis of the helix (inside or tside) at a distance of x centimeters from its center, the magnetizing force gilberts per centimeter is

$$H = \frac{2\pi NI}{l}\left[\frac{0.5\,l + x}{\sqrt{r^2 + (0.5\,l + x)^2}} + \frac{0.5\,l - x}{\sqrt{r^2 + (0.5\,l - x)^2}}\right] \tag{35e}$$

his formula holds only when the thickness of the winding is small compared ith the mean radius r. When l is large compared with r this reduces to

$$H = \frac{4\pi NI}{l}. \tag{35f}$$

r all points inside the solenoid (whether on the axis or not) at a distance from s ends large compared with r, that is, inside the central portion of a long lenoid, the field is uniform over the cross-section of the solenoid and its value given by (35f). An exact formula for field intensity at any point inside a sole- id is given by O. Billieux in *Rev. Gen. d'El.* 6, *p. 827, Dec. 13, 1919.*

Magnetizing Force Inside a Toroid (Fig. 19). — A toroid is a cylinder nt into the form of a closed ring, making a shape like a doughnut. When ch a ring is *uniformly* wound with an insulated wire so that the turns of the re are close together and cover the entire surface f the toroid, the magnetic field is confined entirely ithin the space inclosed by these turns, and there- re, when the core on which the wire is wound is of ni form magnetic material throughout, both the lines f magnetizing force and the flux lines must be circles ncentric with the hole in the "doughnut." The agnetizing force will have the *same* value at every int on the circumference of any *one* of these circles, d, therefore, from equation (34a) the value of H at any point P within the re is

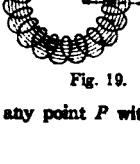

Fig. 19.

$$H = \frac{4\pi NI}{l}, \tag{35g}$$

here N is the total number of turns on the core, I the current in each turn d l the length of the circumference through P. Unless the hole in the "dough- t has a large radius compared with the radius of the cross-section of the core ill not be uniform over this section, since l for the various points in the cross- tion will differ considerably.

It should be noted that the value of H is independent of the material of the re provided only that the core be of uniform material throughout. That is,

Note. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAG- ETIC UNITS.

Digitized by Google

equation (35g) applies to an iron core as well as to an air or wood core, provi the iron is uniform throughout and there is no air gap across the path of the f lines. Even a mechanically perfect contact between two pieces of iron of same kind, however, is sufficient to vitiate the above formula.

MAGNETIC PERMEABILITY (μ). — PARAMAGNETIC AND DI MAGNETIC SUBSTANCES. — The quotient of the magnetic flux dens B at any point by the magnetizing force H at that point is defined as "magnetic permeability" μ of the substance as medium at that point, viz.,

$$\mu = \frac{B}{H}. \qquad (\text{C}$$

Compare with the definition of dielectric coefficient, equation (17.) The c.g electromagnetic system of units is based on the arbitrary assumption of un as the value of the magnetic permeability of air. Any substance which has magnetic permeability greater than that of air is called a "paramagnetic su stance," and any substance which has a permeability less than that of air called a "diamagnetic substance." The only substances which are strong paramagnetic, i.e., which have a permeability considerably greater than th of air, are iron, steel, nickel and cobalt, and certain alloys of non-magne elements. The only substance which is appreciably diamagnetic is bismu which has a permeability of about 0.9998. All other elements are practica non-magnetic, i.e., their permeabilities differ from unity by less than 1 per ce

The permeability of a given sample of any highly magnetic substance is n a constant, but depends upon the value of the magnetizing force; see the curv in the article on *Magnetic Properties of Iron*. The permeability also depen very largely upon the previous heat treatment and the exact composition of t material, and also upon its previous magnetic history; these relations are al discussed in detail in that article. The methods of measuring permeability a described in the article on *Magnetic Testing*.

North and South Poles. — That portion of the surface of any magnetiz body from which the flux lines pass out into the air (or into any substance lower permeability) is said to be a north magnetic pole, and that portion of t surface at which the flux lines enter the body is said to be a south magnetic po A "unit north pole" is a pole from which 4π flux lines emerge into the su rounding air. When a magnetic needle is placed near the surface of a ma netized body its north seeking end points away from this surface when th surface is a north pole and toward the surface when this surface is a south po

Difference of Magnetic Potential (U). — Consider any two points 1 a 2 in a magnetic field (Fig. 20) and let the path between them from 1 to 2 pass through an electric circuit producing a magnetomotive force in the direction from 1 to 2, then from analogy with the electric circuit, equation (2), the expression

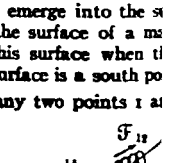

Fig. 20.

$$U_{12} = \int_1^2 (H \cos\theta)\, dl - \mathcal{F}_{12} \qquad (37)$$

is called the "drop of magnetic potential" from 1 to 2. From the definiti of magnetizing force, equation (34), it follows that around any *closed* circuit th drop of magnetic potential is always zero. A magnetomotive force $\mathcal{F}_{12}$ therefore, equivalent to a rise of magnetic potential from 1 to 2.

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMA NETIC UNITS.

Digitized by Google

When there is no source of m.m.f. between 1 and 2 and the path coincides with ne of magnetizing force, the drop of magnetic potential is

$$U_{12} = \int_1^2 H\, dl. \tag{37a}$$

Magnetic potential difference is of the same nature as magnetomotive force and ay, therefore, be expressed in the same units, viz., gilberts or ampere turns.

Magnetic Equipotential Surfaces. — A surface drawn in a magnetic field such a manner that this surface is perpendicular at each point to the magtizing force at this point (i.e., to the line of magnetizing force through this int) is called a "magnetic equipotential surface," compare with *electric equiential surface*.

Magnetic Reluctance ($\mathcal{R}$). — To establish a magnetic flux ϕ through a given rtion of a substance which is *not itself linked by a source of m.m.f.* a difference agnetic potential must always be established between the end surfaces of is substance. Let U be the magnetic potential drop established from one face to the other, then the quotient

$$\mathcal{R} = \frac{U}{\phi} \tag{38}$$

defined as the magnetic reluctance of the given portion of the substance. ompare with electric resistance. The c.g.s. electromagnetic unit of reluctance called the oersted. It should be noted that the above definition is meaningless except when applied to a portion of a substance of which the end surfaces e magnetic equipotential surfaces and through every cross-section of which e same flux passes.

Factors upon Which Reluctance Depends. — The magnetic reluctance a given portion of a substance included between two equipotential surfaces nd bounded laterally by a surface through which no flux line passes depends on 1. the magnetic permeability of the substance, 2. the dimensions of this rtion of the substance and 3. upon the distribution of the flux lines over each ss-section perpendicular to them. The relations are identical with those ich determine the electrical resistance of a conductor, the magnetic permeility taking the place of the electric conductivity. For example, *for a straight r of constant cross-section A and length l, through which the flux lines are straight, rallel and uniformly distributed, the reluctance is*

$$\mathcal{R} = \frac{l}{\mu A}. \tag{38a}$$

Note particularly that this formula for reluctance is applicable only under e special conditions just stated. Formulas for other cases are much more mplex; see Douglas, J. F. H., *Reluctance of Irregular Magnetic Fields*, A.I.E.E., ec., 34, May, 1915.

Magnetic reluctance is not a constant quantity even for a given material and ven flux distribution, unless this material is non-magnetic. For all highly agnetic materials μ depends upon the magnetizing force and therefore also on the flux density. It should also be noted that the magnetic reluctance es not represent a "resistance" in the sense of something which causes a ssipation of energy.

Magnetic Permeance ($\mathcal{P}$). — The reciprocal of magnetic reluctance is called magnetic permeance." The permeance of a straight bar under the conditions ecified above is

$$\mathcal{P} = \frac{\mu A}{l} \tag{39}$$

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGETIC UNITS.

Digitized by Google

The permeability of a substance is, therefore, equal to the permeanc cube of this substance when the flux through the cube is parallel to of the cube and is uniformly distributed over the section at right angl four edges.

Magnetic permeance is analogous to electric conductance, except not a factor which affects the *dissipation* of energy in a substance. however, enter into the expression for the energy *stored* in a magnet the same way that the electrostatic capacity of a dielectric is a d factor in the expression for the energy stored in the electric field.

Kirchhoff's Laws for the Magnetic Circuit. — As already noted (30), the total magnetic flux coming up to any surface in a magnet always zero, provided a flux leaving a surface is considered as a *ne* coming up to that surface. This fact may be represented by the for

$$\Sigma\phi = 0$$

for every surface in the field. Similarly, from the definition of magne tial drop, it follows that the *total* magnetic potential drop around a circuit is zero, or that the total magnetomotive force acting around a circuit is equal to the sum of the reluctance drops around that circuit, w be represented by the formula

$$\Sigma\mathfrak{F} = \Sigma\mathfrak{R}\phi.$$

These two equations are identical in form with those representi hoff's laws for the electric circuit, equation (13). They are, howev easy to use for practical calculations, for the magnetic flux is not c approximately geometrical lines like the currents in a network of wires, but in general fills all space surrounding the coils which est magnetomotive forces; also, when there is iron or other magnetic m the circuit, the permeability depends on the flux density and the history of the iron. (The distribution of magnetic flux in and aroun circuit is analogous to the distribution of current in and around an ur mass of copper of the same shape as the iron circuit immersed in a liqu a conductivity about equal to that of carbon.) Only in the special uniformly wound circular ring or toroid are the lines of induction *entirely* to an iron circuit; in general a certain number also exist in th in whatever other substances are in the vicinity of the iron circuit.

SELF AND MUTUAL INDUCTION. — When the current in electric circuit varies with time the magnetic flux accompanying thi also varies with time, and, since this flux links the current which pr an e.m.f. is induced in each turn of the circuit equal to the rate at whic through this turn is varying, and in such a direction as to *oppose* the the current. That is, an *increasing* electric current is always accompa *back* e.m.f. due to the increase in the magnetic flux which accompanie crease of current. Or, viewed from another point of view, an increa velocity of a stream of electricity develops a back pressure, just as velocity of a stream of water is increasing it develops a back pr "velocity head" due to the inertia of the water. The magnetic field acc ing an electric current may, therefore, be looked upon as a result of its magnetic inertia," or "electromagnetic mass"; see also the article on *Theory*.

Again, when an electric current *decreases* its accompanying flux and an e.m.f. is set up in the circuit tending to oppose this decrease, i.e.

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTR NETIC UNITS.

sing. This is again analogous to the effect of matter.

on or Inductance (L). — In general, the co- change of the current $\left(\frac{di}{dt}\right)$ in any circuit must luced electromotive force e is called the "coeffi- ly the "inductance" of the electric circuit. In e.m.f. in an electric circuit is

$$e = L\frac{di}{dt}, \tag{41}$$

electric circuit and $\frac{di}{dt}$ represents the change in

since $e = \frac{d\lambda}{dt}$, see equation (31a), where λ is the ween the electric circuit and the flux established e may also be defined by the relation

$$L = \frac{d\lambda}{di}. \tag{42}$$

to the increase in the number of linkages per unit the permeability of the magnetic circuit is *con-* onstant equal to the linkages per unit current. by every stream line of electric current, and the etic circuit is constant, then

$$L = \frac{4\pi N^2}{\mathfrak{R}}, \tag{42a}$$

ns forming the electric circuit and $\mathfrak{R}$ is the etic circuit.

f various electric circuits are given in the article *ctance*.

practical unit of inductance is called the henry; nry and the abhenry and millihenry see *Units*

duction. — Mutual Inductance (M). — In which the rate of change of the current $\left(\frac{di_a}{dt}\right)$ lied to give the electromotive force e induced it B, is called the "coefficient of mutual induc- ductance" between A and B; see Fig. 15. In in any circuit B by a varying current i_a in any

$$e_b = M_{ab}\frac{di_a}{dt}, \tag{43}$$

nce between A and B.

ciple of the conservation of energy that the mu- ith respect to a second circuit B must be equal

Digitized by Google

to the mutual inductance of B with respect to A, that is, $M_{ab} = M_{ba}$. the e.m.f. induced in A when the current in B increases by an amount

$$e_a = M_{ab} \frac{di_b}{dt}.$$

Since $e_b = \frac{d\lambda_{ab}}{dt}$, where λ_{ab} is the number of linkages between the and the flux through B due to the current i_a, the mutual inductance be defined by the relation

$$M_{ab} = \frac{d\lambda_{ab}}{di_a}.$$

That is, the *mutual inductance between two circuits A and B is equal crease in the number of magnetic linkages of the circuit B per unit increa current in A*, and vice versa. When the permeability of the magnetic *constant*, the mutual inductance is also a constant equal to the linkages unit current in A, and vice versa. When every flux line linking *both* is linked by every turn in A and every turn in B, then

$$M_{ab} = \frac{4\pi N_a N_b}{\mathcal{R}_{ab}},$$

where N_a and N_b are the number of turns forming the circuits A and ively and $\mathcal{R}_{ab}$ is the reluctance of that *part* of the magnetic circuit which the flux from A to B passes when there is current *in one coil only*

The units of mutual inductance are the same as those of self-in see *Units and Conversion Factors*.

Formulas for mutual inductance for a few special cases are given in t on *Inductance, and Inductive Reactance*.

Instantaneous Potential Drop Through a Coil. — Consider a co which has a resistance r and an inductance L. Then when this coil co other source of e.m.f. than its own self-induced e.m.f., the expression f stantaneous potential drop through the coil is

$$v = ri + L\frac{di}{dt},$$

where i is the instantaneous value of the current and $\frac{di}{dt}$ the increa current per unit of time. Compare with the equation

$$i = gv + C\frac{dv}{dt},$$

for the instantaneous current through a condenser, where g is the con of the dielectric in the condenser, v the potential drop across it, and crease in the potential drop per unit of time.

When there is another coil near the first coil, and the two coils ha ances r_1 and r_2 and self-inductances L_1 and L_2 respectively, and a m ductance M, then the potential drops through them are respectively

$$\left.\begin{aligned} v_1 &= r_1 i_1 + L_1 \frac{di_1}{dt} + M \frac{di_2}{dt} \\ v_2 &= r_2 i_2 + L_2 \frac{di_2}{dt} + M \frac{di_1}{dt} \end{aligned}\right\}$$

where i_1 and i_2 are the currents in the two coils in the *same* direction.

Digitized by Google

Effective or "Total" Inductance. — In certain cases of symmetry, when the algebraic sum of all the currents in the field is zero, the voltage drop along any *portion* of a circuit may be represented by an expression of the form

$$v = ri + L\frac{di}{dt},$$

although there may be several electric circuits in the vicinity in which electric currents are flowing. An example of this is the case of the wires of a three-phase transmission line arranged so that they form the three edges of an equilateral prism; see *Inductance and Inductive Reactance*. The coefficient L in this case is called the "effective self-inductance" of this particular portion of the circuit; it really takes into account not only the self-induction of the particular part of the circuit under consideration but also the mutual induction of the rest of the circuit or circuits with respect to this particular portion. Similarly, when the voltage drop in any portion of a circuit involves not only the current i_1 in this circuit but also a current i_2 in some part of this circuit or in some other circuit, the coefficient M_{12} in the expression

$$v_1 = r_1 i_1 + L_1\frac{di_1}{dt} + M_{12}\frac{di_2}{dt}$$

is called the effective mutual inductance of the part 2 with respect to 1 although it may also be due in part to circuit 2.

Leakage Inductance. — In discussing the action of a transformer (q.v.), which is merely two electric circuits linking the same iron core, it is more convenient to deal with the *resultant* flux due to the currents in *both* electric circuits in windings instead of considering the fluxes due to the two windings separately. Referring to Fig. 21, let ϕ_r represent that portion of the resultant flux due to the currents i_1 and i_2 in the two windings 1 and 2, and let ϕ_1 represent that part of the total flux which links 1 only and ϕ_2 that part of the total flux which links 2 only. Let λ_1 be the linkages between ϕ_1 and circuit 1 and λ_2 be the linkages between ϕ_2 and circuit 2. Then

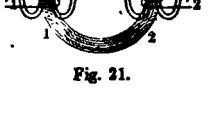

Fig. 21.

$$L_1' = \frac{\lambda_1}{i_1} \quad \text{and} \quad L_2' = \frac{\lambda_2}{i_2},$$

are called the "leakage inductances" of the two windings respectively; the reluctance of the paths of ϕ_1 and ϕ_2 are practically constant since the air portion of these paths forms a greater part of the reluctance in each case.

Let i_1 be the current in winding 1 and i_2 be the current in winding 2 in the *opposite* direction to i_1 (this is the actual relation in a transformer during most of the time) and let e_1 be the impressed e.m.f. across the terminals of the first or primary winding and e_2 the terminal e.m.f. at the terminals of the second or secondary winding when the current i_2 is flowing. Then

$$\left.\begin{aligned} e_1 &= r_1 i_1 + L_1'\frac{di_1}{dt} + N_1\frac{d\phi_r}{dt} \\ e_2 &= N_2\frac{d\phi_r}{dt} - r_2 i_2 - L_2'\frac{di_2}{dt} \end{aligned}\right\} \qquad (47)$$

where r_1 and r_2 are the resistances of the two windings and N_1 and N_2 are the number of turns in the two windings respectively.

Digitized by Google

Comparing equation (47) with (46) and noting that $e_1 = v_1$ and $e_2 =$ i_2 in (47) is taken in the opposite direction from i_2 in (46), it may be sho

$$L_1' = L_1 - \frac{N_1}{N_2} M,$$

$$L_2' = L_2 - \frac{N_2}{N_1} M.$$

Whence the leakage inductance of each winding is very much less total self-inductance of that winding.

Fundamental Equations of the Transformer. — Comparing (47) and (46) it may also be seen that *

$$\phi_r = \frac{M}{N_2}\left(i_1 - \frac{N_2}{N_1} i_2\right).$$

Put $i_2' = \frac{N_2}{N_1} i_2$, that is, i_2' is the current which would be produced in th ary if it had the same number of turns as the primary. The differenc

$$i_m = i_1 - i_2'$$

is called the "magnetizing current," and the quantity $L_m = \frac{M}{N_2}$ may the magnetizing inductance. Then

$$\phi_r = L_m i_m.$$

In the above deduction no account is taken of the eddy-current and l loss in the iron core; these losses (the eddy-current loss in particular looked upon as due to a third current i_3 flowing in a single turn short on itself and having a resistance r_3 and negligible inductance. The for this tertiary circuit is then

$$0 = \frac{d\phi_r}{dt} - r_3 i_3.$$

Whence the corresponding current in the primary winding is $i_3' = \frac{i_3}{N}$ may also be written

$$i_3' = g N_1 \frac{d\phi_r}{dt},$$

where $g = \frac{1}{r_3 N_1^2}$ is called the "leakage conductance" of the transform total primary current is then

$$i_1 = i_2' + i_m + i_3'.$$

From equation (47) and the relations given in the last two paragr complete theory of the transformer may be developed.

ENERGY OF THE MAGNETIC FIELD. — Energy is required lish a flow of electricity just as energy is required to set a column of motion, this "energy of motion" of electricity being analogous to th energy of a moving body. This energy of motion is most conveni

The energy per unit volume at any point in the magnetic field du number of electric circuits is represented by equation (48b), where H are taken as the resultant magnetizing force and flux density respec this point.

When the permeability is not constant the *energy transferred to un* of the magnetic field due to any number of currents is

$$w = \frac{1}{4\pi}\int_0^B H\,dB$$

provided the magnetizing force H and the flux density B are either in the directly opposite directions, as, for example, in the case of a uniformly ma iron toroid. To integrate this expression requires a knowledge of the between B and H. Note also that, due to the phenomenon of hysteresis, part of the energy required to establish a magnetic field i other magnetic substance is dissipated as heat and is not recoverable field disappears; therefore, only part of the energy represented by mula is "stored" in the field in a recoverable form. See article on *Properties of Iron*.

MECHANICAL FORCES IN THE MAGNETIC FIELD. (*article on Electromagnets.*) — Experience shows that all bodies in which a current exists, and all bodies in which a magnetic flux exists, exert i mutual mechanical forces upon one another tending to produce such motion of these bodies as will *increase* the energy of the magnetic fiel be the component of the force tending to move any body in the field i direction and let dW be the increase in the energy of the field due to the body a distance dx in this direction, then

$$f = \frac{dW}{dx},$$

provided this displacement does not alter the existing magnetomotive the field.

Similarly, calling T the component of the torque tending to turn an the field about a given axis, and dW the *increase* in the magnetic ener the turning of the body through an angle of $d\alpha$ radians about this axi

$$T = \frac{dW}{d\alpha},$$

provided this displacement does not alter the existing magnetomotive the field.

Equations (51) and (51a) also give the actual force and torque re during a change in position which *does* cause a change in the magn forces in the field, provided dW is taken to represent the net increa energy of the field. This force and torque may differ greatly from t state force and torque; see article on *Electromagnets*.

Force Produced by a Magnetic Field on a Coil Carrying a Cu From equation (32) the energy *output* of an electric circuit, when the flux threading it in the right-handed screw direction with respect to th in it increases by an amount $d\phi$, is $dW = NI\,d\phi$, where N is the n turns linked by this increase in flux and I is the current in each turn the energy *input* into the magnetic field. Whence if an increase in

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECT NETIC UNITS.

Digitized by Google

duced through the coil when it moves a distance dx, the force acting on e coil in the direction of dx is

$$f = NI\frac{d\phi}{dx}; \qquad (52)$$

represents the increase in the flux linking the coil in the *right-handed* screw ection with respect to the current in it or the number of flux lines which cut e coil as the result of its motion. Similarly, when the coil is so mounted that it can move only about a fixed axis, then the value of the torque tending to rn it about this axis is

$$T = NI\frac{d\phi}{d\alpha}, \qquad (52a)$$

here $d\phi$ represents the increase in the flux linking the coil in the right-handed rew direction with respect to the current in it when the coil turns through an ngle α (in radians).

From these relations it follows that a coil carrying an electric current, when n the magnetic field due to any other agent (current or permanent magnet), ways tends to take up that position in which it will embrace the maximum ssible flux linking the coil in the right-handed screw direction with respect the current in it. This accounts for the attraction of two parallel coils when ey carry currents in the same direction, and the repulsion of two such coils ien they carry currents in opposite directions. This principle is useful in termining the direction of motion of the moving element in such devices as e electric motor, galvanometer, current balance, electrodynamometer (q.v.).

Torque on the Coil When its Plane is Parallel to the Magnetic Field. — When the coil is placed with its plane parallel to the flux lines due to me other agent (e.g., a permanent magnet or another coil carrying a current), the flux linking the coil due to this agent is zero; see Fig. 22. Let e two circles represent sections of the two sides of the coil its plane being perpendicular to the page, and let e dot in the left-hand circle indicate that the current is up through this side of the coil and the cross in the ther circle that it is down through the other side. Let B be the flux density of the field constant for each point along the flux line since the flux lines are parallel, and let A be the area of the coil and let $\phi = BA$, that is, ϕ represents the total flux which *would be produced* through the coil by a uniform field of flux density B at *right angles* to it. Then the torque on the coil when its plane is *parallel* to the field is

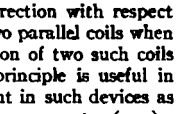

Fig. 22.

$$T = N\phi I. \qquad (53)$$

This relation is useful in calculating the torque on the moving element of a galvanometer, ammeter, electrodynamometer, wattmeter, etc.

Average Torque on a Coil Rotating in a Magnetic Field. — Consider a coil which is rotating with an angular velocity ω about a fixed axis n a magnetic field due to some other agent (e.g., an armature coil rotating in the magnetic field produced by the current in the field coils). Let the current in this coil be constant and in the same direction with respect to the coil while the coil turns from the position in which it embraces the maximum flux ϕ in the left-handed screw direction to the position (a half revolution in a 2-pole machine) when it embraces this same maximum flux ϕ in the right-handed

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

Digitized by Google

screw direction. The total change in the flux while the coil turns thro angle, π radians in the case of a 2-pole machine, is 2ϕ, whence the torque turning the coil through this half revolution is

$$T = \frac{2N}{\pi} I\phi \cdot$$

That is, the average torque is proportional to the product of the current total flux per pole. When a commutator is provided to change the d of the current every half turn, then the torque is in the same directio complete turn. See *Motors*.

When the coil is mounted in a slotted iron core which rotates with as in an ordinary motor, this torque is exerted partly on the wire and pa the teeth of the core.

Force on a Wire in a Magnetic Field. — Consider a wire of l forming part of a closed circuit, Fig. 23. Let B be the value of the flux at the wire, I be the current in the direction indicated, and let the lines representing the flux be perpendicular to the wire in the direction from the eye to the page. When this wire moves a distance dx to the left the flux threading the closed loop formed by the circuit is increased by an amount $d\phi = Bldx$, whence the force acting on the wire is, from equation (51),

Fig. 2

$$f = BlI.$$

Left-hand Rule. — The relative directions of this force, the flux B and the current I may be conveniently determined by pointing the fo of the left hand in the direction of the flux and the middle finger in the d of the current (I), then if the thumb is held perpendicular to these two it will point in the direction in which the force tends to move the wire. pare with the right-handed rule for e.m.f.

Force between Two Current-Carrying Conductors. — The force between any two electric circuits carrying currents i_1 and i_2, due magnetic field of these currents, may be readily found by combining eq (49) and (51). This gives for the component of this force in any direct value

$$f_x = i_1 i_2 \frac{dM}{dx}$$

where dM is the increase in the mutual inductance between the two when one circuit is displaced a distance dx with respect to the other, tance dx being measured in the direction in which it is wished to find t ponent of the force. In this formula i_1 and i_2 are both to be consid positive when they link the mutual flux in the same direction. Fr relation follows the well known fact that two coils, or conductors, c currents which are in the *same* direction *attract* each other, since when is moved *toward* the other their mutual inductance *increases*.

The mutual inductance of two long parallel wires when these are fa relative to their diameters is

$$M = 2l \log_e \frac{2l}{D},$$

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTR NETIC UNITS.

portional to the square of the flux density in the rod.

HYPOTHESIS REGARDING THE NATURE OF MAGNE

The peculiar properties possessed by a magnetic needle or other magn
accounted for by assuming that at least some of the molecular ch
magnetic substance have an orbital motion without friction, forming
"molecular solar system." The magnetization of such a substance is
to the setting of the molecular currents in planes more or less paral
plane of the magnetizing current. In the case of a permanent mag
molecular currents retain their parallel or "polarized" condition even
magnetizing current is removed. For example, when a needle is m
by a current in a coil placed around it, the molecular currents are s
angles to the axis of the needle. A magnetic needle placed in a magn
therefore, tends to set itself so that each molecular current embraces
flux and hence "points" in the direction of this flux.

ECTROCHEMICAL PROCESSES, INDUSTRIAL. — (*See also* trochemistry, *Principles of; Furnaces, Electric.*) The principal industrial trochemical processes are the following :

Electroplating,
Galvanoplasty, including electrotyping,
Electrolytic refining of metals,
Electrolytic winning of metals,
Electrolytic oxidation and reduction,
Electrolysis of sodium and potassium in chloride solutions,
Electrolysis of water,
Electric-furnace processes (*see Furnaces, Electric*),
Production of ozone.

Some of the more important of these various processes are briefly described low.

ELECTROPLATING. — Electroplating consists in covering a conducting face (usually metallic) with a thin, smooth, compact, well-adhering layer of tal by depositing this metal electrolytically from an aqueous solution of one its salts. The anode of the electroplating vat consists of rods or plates of the e metal as that of the salt in solution and is connected to the positive ter- nal of the source of electricity. The object to be plated forms the cathode, ich is connected to the negative terminal. The anode dissolves approximately the same extent that the cathode gains, so that the amount of the metal ions the bath remains nearly constant.

Suspension of Objects to be Plated. — The cathodes are always sus- ded in the bath between two rows of anodes, so that they will be plated iformly on both sides. When the cathode is of irregular shape, or very large, must be turned frequently during the plating in order to get a uniform de- sit. The cathodes and anodes are suspended by copper wires from hori- ntal metallic tubes, the ends of which rest on the edge of the plating vat. e metallic tubes are permanently connected to the source of the electricity, that as soon as the cathodes are suspended in the bath, electrolysis begins. mall objects, such as tacks, pins and screws, are suspended in the vat in a ire basket, which is, of course, plated simultaneously. To get a uniform ished surface the objects should be well shaken during electrolysis. The odes are removed from the bath only when they are nearly used up and have be replaced.

Construction of Vats. — Large plating vats are made of wood lined with me specially prepared substance resembling pitch, or with lead. Small tanks silver or gold plating are usually porcelain lined.

Voltage and Current Density. — Electroplating tanks are always connected parallel, so that they will be electrically independent of each other.

Low-voltage generators of from 5 to 6 volts are, therefore, used in plating, d each tank must be connected directly to the generator through a regulating ostat in order to regulate the voltage.

The proper current density in any plating process is that density at which a od deposit is formed. This may vary within certain limits for a given solu- on and temperature; it is a function of the temperature and the nature of the lution.

Washing and Pickling. — In order to make the metal adhere well to the rface to be plated, the surface must be smooth and perfectly clean. It is first olished, and the grease is then removed by dipping it into a hot alkaline bath ntaining 10 per cent, by weight, of sodium carbonate or sodium hydrate.

After washing off the alkali, the object is dipped into a bath called a ' the purpose of which is to remove any oxide that may have been proc the alkali, and to give a bright surface. The pickle is then washed off wi and the object is suspended immediately in the electroplating vat.

Pickling Solutions. — The pickle varies with the nature of t treated. Cast iron and wrought iron are pickled in a solution cons 15 parts, by weight, of water to 1 part of concentrated sulphuric acid. able pickle for zinc is dilute sulphuric or hydrochloric acid. Coppe bronze and German silver are pickled first in a bath consisting of 200 weight, of nitric acid of specific gravity 1.33, 1 part of common salt ar of lampblack. The lampblack is intended to form some nitrous acid nitric acid. The object is then washed in boiling water and is imme "bright dipping bath," to give a bright surface. This bath consists of by weight, of nitric acid of specific gravity 1.38, 100 parts of concentr phuric acid and 1 part of common salt.

After the plating is finished, the object is removed from the plati washed in hot water and placed in warm sawdust to dry.

Plating by Dipping. — A thin film of metal may be deposited on a dipping it into a solution of a salt of a metal which is electronegative *trochemistry, Principles of*) with respect to the metal to be plated, e.g. ping iron into a copper-sulphate solution. A small amount of iron and an equivalent amount of copper is deposited on the remaining course, only a thin film can be produced in this way, for, as soon as t covered with copper, the action ceases. No external electric current in this process.

Plating by Contact. — When the metal to be plated is electronega respect to the metal to be deposited on it, the electro-deposition ca tained by connecting the former to a zinc rod. In this case, the solut be of a complex salt, in order to reduce the deposition of the metal in on the zinc itself. For example, silver may be deposited on copper by ing a zinc rod or plate to the copper object by a wire and dipping bo potassium-silver-cyanide solution; the zinc dissolves and silver is dep the copper, while some silver is also deposited on the zinc. No externa is needed in this process.

Nickel Plating. — The solution ordinarily used consists of 50 parts, b of the double nickel-ammonium sulphate, $NiSO_4 \cdot (NH_4)_2SO_4 \cdot 6\,H_2O$ w 25 to 50 parts of ammonium sulphate to 1000 parts of water. The an nickel. The solution is made acid enough to redden litmus slightly, addition of a small amount of sulphuric acid or one-half per cent of ci The proper current density on the cathode is about 0.6 ampere per squ meter (5.5 amperes per square foot) of exposed surface, which requires volts. The surface should be perceptibly coated with nickel in two minutes, and a few bubbles of hydrogen are liberated continuously. current is too weak, the surface becomes discolored, and if too strong h is evolved more rapidly and the surface turns dark.

Iron is sometimes copper plated before it is nickel plated, but thi necessary, for nickel adheres to iron perfectly well if the surface has been cleaned.

A nickel-chloride solution gives good results in plating any metal exc Iron always eventually rusts if plated in a chloride bath.

Copper Plating. — The metals on which copper is usually plated, zinc, iron and tin, are more electropositive than copper. On dipping these metals into an acid copper-sulphate bath, they would become with a layer of copper, which in some cases is spongy and does not

With the electrodes 15 centimeters apart, current density 0.3 ampere p decimeter (2.78 amperes per square foot) about 3 volts are required.

1 liter water,
15 grams double cyanide of potassium and copper, crystallized,
16.5 grams double cyanide of potassium and zinc,
25.0 grams sodium sulphite,
2.0 grams potassium cyanide, 98 per cent.

Current density 0.3 ampere per square decimeter (2.78 amperes per squ requiring 3 volts when the electrodes are 10 centimeters apart. (*Galvanostegie, 1. Teil, p. 238, 1910.*)

Silver Plating. — The double cyanide of potassium and silver is u used for silver plating on account of the smooth deposit obtained solution. The deposit from a nitrate comes down in the form of isolated which do not cover the surface completely. The solution contains f 5 per cent silver as potassium-silver cyanide, $KAg(CN)_2$, with 0.5 per ce potassium cyanide. Too much or too little free cyanide gives a bad co deposit. A good silver plating bath may be made up as follows:

20 grams potassium silver cyanide,
10–12 grams potassium cyanide, 99 per cent,
1 liter water.

The current density is 0.3 ampere per square decimeter, at abou (*Schlötter, Galvanostegie, 1. Teil. p. 149, 1910.*) The anodes are silver Silver is deposited only on a surface of copper or copper alloy. Oth must be copper plated before silvering. In order to make the silver ad the copper surface must be amalgamated by dipping the cleaned sur "quicking bath," consisting of a solution of 30 grams of potassium cyanide, $KHg(CN)_2$, and 30 grams of potassium cyanide in 1 liter On removal from the quicking bath, articles are washed and placed ately in the silvering bath.

Gold Plating. — The solution used in gold plating contains from per cent of gold as the double cyanide of gold and potassium, $KAu(C$ twice as much free potassium cyanide. The current density on the c about 0.2 ampere per square decimeter (1.9 amperes per square foo requires about 1.5 volts. The anodes are pure gold. The solution ma hot or cold. The deposit from a hot solution is more dense, more uni of a richer color. The color of the gold deposit may be influenced l taneously depositing some other metal. Green gilding may be obt adding a little silver cyanide to the bath, until the desired tint is obtain solution should be cold. To give the deposit a red tint, a little coppe is added to the solution.

Other Plating Processes. — Plating with the following metals is s carried out: platinum, tin, lead, iron, antimony, and arsenic.

Plating on Aluminum frequently does not wear well, on account of culty in getting a perfectly clean aluminum surface on which to plate. due to the rapidity with which a thin invisible film of oxide or hydroxi on aluminum when exposed to the air or to any solution. One method coming this difficulty is to immerse the aluminum in a solution of p hydrate until hydrogen is evolved, and then dip without previous was potassium-silver-cyanide solution. The aluminum is immediately cov a layer of silver. It is still better to amalgamate by dipping into a 0.5 solution of mercuric chloride immediately after treating with hydra chloride is rinsed off, and the object again treated with potassium hyd

ten immediately suspended in the silvering bath. (*Langbein, Electrodeposition of Metals, 4th ed., p. 409, 1902.*)

Burgess (*Electrochem. Ind., Vol. 2, p. 85, 1904*) recommends cleaning first with dilute hydrofluoric acid, then with a mixture of 100 parts of sulphuric acid and 5 parts of nitric acid, both concentrated. After rinsing with water the surface is immediately plated with zinc, as this metal is found to adhere better than many others. Starting with the zinc surface, other metals are readily deposited.

GALVANOPLASTY. — Galvanoplasty is the art of reproducing by electrolysis articles of various kinds, or of making finished products, such as set-up type, copper tubes, etc.

Electrotyping. — The object is to make a copper plate which shall be an exact duplicate of type which has been set up ready for printing. First an impression of the type is made in wax, which is then covered with a thin layer of graphite, by dusting the fine powder over the wax surface with soft brushes. A thin layer of copper is then formed by sprinkling the surface with iron filings and pouring over the surface a solution of copper sulphate. The iron goes into solution, depositing copper on itself and on the graphite. The wax plate is then washed in water and suspended in an acid bath of copper sulphate, where copper is deposited electrolytically until a thin sheet that can be stripped from the wax has been formed. After removing the copper sheet from the wax plate, a melted lead-antimony alloy is poured on its reverse side, making a plate approximately 0.5 inch thick. This is then used for printing in place of the original type. The economy of this procedure comes in the saving of wear on the type, and the relatively small amount of type which has to be kept in stock.

The current density ranges from 1 to 2 amperes per square decimeter (0.9 to 1.8 amperes per square foot) and the volts per cell from 0.75 to 1.5.

Copper tubes are made by the Elmore process by depositing copper on a conducting cylinder which rotates in an acid copper-sulphate bath. The surface must be conducting, but the copper must not stick so firmly that the cylinder cannot be slipped out of the tube when finished. In order to keep the outer surface of the tube smooth, it is frequently polished during the deposition of copper. Copper sheets may be made by making tubes of large diameter and cutting them open.

Metallic foil may be made by the electrolytic deposition of a thin metallic layer on a surface from which it can be removed.

Parabolic mirrors are made by depositing copper electrolytically on a parabolic glass surface that has been silvered, and separating the metal from the glass by warming. (*Cowper-Coules, Electrolytisches Verfahren zur Herstellung parabolischer Spiegel, 1904.*)

ELECTROLYTIC REFINING. — The method of refining metals electrolytically is as follows. The impure metal is made the anode of an electrolytic bath, the electrolyte of which is, at the start, a solution of a pure salt of the metal to be refined, and the cathode is a sheet of the refined metal. On passing the current, metal dissolves, along with certain of the impurities. The impurities which are electronegative with respect to the principal metal dissolve; those electropositive with respect to the principal metal remain adhering to the anode. When the latter finally drop from the anode they may be dissolved by the free acid, in which case they would be precipitated again on coming in contact with the anode or the cathode. Some metals are precipitated as an insoluble salt as soon as they dissolve, and are thus removed from the further action of the current.

When it goes into solution, the principal metal is, therefore, separated from those metals which are electronegative with respect to it. When it is deposited

on the cathode, it is separated from those metals which are electropositi respect to it. The bath thus becomes contaminated with certain of the ties in the anode, and these would eventually be deposited on the cathod bath is not purified from time to time.

Anode Mud. — The metals which do not dissolve drop to the of the tank forming the "anode mud." It is from this mud that the pla gold and silver are recovered in copper refining. For methods of work anode mud, see Kern, *Met. and Chem. Eng.*, Vol. 9, p. 417, 1911.

Copper Refining. — The object in refining copper electrolytically obtain as pure copper as possible for electric conductors and to obt precious metals contained in the crude copper. A representative comp of crude copper anodes for American refineries is the following:

Copper	98–99.5 per cent.
Silver	0–300 oz. per ton.
Gold	0–40 oz. per ton.
Arsenic	0–2 per cent.

The refined copper is about 99.95 per cent copper. The electrolyte is tion of $CuSO_4$ and H_2SO_4 containing from 4 to 10 per cent of free acid an 12 to 20 per cent of $CuSO_4$. The current density ranges from 0.43 to 4.8 a per square decimeter (4 to 45 amperes per square foot) of cathode surfa the volts per cell range from 0.1 to 0.3. (*Ulke, Die Elektrolytische Raf des Kupfers, p. 42, 1904.*) The electrolyte circulates slowly from tank t The cathodes, called *starting sheets*, are thin sheets of refined copper.

Multiple and Series Systems of Arranging the Electrodes. tanks for holding the solution and electrodes are made of wood and a quently lined with lead. There are two methods of arranging the elec In the "multiple system" all the cathodes of one tank are connecte likewise the anodes, the cathodes having an anode on each side, as sh Fig. 1.

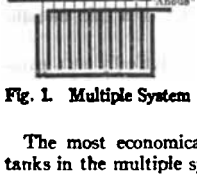

Fig. 1. Multiple System

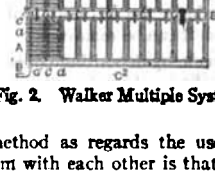

Fig. 2. Walker Multiple System

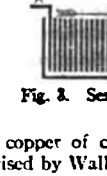

Fig. 3. Series

The most economical method as regards the use of copper of conn tanks in the multiple system with each other is that devised by Walker *Pat. 687, 800, 1901*). In this system the current flows from tank to tank out being collected in a single bus bar in this passage. The *cathodes* first tank rest on a conducting bar G (Fig. 2) on which the *anodes* of the tank also rest. The figure shows two series of tanks with a leading in bus bus bar B' connecting the two series, and leading out bus bar B^2. A more improvement is to have the cathodes of a tank make direct contact wi anodes of the adjacent tank.

In the Hayden or "series system," the electrodes are arranged as sh Fig. 3. The impure copper plates are suspended in the solution at equal dis apart, only the end ones being connected to the dynamo. The current at the electrode A, which dissolves, and on flowing through the tank through the intermediate plates. Pure copper is deposited on the sides plates facing A, and dissolved from the opposite surfaces facing B.

Digitized by Google

ducting preparation is painted over the sides of the intermediate electrodes ng *A*, so that the copper deposited can be separated from the impure copper. en a certain amount of the impure copper has been dissolved, the electrodes emoved, the pure copper is separated from the impure, and the latter is ted and cast into new electrodes. This method is in use at the large plant the Nichols Copper Company, Laurel Hill, New York, and at the Baltimore pper Smelting & Rolling Co., Canton, Md. All others use the multiple system.

Comparison of the Two Systems. — The energy required in the series tem is about 70 per cent of that required in the multiple system. Contacts e more trouble in the multiple than in the series system. The electrodes in series system cost more to prepare than in the multiple system. The estment in a series plant of given capacity is less than in a multiple plant. re lead-lined tanks cannot be used in the series system, the maintenance pense of a series plant is greater than that of a multiple plant.

Nickel Refining. — Nickel may be refined by using a weakly acid solution of kel chloride or nickel sulphate. To get thick deposits the solution must be ted to from 50° to 90° C. Nickel and copper may be separated by the David Brown process, in which nickel is separated from an alloy of nickel and copper depositing the nickel electrolytically. Very pure nickel required for special poses is refined electrolytically by the Orford Copper Company, by a secret ess. Foerster obtained good results with a current density of 0.5 to 2.5 peres per square decimeter (4.5 to 23 amperes per square foot) between 50° C. 60° C. The neutral nickel-sulphate solution contained 30 grams of nickel r liter. Günther obtained good deposits at 60° to 65° C., with 4 to 5 amperes square decimeter (37 to 45 amperes per square foot) at 3.5 to 4 volts, with kel sulphate baths.

Silver Refining. — Two cases arise, (1) the separation of silver from copper an alloy consisting mainly of these two metals, and (2) the separation of silver m relatively small amounts of gold and platinum.

Dietzel Process. — One method of separating silver and copper is the etzel process. This consists in dissolving both of the metals as anode in a ghly acid solution of copper nitrate. The solution is then transferred to other vessel and the silver is precipitated by metallic copper, following which copper is deposited electrolytically.

The current density is about 1.5 amperes per square decimeter (14 amperes r square foot) of cathode surface, and the voltage per cell from 2.5 to 3.5 volts.

Moebius Process. — Silver is separated from small amounts of other tals by the Moebius process. In this process the anodes consist of the impure er, the cathodes of thin sheet silver, and the electrolyte is a slightly acid ate silver-nitrate solution. In the earlier type of apparatus the cathodes re stationary; in the later type the cathode is a rotating sheet of silver. In th the pure silver is scraped off as crystals.

The current density is about 3 amperes per square decimeter (28 amperes per are foot) of cathode surface, and the voltage per cell from 1.4 to 1.5 volts other type is the Balbach-Thum cell (*Met. and Chem. Eng., Vol. 9, p. 444,* 911).

Gold refining is carried out in a slightly acid solution of gold chloride. Gold ks do not dissolve in a solution of gold chloride $AuCl_3$, or of chloroauric d, $HAuCl_4$, but the chlorine liberated comes off in the gaseous form. If some e alkali chloride or hydrochloric acid is present, the gold dissolves. The sulting gold is never less than 999.8 fine, and frequently is 1000 fine.

The baths contain about 3 per cent of free hydrochloric acid with 30 to 40 rams of gold as chloroauric acid per liter. The bath is heated to 60° or 70° C.,

Digitized by Google

and the current density is about 10 amperes per square decimeter (93 amp per square foot) at about 1 volt.

Lead refining is carried out by the Betts process. The electrolyte solution of lead fluosilicate ($PbSiF_6$) containing 60 to 70 grams of lead 120 to 130 grams of SiF_6 per liter, and 0.1 per cent of glue. The objec refining lead is to recover the copper, antimony, bismuth, gold and silver. cannot be separated from the lead electrolytically, on account of its proxi to lead in the electrolytic series.

The current density ranges from 1.3 to 1.7 amperes per square decimeter to 16 amperes per square foot) of cathode surface, and the voltage per cell f 0.30 to 0.38 volt.

According to Duisberg (*Journ. of Ind. and Eng. Chem. for 1912, p. 752*) is now refined electrolytically by the firm Langbein-Pfanhauser & Co., Leip It has valuable magnetic properties, and is used in electromotors. The trolysis is carried out at 100° to 120° C. See also Guillet, *J. Iron and Steel* Vol. 90, pp. 66–80, 1914, and Story, *Tr. Am. Electrochem. Soc.*, Vol. 29, pp. 3 367, 1916.

Refining of Other Metals. — A number of other metals may be refi electrolytically, such as mercury, tin, bismuth, and antimony, but these relatively unimportant.

ELECTROLYTIC WINNING OF METALS. — The attempts that h been made to win metals directly from their ores or from matter are based the same principle as that underlying metal refining. These attempts h not been successful until recently, however, on account of the large amount impurity that gets into the bath and on account of mechanical difficulties. best known of such attempts, are the following.

Marchese Process. — In the Marchese process it was attempted to tain pure copper from a matte containing principally copper, lead, iron sulphur, by electrolyzing this matte as an anode in a sulphate bath. process seemed a success at first, but finally failed.

Siemens and Halske Process. — The Siemens and Halske process for tracting copper consists in electrolyzing a solution of iron sulphate and cop sulphate in a cell in which the anode and cathode are separated by a linen phragm. The anode was carbon; the cathode pure copper. In the cath compartment the solution loses copper by deposition on the cathode. solution then circulates to the anode compartment, where the ferrous sulph is oxidized to ferric sulphate. See below, under *Electrolytic Oxidation*. Fr here the solution circulates to another vat where fresh ore, consisting of cop pyrites ($Cu_2SFe_2S_3$) that has been roasted so as to change the iron sulphide oxide, is treated. The ferric sulphate dissolves the cuprous sulphide as follo

$$Cu_2S + 2\,Fe_2(SO_4)_3 = 2\,CuSO_4 + 4\,FeSO_4 + S.$$

This solution, enriched in copper, is then conveyed to the cathode compartme and the cycle is completed. This process also failed when tried on a commerc scale.

Hoepfner Process. — In the Hoepfner process the copper ore, consisti of copper sulphide, is dissolved in a cupric chloride solution containing a re tively large amount of sodium chloride. The reaction is as follows:

$$Cu_2S + 2\,CuCl_2 = 4CuCl + S.$$

The cuprous chloride, insoluble in water, is held in solution by the sodium ch ride. The anode and cathode of the electrolytic cell are separated by a di phragm. The solution first circulates to the cathode compartment, where pa

Digitized by Google

le copper is deposited, and then to the anode, where the cuprous chloride idized to cupric chloride. The solution from the anode then circulates to ore.

pper Hydrometallurgy at Chuquicamata. — A process is now being ted by the Chile Exploration Company for winning copper directly from e of the Chuquicamata copper mine, in Chile. The ore is dissolved in dilute uric acid in leaching tanks. The solution is then conducted to the electro- tanks where the copper is deposited, using insoluble anodes and copper starting sheets. Originally fused magnetite anodes were used, but were later replaced by *duriron* (ferro-silicon containing 12 per cent silicon). electrolytic refinery will have a capacity of 335,000 pounds of copper per (*E. A. Cappelen Smith, Met. and Chem. Eng., 1914, Vol. 12, pp. 291–294.*

lsom Process. — Lead was at one time extracted from galena (PbS) by Salom process, consisting in electrolyzing the powdered galena as cathode sphuric acid. The hydrogen deposited on the galena combines with the ur, forming hydrogen sulphide and leaving the lead as lead sponge. This ss was given up, partly at least, on account of the poisonous action of the gen sulphide. (*Trans Am. Electroch. Soc. Vol. 1, p. 87, 1902; Vol. 4, 1903.*)

ctrolytic Zinc. — Within recent years a large quantity of high grade lytic zinc has been produced in the United States and Canada, by a process r to that used for copper at Chuquicamata. Sulphate solutions are used, lead anodes and aluminum cathodes, from which the zinc is stripped in sheets. The solution must be free from impurities in order to get good sits. See Hansen, *Bull Am. Inst. Mining Eng.*, Vol. 135, p. 615, 1919; French, *Trans. Am. Electroch. Soc.*, Vol. 32, pp. 321–328, 1917; *Met. and m Eng.*, Vol. 18, pp. 549–550, 1918.

Detinning Tin Scrap and Old Cans. — The two principal methods of overing tin from tin scrap and old tin cans are due to Goldschmidt. The consists in electrolytically dissolving the tin and depositing it in the metallic te; the second method, which however is not electrolytic, converts the tin o tin tetrachloride by treating with dry chlorine.

In the electrolytic method the solution consists of a sodium hydrate solution, taining a certain amount of carbonate, absorbed from the air, and sodium nnate. The best concentrations are: 10 to 12 per cent alkalinity, not over er cent free alkali; carbonate not over 3 per cent; stannate not over 5 per nt. Temperature, 60° to 70° C. About one-tenth of the solution must be laced every week.

The tin scrap is suspended in the solution in baskets (39 by 35 by 18 inches) perforated sheet iron, containing 100 to 130 pounds of scrap. Old cans are ached, compressed and then cut up. The cathodes are sheet iron 39 by 35 hes. The tin dissolves from the anode and is deposited as spongy tin on the thode. The scrap is left in the bath for three hours. The spongy tin is com- ssed by a hydraulic press into cylinders weighing six pounds; these are sub- quently melted in a furnace with sealed tubes. This sponge contains 50 per nt tin and 50 per cent ash. The ash is subsequently reduced with carbon in open-hearth furnace, yielding 70 per cent of the tin.

Very careful working is necessary to remove the tin so completely that the n can be sold to open-hearth plants. Even then the iron contains 0.1 to 0.5 r cent tin.

The cathode current density is never over 0.75 ampere per square decimeter amperes per square foot), at 2 to 3 volts per cell. (*Electrochem. and Met. Ind., l. 7, p. 79, 1909; Met. and Chem. Eng., Vol. 10, p. 202, 1912.*)

ELECTROLYTIC OXIDATION AND REDUCTION is frequ
ried out on substances in solution. One of the advantages of the e
method is that no other substance has to be added to the solution. I
out an electrolytic oxidation or reduction a porous diaphragm is used t
the anode and cathode compartments. The substance to be reduced
in the cathode compartment, where the whole or a part of the hydr
would be evolved by the current while in the nascent state, acts on
stance in question. The intensity of the reduction may be varied b
the potential difference between the solution and the cathode. This
plished either by increasing the current density on the cathode, or b
the cathode of different metals on which the overvoltage (*see Electro
Principles of*) is different. It frequently happens that the metal comp
cathode has a marked accelerating effect on the velocity of the
Thus the reduction may be much more complete on one metal than on
though the potential difference between the metals and the soluti
same in both cases. The same considerations apply to oxidation
anode.

Typical Reduction and Oxidation Processes. — Examples w
trolytic reduction has been found useful are: in the manufacture of
by corroding a lead anode in a suitable solvent, e.g., the Luckow proce
preparation of the lower salts of vanadium, molybdenum and titanium.
where electrolytic oxidation has been employed are: in the oxidati
lower cerium sulphate, $Ce(SO_4)$, to $Ce(SO_4)_2$, the latter being useful
dizing agent; in oxydizing potassium manganate, K_2MnO_4, to perm
$KMnO_4$; in the oxidation of potassium ferrocyanide, $K_4Fe(CN)_6$, to
cyanide, $K_3Fe(CN)_6$; and of chromium sulphate to a chromate.

Sodium permanganate has been made on a semi-commercial scale by
zing ferro-manganese anodes in sodium carbonate or hydrate solution
Am. Electrochem. Soc., Vol. 35, pp. 371–384, 1919). Potassium perm
has been made in the same way (*Chem. and Met. Eng., Vol. 21, pp. 680–6*

ELECTROLYSIS OF SODIUM OR POTASSIUM CHLOR
The electrolysis of sodium or potassium chloride may yield several
products, depending on the kind of cell employed. In the followin
sion the reactions for sodium choride are given; these reactions also
potassium chloride when K is substituted for Na.

Production of Electrolytic Bleach. — If there is no diaphragm
solution is kept cool, the chlorine and hydrate react on each other
principally sodium hypochlorite or "electrolytic bleach," according
equation

$$2\,NaOH + Cl_2 = NaOCl + NaCl + H_2O.$$

As soon as hypochlorite is formed, it begins to change to chlorate, bu
not as rapidly as it is formed. As the concentration of the hypochl
creases, a larger and larger proportion changes to chlorate, until fi
concentration of the hypochlorite reaches a limit, which depends on
perature, original salt concentration, current density, and other facto
hypochlorite then changes to chlorate as rapidly as it is formed.

The reactions by which hypochlorite changes to chlorate are two;
action of the discharged ClO ion on water:

$$6\,ClO + 3\,H_2O = 2\,HClO_3 + 4\,HCl + 1\tfrac{1}{2}\,O_2,$$

and (2) in a slightly acid solution:

$$2\,HOCl + NaOCl = NaClO_3 + 2\,HCl.$$

Digitized by Google

e solution is warmed to about 50° C. the conditions are so changed that the ing concentration of hypochlorite is much lower than when cold. Sodium potassium hypochlorites are used only in solution, but the chlorates are allized out.

further electrolysis of a cooled sodium (or potassium) chlorate solution, rcrate, $NaClO_4$, is produced by the action of the liberated ClO_3 ion on r:

$$2\,ClO_3 + H_2O = HClO_4 + HClO_2$$

$$HClO_4 + NaOH = NaClO_4 + H_2O.$$

most of the cells used for producing hypochlorite, a vessel is divided into mber of narrow compartments by bipolar or intermediate electrodes, con- of carbon plates (Hass and Oettel) or platinum-iridium wire wound on plates (the Kellner cell). The solution is cooled by circulation. There essential difference between a hypochlorite and a chlorate cell, except the latter is used at a higher temperature. (*See numerous volumes in the ardt Monographs.*)

Production of Chlorine and Caustic. — If the anode and cathode are ated by a diaphragm of some kind, sodium hydrate is produced at the e by the action of the alkali metal on water:

$$2\,Na + 2\,H_2O = 2\,NaOH + H_2,$$

e at the anode chlorine is set free, which may be used to make bleaching der.

Various devices are used to separate the hydrate and chlorine in cells intended these products. In the McDonald cell (*Electrochem. Ind., Vol. 1, page 387,* and others a porous diaphragm is used. In the Hargreaves-Bird cell *S. Pat. 655,343, 1900; 596,157, 1897*), the porous diaphragm is supported a heavy copper gauge cathode, which is wetted only by the solution percolat- through the diaphragm. In the Townsend cell (*Electrochem. and Met. Ind., 5, page 209, 1907*) the cathode compartment is filled with kerosene oil. ing electrolysis the solution in the anode compartment percolates through porous diaphragm and the perforated cathode, and on coming in contact with oil forms drops and sinks to the bottom of the cathode compartment where is collected. In the "bell process" the anode is inside an inverted non- ducting, nonporous bell, and the cathode is a conducting ring outside. Two portant diaphragm cells are the Allen-Moore cell and the Nelson cell (*Trans. Electrochem. Soc., Vol. 35, pp. 239–249, 1919*).

In the Castner cell the compartments are separated by a mercury diaphragm, ing as an intermediate electrode; and in the Solvay and the Whiting cells rcury cathode is used, which, when charged with sodium in the electro- cell, is decomposed by water in a different compartment. The sodium lgam reacts with water like metallic sodium. (*See the Engelhardt Mono- hs.*)

ELECTROLYSIS OF WATER. — The electrolysis of water is carried out commercial scale for the production of hydrogen and oxygen. The elec- lyte is usually a 15-per cent sodium hydrate solution. A diaphragm of is used to separate the hydrogen and oxygen in the Flamand cell, now e by the International Oxygen Company at Newark, N. J. The vessel aining the electrolyte is cast iron and acts as the cathode; the anode is el. In the Siemens and Halske apparatus the gases are separated by a tallic gauze while bubbling to the surface of the solution; the Garuti and

Pompelli apparatus is based on a similar principle. (*See Viktor E Die Elektrolyse des Wassers, 1902.*)

ELECTROTHERMAL PROCESSES. — Some of the more i industrial electrothermal processes and products and the various types furnaces are described in the article on *Furnaces, Electric.*

OZONE (O_3) is made by the silent discharge of electricity throug The electrodes are water cooled, and protected to prevent the passage From 8000 to 50,000 volts alternating are applied, this voltage being from a small step-up transformer. For the Siemens and Halske ozo concentration of the ozone is about 2 or 3 grams per cubic meter of the passes through it, and the yield is from 18 to 37 grams per kilowatt ho *trochem. Ind., Vol. 2, p. 67, 1904.*) Milk has been sterilized by hig discharges; one process being the Shelmerdine process (*Electrical Time pp. 502–505, 1914*).

CTROCHEMISTRY, PRINCIPLES OF. —(*See also Electricity Magnetism, Principles of; Elements, Chemical; Electrochemical Processes, rial; Furnaces, Electric.*) Electrochemistry is the science which deals the phenomena resulting from the direct transformation of electrical into cal energy or the converse transformation of chemical into electrical . By general usage the term, especially as applied to industrial processes, ne to include also those thermochemical phenomena which occur at tem- re produced in electric furnaces, although in such processes electrical frequently plays no other rôle than that of generating heat.

FINITIONS. — The following terms are commonly used:

ment. — An element is a substance which cannot be decomposed into er substances by any known means of chemical analysis. (*See Table of rochemical Equivalents below, and article on Elements, Chemical.*)

oms and Atomic Weights. — An atom is the smallest mass of an element can enter into chemical combination with another element or itself. The ic weight of an element is a number which is proportional to the smallest n combining mass of the element, that of oxygen being chosen as the stand- and taken as 16. The relative proportions, by mass, of the elements form- any substance are simple multiples of these numbers. For table of the ic weights of the more common elements see below, and for a complete t see article on *Elements, Chemical*. On the atomic theory the atomic ht is proportional to the mass of the atom.

lecules and Molecular Weight. — A molecule is the smallest mass of stance which can exist and preserve its chemical properties. The molec- weight of an element or of a chemical compound is equal to the sum of the ic weights of the atoms contained in the molecule, and may readily be ulated from the atomic weights when the molecular symbol of the com- d is known. Thus the molecular weight of oxygen, O_2, is $2 \times 16.00 = 32.00$ there are two atoms in the molecule. The molecular weight of silver ite, $AgNO_2$, is $107.88 + 14.01 + 3 \times 16.00 = 169.89$.

adical. — A radical is a combination of two or more elements which per- as a group in chemical reactions, e.g., the SO_4 in H_2SO_4 is a radical, as plified by the reaction $H_2SO_4 + Zn = ZnSO_4 + H_2$.

ormula Weight. — The formula weight of an atom, radical or molecule is sum of the atomic weights of the elements of which it is formed. For mple, the formula weight of an oxygen atom, O, is 16; the formula weight

Digitized by Google

of an oxygen molecule, O_2, is 32; the formula weight of the radical $14.01 + 3 \times 16.00 = 62.01$.

Valency. — An adequate consideration of valency would involve a dis beyond the limits of this article. As a simple definition, the valency acid or acid radical may be taken as the number of replaceable hy atoms which the acid molecule contains, the valency of the hydrogen atom always equal to unity. Thus hydrochloric acid, HCl, and nitric acid, HN are univalent acids and the elements H and Cl and the radical NO_3 ar valent; sulphuric acid, $H_2(SO_4)$, is a bivalent acid and SO_4 a bivalent r $H_3(PO_4)$ is a trivalent acid and PO_4 a trivalent radical, etc. Similarly, in like sodium chloride, NaCl, sodium is a univalent metal, since one at sodium replaces one atom of hydrogen in the corresponding acid. I barium chloride, $BaCl_2$, barium is a bivalent metal, as it replaces the hy of two molecules of hydrochloric acid to form the salt. To completely de the valency of a salt it is therefore necessary to stipulate the valency basic and acid constituents; thus sodium chloride, NaCl, is a uni-uni salt; sodium sulphate, Na_2SO_4, is a uni-bivalent salt, the basic constituent univalent and the acid constituent bivalent. Barium sulphate, $BaSO_4$, other hand, is a bi-bivalent salt. The valency of a number of elements according to the compound of which the element forms a part, e.g., cop bivalent in cupric salts like $CuSO_4$ but univalent in cuprous salts as CuCl is bivalent or trivalent according as it is a constituent of a ferrous or ferr respectively.

Bonds or Affinities. — An atom or radical is sometimes said to pos number of "bonds" or "affinities" equal to its valency in the compou which it forms a part.

Equivalent Weight — Chemical Equivalent. — The equivalent weight atom, ion or radical is defined as its formula weight divided by its va The equivalent weight of an element or compound is also referred to "chemical equivalent." The equivalent weight of an acid, base or salt molecular formula weight divided by the highest valency of either of its As hydrogen exhibits no other valency than unity its equivalent weigh atomic weight are identical. Similarly, the equivalent weight and mol weight of hydrochloric acid, HCl, are each 36.47. Copper in copper sulp $Cu(SO_4)$, and in cupric chloride, $CuCl_2$, has a valency of 2, hence equiv weights of these salts are one half their molecular weights respectively.

In computations of electrochemical reactions it is frequently convenie take as the unit of mass (or weight) of a substance, a mass in grams equ the number expressing the atomic weight, ionic weight, molecular weig equivalent weight of the substance. The following names have been given units.

Gram-Atom or Gram-atomic Weight. — A number of grams of an ele equal to its atomic weight, e.g., one gram-atom of oxygen is 16 grams.

Gram-Molecule or Mol. — A number of grams of a substance equal molecular weight, e.g., one mol of silver nitrate, $AgNO_3$, is 169.89 grams.

Gram-Equivalent. — A number of grams of an atom, radical or mol equal to its equivalent weight, i.e., to its formula weight divided by its val For example, a gram-equivalent of sulphuric acid is $98.09/2 = 49.04$ gr A gram-equivalent is usually represented by the chemical formula divide the valency, e.g., a gram-equivalent of sulphuric acid is denoted by $\frac{1}{2} H_2S$

Electrolyte — Electrolysis. — When an electric current is passed thr certain substances a chemical reaction takes place at the places where current enters or leaves the substance. Such substances are called "ele

Digitized by Google

s;" if the current effects a decomposition or chemical change in the elec-
te the process is called "electrolysis."

lectrodes — Anode and Cathode. — Electrodes are the conductors by
ch the current enters and leaves the electrolyte. The electrode at which the
ent enters the electrolyte is called the "anode," and that by which the cur-
leaves the electrolyte is called the "cathode." The anode is therefore that
ode which is connected to the positive terminal of the generator; the
ode that connected to the negative terminal.

ons — **Anions and Cations.** — The constituents of an electrolyte which are
ually liberated or deposited from an electrolyte at the electrodes are called
ns. The term also applies to the constituents of an electrolyte which con-
the current. (*See sections below on Dissociation Theory and Theory of Elec-
ic Conduction.*) The ions liberated at the anode are called "anions," while
e liberated at the cathode are called "cations." For example, when a
ent enters and leaves an aqueous solution of copper sulphate, $CuSO_4$, at
latinum electrodes, the $CuSO_4$ is decomposed, the copper Cu being liberated
the solution and deposited on the cathode, and the SO_4 being liberated
the anode where it reacts with the water to form oxygen gas and sulphuric
d. The copper in the sulphate solution is therefore a cation and the SO_4 an
n. In general the metal atoms in salts and bases and the replaceable
drogen atom in acids are cations, while the acid radicals (e.g., SO_4) and the
adicals (e.g. OH in KOH) are anions.

The terms anion and cation are also used to designate specifically the negative
positive constituents of an electrolyte. For example, in dilute aqueous solu-
a molecule of hydrochloric acid, HCl, is looked upon as consisting of one hy-
gen cation and one chlorine anion; sulphuric acid, H_2SO_4, of two hydrogen
ons and one SO_4 anion. There is much evidence to indicate that a nega-
e charge of fixed amount is associated with each anion and a positive charge
deficit of negative electricity) of equal amount is associated with each cation,
espective of the chemical nature of the ion, except that the charges carried
any ion are directly proportional to its valency. The charge carried by each
dividual univalent ion as determined by Millikan, is $4.774 \pm 0.005 \times 10^{-10}$
ctrostatic units, the charge carried by every bivalent ion is twice this amount,
$4.774 \pm 0.005 \times 10^{-10}$ electrostatic units of negative electricity being the
rge of an electron. Hence on the basis of the electron theory, a univalent
on as Cl has associated with it one free electron, a divalent anion as SO_4 two
electrons, while a univalent cation as H has a deficit of one electron, a divalent
ion as Cu has a deficit of two electrons, etc. See *Electron Theory.*

To distinguish cations and anions from neutral atoms or molecules, small
s or minus signs are often written over the symbol, the number of such signs
ng equal to the valance of the ion. Thus

$\overset{+}{Na}$, $\overset{++}{Cu}$, $\overset{+++}{Fe}$ (ferric iron) represent cations; $\overset{-}{Cl}$, $\overset{-}{NO_3}$, $\overset{--}{SO_4}$, $\overset{---}{PO_4}$ anions, etc.

Ionic Weight. — The formula weight of an ion is called its ionic weight.

Gram-Ion. — A number of grams of an ion equal to its ionic weight, e.g.,
gram-ion of hydrogen is 1.008 grams, and one gram-ion of SO_4 is 96.07 grams.

Electrochemical Equivalent. — The electrochemical equivalent of an ion is
mass in grams of the ion liberated or deposited by one coulomb of electricity.

Electrochemical Constant or "Faraday." — The electrochemical constant,
noted by F, and called the "Faraday," is the number of coulombs required
liberate one gram-equivalent of any ion. It is a constant for all ions, and
value, as adopted by the International Congress of Applied Chemistry in
03, is $F = 96{,}540$ coulombs. (*See also page 452.*)

Digitized by Google

Solvent, Solute and Solution. — When a substance A "dissolves" substance B, the substance A which dissolves is called the "solute substance B is called the "solvent." The two substances togeth "solution."

Osmotic Pressure. — The osmotic pressure of a solution may b as the force in virtue of which a solute tends to diffuse from region to regions of lower concentration. It can be measured by separatin tion and solvent by means of a diaphragm which is permeable to the s not to the solute. (See section below on *Theory of Solutions*.)

Specific Conductance (κ). — The specific conductance of a solu reciprocal of its specific resistance, i.e., it is the conductance of a liquid one centimeter long and one square centimeter cross section. pressed in reciprocal ohms, or mhos, and is denoted by κ.

Concentration (c). — The concentration (c) of a solution is the q the solute contained in unit volume of the solution. Thus it may be as grams per cubic centimeter or grams per liter, etc.

Equivalent Concentration (η). — The equivalent concentration of is the number of gram-equivalents of solute contained in one cubic of the solution; it is denoted by η. Calling w the equivalent weig solute, $\eta = c/w$.

Dilution (ϕ). — The dilution of a solution is the reciprocal of its tion, i.e., it is the number of cubic centimeters of solution in which equivalent of solute is dissolved. It is denoted by ϕ. Hence, ϕ $\eta = 1/\phi$.

Normal Solution. — A normal solution is a solution containing equivalent of solute per liter. For such a solution $\eta = 10^{-3}$ or $\phi =$

Equivalent Conductance (Λ). — The equivalent conductance of at the dilution ϕ is the conductance which a volume (in cu. cm.) of th containing one gram-equivalent of the solute would have, if placed parallel plate electrodes one centimeter apart. It is denoted by Λ_ϕ or Λ ing as the dilution or concentration of the solution is given. Hence or $\Lambda_\eta = \kappa/\eta$.

The dilution or concentration of a solution should always be stat nection with its equivalent conductance, otherwise the expression is in

Heat of Reaction. — The heat of reaction is the heat energy giv absorbed in a chemical reaction. It is usually expressed in calories; *and Heat Effects*. Ostwald recommends the use of a calorie equal to the mean gram-calorie for expressing thermochemical data and th adopted in the present discussion. It will be denoted in this article

Exothermic Reactions. — Reactions in which heat is given out t rounding bodies.

Endothermic Reactions. — Reactions in which heat is absorbed surrounding bodies.

NOTATION. — The notation used in this article is, in most insta proposed by the Bunsen Gesellschaft and adopted by the Fifth Int Congress of Applied Chemistry in Berlin, 1903. For convenience of the symbols most frequently used are tabulated below.

κ = specific conductance in reciprocal ohms;

η = concentration, expressed as gram-equivalents of solute per cu meter solution;

ϕ = dilution, expressed as cubic centimeters of solution per gram-e solute;

the voltage and intensity of the current, size of electrodes and con of electrolyte, so long as the total *quantity* of electricity flowing th circuit remains constant. (These factors, however, do affect the *ulti ucts* of an electrolysis.)

Second Law. — A given quantity of electricity always decomposes weights of different electrolytes irrespective of their nature. For e three electrolytic cells containing aqueous solutions of silver nitrat copper sulphate $CuSO_4$, and cuprous chloride CuCl (dissolved i chloride), respectively, be connected in series and the same quantit tricity passed through each, it will be found if a grams of silver are de the first cell, b grams of copper in the second and c grams of copp third, that the following proportion holds between these weights: $\frac{107.88}{1} : \frac{63.57}{2} : \frac{63.57}{1}$, where 107.88 and 63.57 are the atomic weight and copper respectively. In copper sulphate the valency of copper i in cuprous chloride its valency is 1; silver is always univalent and weights a, b, c are proportional not to the atomic weights but to the *weights* of the metals in the compounds from which they are electrol follows from this that a given current will deposit in a given time weight of metal from a salt in which it is combined with a valency of a salt in which it exists with a valency of 2. Thus, the same curren in a given time twice the weight of copper from a cuprous as from salt solution. In general, if the ion in a compound has a valen quantity of electricity required to liberate it will be n times as gre required to liberate the same ion from a compound in which it is univ

It is to be noted, since the numbers expressing the atomic weights ments, and hence their equivalent weights, are purely relative, that th weights of substances decomposed by a given quantity of electricit expressed in grams, kilograms, pounds or any other unit of weight. the above illustration the quantity of electricity which will deposit $\frac{63.5}{2}$ pounds of copper from a copper sulphate solution will deposit 107.88 silver.

Faraday's Laws are the expression of the results of direct experi have been tested to the limit of precision with which physical and measurements are capable of being carried out at the present time. dence indicates that they hold rigidly, i.e., that they are exact laws In cases where exceptions have seemed to exist these have been show from secondary causes. See Kraus, *Trans. Am. Elec. Chem. Soc.*, *21*, for special cases of electronic and ionic conduction.

Value of the Electrochemical Constant or Faraday. — The dete of the number of coulombs required to deposit one gram-equivalent i.e., the constant connecting the quantity of electricity and the mass stance liberated, involves two distinct investigations; first, the mea of the number of coulombs which pass through a given electrolytic second, the determination of the amount of the chemical decompositi importance of the constant has enlisted the skill of a number of t physicists, and its value is still being investigated at the present time.

The various methods which have been employed vary primarily in t adopted for measuring the current. A primary instrument the co which can be computed from its dimensions, is essential. Tangent g eters and various forms of current balances or dynamometers have structed for this purpose. The ultimate precision of the measurem these instruments is thus referred back to instrumental constants a

racy with which the horizontal component of the earth's field, or the value he acceleration due to gravity, is known at the place where the research is ied out, respectively.

he amount of silver deposited from a silver nitrate solution has been adopted st universally for the chemical part of the research. The amount of silver osited depends to a slight extent upon whether or not the solution at the de is allowed to diffuse to the cathode. The following résumé of the determiions of the mass of silver in milligrams deposited by one coulomb is given he, *Bulletin of the Bureau of Standards, 1905, Vol. 1, p. 363*).

TABLE I. — ELECTROCHEMICAL EQUIVALENT OF SILVER IN MILLIGRAMS PER COULOMB

Observer	Year	Found	Electrochemical equivalent corrected by		
			Richards and Heimrod	Van Dijk	Guthe
		mg.	mg.	mg.	mg.
lucart	1884	1.1156	.....	1.1155	1.1153
l and W. Kohlrausch..	1884	1.1183	1.1173	1.1182	1.1177
ayleigh and Sidgwick..	1884	1.1179	1.1175	1.1178	1.1176
ray	1886	1.1183	.....	.....	1.1178
ocpael	1887	1.1174	.....	.....	1.1169
Blat and Potier	1890	1.1192	.....	1.1191	1.1189
tterson and Guthe	1898	1.1192	1.1175	1.1180	1.1177
Blat and Leduc	1903	1.1195	.....	1.1192	1.1190
n Dijk and Kunst	1904	1.1182	.....	1.1180	1.1178
				Mean	1.1176

If the atomic weight of silver be taken as 107.88 (latest corrected value) value of the Faraday from the average of Guthe's corrected values is

$$\frac{107.88}{0.001117 6} = 96{,}530 \text{ coulombs.}$$

This value agrees very closely with the ue $F = 96{,}540$ adopted by the International Congress of Applied Chemistry 1903 and based on the atomic weight of silver = 107.93, and on the definition the legal ampere as that current which in one second deposits 0.001118 gram silver. (*See Report of International Electrical Congress, 1893; Definition legalized the U. S. Government in 1894.*) In view of the above agreement it seems visable to adhere to the value 96,540 until by international agreement another ue shall be adopted. For a complete résumé of recent work on the value of raday the *Bull. Bureau of Standards, 13*, 479, 1916, should be consulted. The reau of standards gives 96,503 as the most probable value, and recommends ,500 as the best round value.

ELECTROCHEMICAL EQUIVALENTS OF THE ELEMENTS. — m the definitions of the electrochemical equivalent and the Faraday, it lows that the electrochemical equivalent of any ion, expressed in grams per ulomb (one ampere per second) is equal to

$$\frac{\text{gram-equivalent of the ion}}{96{,}540}.$$

ROLYTIC CELLS. — When a cell formed by two ctrolytes gives out electric energy the cell is called ry chemical batteries are voltaic cells. If across

Digitized by Google

the terminals of a cell an external electromotive force, greater than
tromotive force developed within the cell, is impressed, then a curren
through the cell in the opposite direction, and the cell will absor
energy. A cell which absorbs electric energy is usually referred
"electrolytic cell." The cells used in electrolytic refining and similar
are electrolytic cells. An electrolytic cell may or may not have a
motive force on open circuit, but may develop an electromotive force
of the chemical changes or changes in concentration which take pla
the current forced through it by some external source. A voltaic cel
an electrolytic cell when the electromotive force impressed across its
exceeds (and opposes) its own electromotive force.

POLARIZATION. — When an electric current passes through
voltaic or an electrolytic cell there is, in general, developed at the ele
the cell as a result of the chemical actions and changes in concentrati
take place, a *back* or *counter-electromotive* force, in addition to its op
electromotive force (if any), and an *increase in the resistance* of th
addition to the change in resistance due to the heating effect of the
Both of these effects cause a decrease in the strength of the current
the cell. These two phenomena are said to be due to "polarizat
"transition resistance" respectively.

Even in the case where the electrolyte, as a whole, suffers no chang
centration, as in the electrolysis of copper sulphate between copper e
a counter e.m.f. of polarization is produced in consequence of the
in concentration of the copper ions in the neighborhood of the anode and
Vigorous stirring of the electrolyte tends to reduce this concentration
and the resulting polarization, but, except for very low current de
cannot be completely eliminated. It is for this reason, in refining proce
energy is required to transfer the metal from anode to cathode in ac
that necessary to overcome the internal resistance of the cell.

A transition resistance results from the formation of a film of pc
ducting material over the electrode and may or may not be present
to the character of the electrolysis.

Measurement of E.M.F. of Polarization and Transition Resis
As both transition resistance and polarization tend to cut down th
flowing through the cell, they cannot be distinguished by this effe
The transition resistance may be determined by measuring the ohmic
of the cell before and after the passage of the current by the usual alt
current method. The existence of an e.m.f. of polarization in a c
normally has no open-circuit e.m.f. may be qualitatively demonst
short-circuiting the cell through a galvanometer immediately after
the primary circuit; if the cell be polarized, a current which diminish
will flow through it in the reverse direction. A voltmeter, or, better
trometer connected across the electrolytic cell, will indicate the po
voltage the instant after the current is broken. This voltage will di
the polarization disappears, the rate depending upon the current thr
voltmeter and the rate of diffusion of the electrolytic products ca
polarization. Owing to the rapidity with which the e.m.f. of polariza
off after the exciting cause is removed, special precautions must be
In its measurement. One of the best methods is to connect up th
containing the applied e.m.f., and electrolytic cell with a tuning-fork in
and electrometer so that at the instant the battery current is broke
vibration of the fork, the circuit containing the cell and electrometer
meter is closed, and vice versa. By this arrangement, the e.m.f. of po
is measured during the fraction of a second that the battery circuit

d before it has had time to sensibly diminish. The polarizing current may o be regarded as practically constant.

It is frequently of importance to know, not the polarization of the cell as a hole, but the polarization at each electrode. This is obtained by measuring e drop in potential at each electrode against a normal hydrogen or calomel ectrode while the impressed e.m.f. is acting on the electrolytic cell, or immeiately after the current through the cell is interrupted.

REVERSIBLE ELECTRODES — DEPOLARIZERS. — If the chemil and thermal actions which take place at a given electrode when a given uantity of electricity passes in one direction through a cell are exactly the verse of the actions which take place when the same quantity of electricity asses through it in the opposite direction, the electrode and the solution with hich it is in contact are said to form a "reversible electrode." Such an elecode does not polarize provided the concentration of the solution is kept conant.

There are two types of reversible metal-liquid electrodes, namely:

Electrodes of the First Type, consisting of a metal in contact with a olution of one of its own salts, e.g., copper in copper sulphate, zinc in zinc ulphate, etc. The two electrodes of a Daniell cell are of this type.

Electrodes of the Second Type, consisting of a metal in contact with a olution containing one of its difficultly soluble salts and a second soluble salt f some other metal, having the same anion. The difficultly soluble salt, called he "depolarizer," must be present in excess as solid. Such an electrode is ercury in contact with a solution of zinc sulphate containing mercurous sulhate in excess as solid; this is one of the electrodes of the Clark cell.

Reversible Gas Electrode. — An electrode consisting of "platinum black" aturated with an atmosphere of hydrogen gas and dipping partially into a olution containing hydrogen ions is also a reversible electrode. This is a pecial form of electrode of the first type in which a gas by being occluded in latinum is made to play the rôle of a metal.

Other "gas electrodes" e.g., chlorine, may be similarly prepared.

CONTACT POTENTIALS; ELECTROMOTIVE FORCE. — The lectromotive force of a voltaic cell, the back-electromotive force of an electrolytic ell, and the electromotive force of a thermocouple, are all due to differences of otential which always exist at the junction of dissimilar substances. These ingle potential differences are called "contact potentials," the word "differnce" being understood. For a general discussion of this subject see Langmuir, *Trans. Am. Elec. Chem. Soc.*, 29, 125, 1916.

Metal-metal Potentials. — The potential at the junction of two dissimilar etals may be measured either by the Peltier effect, i.e., by the heat developed r absorbed at the junction when a known quantity of electricity is forced across t, or by the thermoelectric force set up in a circuit formed by the two metals in uestion when the two junctions are kept at different temperatures. In the ormer case the potential may be calculated from the expression $e = H/nF$ hen H is the Peltier heat developed or absorbed at the junction by the passage f nF coulombs. In the latter case $e = T\frac{de}{dT}$, where $\frac{de}{dT}$ is the thermoelectric oefficient of the junction at the absolute temperature T. Both methods give esults which prove that the potential difference thus arising is of the order of magnitude of a few millivolts, except in the unusual combination of antimony nd bismuth where it amounts to about 0.03 volt. Table III taken from an rticle by Caswell, *Physical Review, 33, 401, 1911*, contains the values of the metal-metal potentials for the more common metals against copper at ordinary

temperatures. The columns headed *A* give the values as determined first method, columns headed *B* give the values as determined by the method. The plus sign (+) indicates that at a junction formed by t metal and copper the given metal is at the higher potential, the minus s that it is at a lower potential than the copper.

The contact potential difference between any two of these metal *algebraic* difference between the potentials of the two metals against e.g., the contact potential difference between iron and platinum acco Jahn's measurements (*A*) is + 0.37 − (− 3.68) = 4.05 millivolts.

The contact potential difference between any two metals is a functio temperature, the sign of the potential for a given pair of metals so reversing as the temperature rises. Although of importance in ther pyrometry and radiometry, metal-metal potentials are of little signifi considerations of the voltaic cell.

Metal-gas Potentials. — The contact potential differences between two metals should be carefully distinguished from potential differences having their origin in the so-called "Volta effect," i.e., potential differences which are manifested when two dissimilar metals in metallic contact are separated by an air or other gaseous gap. The two phenomena are quite distinct, there being no known relation between them.

a rise of potential through the electrolyte of 0.283 volt, hence, if from gen electrode to any metal electrode the rise of potential is e_h, and calomel electrode to any metal electrode the rise of potential is e_c, th

$$e_h = e_c + 0.283 \text{ volt.}$$

The difference between any two metal-liquid potentials remains the spective of the normal electrode to which they are referred.

Specific Electrode Potentials. — On the assumption that the e conductance ratio is a true measure of the degree of ionization of an el and that the gas laws hold for solutions up to normal concentration, it i to calculate from electrode potential measurements against a normal what the potential difference would be between an element and a solu taining ions of that element at a concentration of one gram formula w liter. Such potential differences (measured directly or calculated) specific electrode potentials. Much experimental work remains to before these fundamental constants are known with precision. For o metals are there known at present better than + 0.01 volt. The table contains values for some of the more typical electrochemical These values are all referred to the hydrogen electrode as standard. T thesis ( ) signifies one electronic change which is subtracted from or ad atom or ion. For a more complete table see the Monograph of Abe bach and Luther, *Abhandlungen Deutsch. Bunsen Gesellschaft*, Vol. (1911) and No. 8 (1915), or Washburn's *Principle of Physical Chemistr*

Variation of Electrode Potentials with Concentration. — ing to Nernst's theory of electrode potentials (*see below*) the *change* in t of these potentials with concentration may be calculated by the following

$$e_1 - e_2 = \frac{0.000198\,T}{n} \log_{10} \frac{c_1}{c_2},$$

where e_1 is the potential at concentration c_1, and e_2 the potential at conc e_2, T is the absolute temperature, and n the valence of the metal in the

ɲ formula is also justified by experiment. For example, the electrode ɲtial of silver in a normal silver-nitrate solution at 25° C. is 0.80 referred the normal hydrogen electrode. If the concentration of the silver ions be ɲced to 1/1,000,000 its value in a normal solution, the electrode potential of ɲr will become

$$e_2 = 0.80 - \frac{0.000198 \times 298}{1} \log_{10}\left(\frac{1}{10^{-6}}\right)$$

$$= 0.80 - 0.0590 \times 6 \times 0.45 \text{ volt.}$$

Electrochemical Series — Nobility of the Elements. — The elements, as ɲged in Table IV, constitute the "Electrochemical Series." Those elements ɲ which e_h is negative are said to be less "noble" than hydrogen, while those ɲ which e_h is positive are said to be more "noble" than hydrogen. The alkali ɲals having the greatest tendency to form ions in water stand at one end, ɲke the "noble" metals, such as gold, platinum, palladium, having but a very ɲht tendency to form ions, are at the other end. The halogens which go into ɲution as negative instead of positive ions stand at the lower end of the series. ɲher series have been given which differ from the above in that the elements ɲ not compared under similar conditions in regard to the concentration of the ɲution with which they are in contact. Changing the electrolyte, e.g., to ɲssium cyanide, alters not only the numerical values of the potentials, but may ɲpletely change the order in which certain elements occur in the series.

ɲy metal if placed in a solution of a salt of a metal standing below it in the ɲies will tend to replace it; thus, zinc precipitates iron, copper, silver, etc., ɲm their solutions but will not displace the alkali metals from solutions of ɲir salts. Any metal standing above hydrogen will tend to displace it from ɲ acid solution with evolution of hydrogen. Metals below hydrogen in the ɲies will not dissolve in acid by a simple replacement of hydrogen. From ɲchemical standpoint the adoption of the hydrogen electrode as a standard ɲs the advantage over the calomel standard that it divides the metals into ɲo groups according to their behavior towards acids.

The approximate electromotive force of a battery consisting of two metals ɲpping into normal solutions of their respective salts may also be computed ɲ once from the table by taking the difference of the two corresponding elec- ɲode potentials. Thus a zinc-copper cell should have an electromotive force ɲual approximately to $E_{Zn-Cu} = (e_h)_{Zn} - (e_h)_{Cu} = -0.76 - 0.34 = 1.10$, the ɲe of potential being from the zinc to the copper in the cell. As a matter of ɲct, this combination, the Daniell cell, has an electromotive force of approxi- ɲately 1.10 volts. Other conclusions to be drawn from t. ' table will be pointed ɲut below.

ELECTROMOTIVE FORCE AND HEAT OF REACTION. — The ɲlectromotive force of a reversible cell maintained at constant temperature may ɲe readily calculated from the first and second law of thermodynamics (*see Thermodynamics*). By a "reversible" cell is meant a cell which does not polarize ɲnd which operates under conditions such that changes which take place within ɲhe cell constitute a thermodynamically reversible process. (*See Thermody- ɲamics, Principles of.*) The discussion given below also applies, with a rough ɲegree of approximation, to most commercial cells, which, as a rule, are not ɲstrictly reversible.

Gibbs-Helmholtz Equation. — In the case of a reversible cell, such, for ɲxample, as the Daniell cell,* shown in Fig. 1, the relation between the heat of ɲeaction (H) and the electromotive force (E) of the cell is calculated as follows.

* The special construction of this cell renders it reversible.

Digitized by Google

From Faraday's Laws, the quantity of electricity which must flow the cell in order to deposit or liberate one gram-ion at either electrod coulombs, where n is the valency of the ion of highest valency involve chemical reaction and F is the electrochemical constant (*see above*). Hence, the external work done by the cell (when there is no other external work than electrical work) is nFE joules, where E is the e.m.f. of the cell. If the cell is kept at the same temperature (T degrees, absolute scale) as the surrounding bodies, then the external work nFE done by the cell is the maximum external work it can do at this temperature T (*see Thermodynamics, Principles of*). Hence, from equation (8) of the article on thermodynamics,

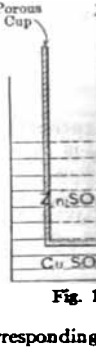

Fig. 1

$$nFE = H' + nFT\frac{dE}{dT},$$

or

$$E = \frac{H'}{nF} + T\frac{dE}{dT},$$

where H' = the heat of reaction, in joules per gram-ion, corresponding chemical change which takes place.* H' gives the change in intrinsic corresponding to the chemical changes which take place within the cell can be found by an independent calorimetric measurement, by caus reaction to take place under such conditions (*constant volume*) that hea only form of energy produced.

Temperature Coefficient of Electromotive Force. — Fro above equation it follows that the energy developed by the cell is equal heat energy of the chemical reaction taking place within it plus a certai quantity of energy equal to $nFT\,dE/dT$. This may be either positive o tive, according as the temperature coefficient of electromotive force dE plus or minus, i.e., according as the electromotive force of the cell incre decreases with the temperature. If the electromotive force on open increases with the temperature of the cell, then on closed circuit the c tend to cool, i.e., its temperature will fall, and its electromotive force w wise decrease, the energy $nFT\,dE/dT$ being derived from the heat within the cell (or surroundings). If the electromotive force on open decreases with increasing temperature of the cell, then on closed circuit will tend to heat up, i.e., its temperature will rise and its electromotiv will decrease. A cell for which dE/dT is other than zero can work at co temperature only by absorbing heat from or giving out heat to some sur ing body.

Only for the unique conditions that $dE/dT = 0$, or that $T = 0$, i.e. the electromotive force is independent of the temperature or the cell wo temperatures approaching absolute zero, is $E = H'/nF$. By a curious it happens that the first of these conditions practically obtains in the the Daniell cell considered above. The electromotive force of the cell is independent of the temperature. Its observed value is $E = 1.10$ volts, its value computed by the above equation, putting $dE/dT = 0$, is 1.09 v

Thomson's Rule. — In computing the electromotive force of a b from heats of reaction it is usually necessary to content oneself with

* Since 1 large mean calorie (Ostwald calorie) = 4 18.6 joules and $F = 96,54$ may be written, putting H = heat of reaction in large mean calories,

ELECTROLYTIC DECOMPOSITION. — Faraday's laws en to determine the amount of the substances primarily liberated or dep the electrodes of any electrolytic cell, but they do not enable one to p nature of the secondary chemical actions which may take place. (S *on Secondary Reactions.*) The factors which determine what product formed in any given case are numerous. The chemical process occ the cathode is always of the nature of a reduction; at the anode, of an o these terms being used in their most general sense. It may be that trolyte, taken as a whole, undergoes no change, as is the case, for exam copper-sulphate solution when electrolyzed between copper electrode the chemical reaction at the cathode is the exact reverse of that at th Generally, however, this is not the case; different chemical prod usually formed at the two electrodes, and appear either in the form o as a solid precipitate, or remain dissolved in the electrolyte.

Decomposition Voltage of Electrolytes. — When a gradually in difference of potential is applied to the electrodes of an electrolytic trolysis does not in general begin at once but only after a certain electromotive force is reached, even though the cell has no open-circ It should be noted that this condition does not apply to the case electrodes are such that the electrolyte as a whole undergoes no cha result of electrolysis. Thus, in the electrolysis of a zinc-sulphate between zinc electrodes an exceedingly small electromotive force is to maintain a steady current through it indefinitely (assuming t centration changes at the electrodes are completely eliminated by Although, in this case, electrolysis starts at once, the electrolyte as a not decomposed, for as much zinc dissolves at the anode as is deposit cathode. If a platinum anode be substituted for the zinc anode so result of electrolysis zinc is separated at the cathode and oxygen gas is at the anode, an e.m.f. of 2.35 volts is required to start the electrolysis. if the electrolyte is an aqueous solution of sulphuric acid it requires a m voltage of 1.67 volts to liberate oxygen and hydrogen gas against smoo num electrodes. The minimum voltage necessary to decompose a co electrolytically is called its "decomposition voltage." It is influenc variety of factors and conditions which will now be considered.

Measurement of Decomposition Voltage. — Decomposition volta been experimentally determined in several ways. Certain investigat taken the value necessary to produce visible electrolysis as the criterion; others have followed the polarization at the electrodes until it became constant and assumed this value as that at which electrolysis begins. Results obtained by the so-called ammeter-voltmeter method must be accepted with caution. In this method the value of the electromotive force applied to the cell is gradually increased from zero and plotted as abscissas and the corresponding currents through the cell plotted as ordinates. The resulting curves have the general form shown in Fig. 2.

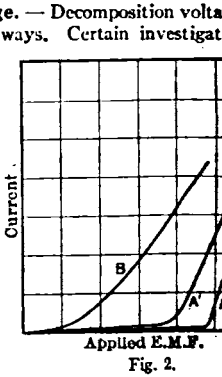

Fig. 2.

The slope of these current-voltage curves depends upon the internal resistance of the cell, the size and the distance apart of electrodes. The critical at which the current suddenly increases in value is, however, quite

a few instances, one usually employs Thomson's rule, which gives a fair mation in the case of most commercial processes, even though these are not strictly reversible. That is, calling H the heat of formatio compound which is decomposed from the substances which are liberate electrodes (i.e., H is the heat of the reverse reaction correspondi complete chemical actions which take place in the cell), the decon voltage is

$$E = \frac{H}{230.5\,n},$$

where n = the valency of the ion of highest valency involved in the r and H is expressed in large mean calories per gram-molecule.

Tables giving the voltages required to liberate a number of eleme radicals from various electrolytes computed by Thomson's rule fro of formation in dilute solutions are given by J. W. Richards in *Jour. lin Institute*, 1906.

Example. — In the formation of one mol of solid lead chlori metallic lead and chlorine gas 828 large mean calories are liberate valency of lead is 2; of chlorine, 1. As solid lead chloride does not electricity appreciably at ordinary temperatures, to decompose it ele cally, it must be either dissolved or fused. If a saturated solution co an excess of solid lead chloride be electrolyzed, metallic lead will be d at the cathode, chlorine gas liberated at the anode, and an equivalent of solid lead chloride will pass into solution, the net result then bei composition of solid lead chloride into its elements lead and chlorine. these conditions the decomposition voltage by Thomson's rule is

$$E = \frac{828}{230.5 \times 2} = 1.79 \text{ volts},$$

as against 1.612 volts by actual measurement.

It should be pointed out that Nernst has recently applied his new heat (*see above*) to the calculation of the e.m.f. of cells similar to the abo very satisfactory results. Thus the computed value of the e.m.f. in th case from thermal data by the formula developed by Nernst is $E = 1.59$ in excellent agreement with the observed value. See Nernst's *Th Chemistry*.

Calculation of Decomposition Voltage from Electrode Potent Le Blanc was the first to measure by means of a normal electrode th potential drop at the cathode when various salts were electrolyzed an that the cathodic drop in potential necessary to discharge a given c numerically equal to the electrode potential which would be establishe separated metal were substituted for the actual cathode. For exam deposit metallic zinc from a normal zinc-sulphate solution it is nece impress a potential from solution to electrode as measured against a hydrogen electrode of at least 0.76 volt, to overcome the natural rise of p from the zinc electrode to the solution (as measured by the normal h electrode) of this amount. See table page 460.

Before continuous electrolysis can begin, however, not only must the e.m.f. be sufficient to establish the necessary cathodic drop e_c, but in a it must also raise the anode potential to a value e_a, corresponding to t trode potential of the anion which is liberated. If, as is usually the case, different anions are present in the electrolyte that one will be liberat which can part with its negative charge with the least expenditure of i.e., at the lowest voltage. It frequently happens that e_c is establish

Digitized by Google

here e_a is reached, in which case Le Blanc found that e_c remains constant ile the impressed voltage E (and hence e_a) is increased up to the decom-ition point. The minimum e.m.f. at which decomposition of a given trolyte begins may therefore be written $E = e_c + e_a$ where e_c and e_a the cathodic and anodic polarization values produced by that cation and ion respectively which gives up its charge most readily. In an electrolyte taining several different anions and cations all take part in the *conduction* a current through the solution, but only specific ions are effective in elec-lysis, i.e., in giving up their charges to the electrodes.

Overvoltage. — When a gas is evolved at either electrode the above ations are usually more complicated owing to the phenomenon known as over-tage. Thus in the electrolysis of an acid between polished platinum or er metal electrodes, hydrogen gas is evolved, to liberate which the cathode ential must be raised to a value in excess of that required to liberate drogen at a reversible (platinum black) electrode.

The excess of voltage which is necessary to liberate a gas at any electrode r that required to liberate the same gas against a *reversible* gas electrode is ed "overvoltage." Its value depends upon the character of the material the electrode against which the gas is set free and upon the nature of the gas. s particularly large in the case of hydrogen. In Table VI are given values the overvoltage for hydrogen as determined by Caspari when this gas is *visibly* free. The magnitude of the effect is closely related to the power of the al surface to occlude the gas in question. Thus, platinum and (to a less ent) iron absorb hydrogen readily and hence these metals exhibit slight rvoltage phenomena. Zinc and mercury, on the other hand, have little or tendency to absorb hydrogen and hence this gas is liberated with great diffi-ty against cathodes of these metals, with correspondingly high overvoltages. For discussion of overvoltage phenomenon, see Möller, *Ann. d. Physik*, 27, 566, 08; Crabtree, *Trans. Faraday Soc.*, Vol. 9, 125, 1913; Bennett and Thompson, c. *Am. Elec. Chem. Soc.*, 29, 269, 1916; MacInnes, *Am. Chem. J.* XLI, 194, 09.

Electrolytic Separation of Metals. — The reason that two or more tals can be electrolytically separated from each other by a regulation of oltage follows from the preceding discussion. Consider a solution con-ining two salts, say silver and copper nitrates, each of normal concentration. a gradually increasing e.m.f. be applied to inert electrodes dipping into this olution, electrolysis will begin when a voltage is reached sufficient to set free

Digitized by Google

simultaneously any anions and cations present in the solution. Re
Table IV, it will be seen that copper stands 0.80 − 0.34 = 0.46 v
silver in the electrochemical series, and hence, the latter metal can be
from the solution with e.m.f. nearly half a volt less than copper. N
ions can separate until the applied e.m.f. has been increased 0.46 v
that necessary to first separate the silver. The decomposition e.m.f.
will, of course, depend on the nature and concentration of the anion
As electrolysis proceeds, the solution becomes weaker and weaker wit
to silver ions and the voltage necessary to separate them from the
increases. If the electrolysis is continued until the silver remaining i
has a concentration only 1/1,000,000 that at the start (the limit of
determinations), the change in voltage will be approximately 0.35
section above on Variation of Electrode Potentials with Concentration).
still insufficient to bring the applied e.m.f. up to a value sufficient
the copper to deposit, and hence, silver and copper may be complete
practical purposes, separated from each other.

It is to be noted that as the electrolysis proceeds and the silver is
from the solution a greater and greater percentage of the current is
by the copper. The solution in the neighborhood of the cathode
continually weaker with respect to silver ions. In a quiet electrolysis
ions at the cathode are replenished by diffusion from the interior of
trolyte. This process may be greatly accelerated by violently sti
solution, as, for example, by the use of a rapidly rotating electrode.
mits good deposits being obtained with higher current density an
reduces the time required for the separation.

Secondary Reactions. — In the preceding sections the principle
lying *primary* electrolysis have been explained. The ultimate produ
are produced at the anode and cathode are often quite different from t
ions or ionic complexes liberated by the action of the current. In ge
primary process of discharge of ions at cathode and anode is follo
secondary reaction of one of the following types:

1. The discharged ions form molecules, e.g.:

   At cathode $2\,H = H_2$ gas,
   At cathode $x\,Cu = Cu_x$ solid,
   At anode $2\,Cl = Cl_2$ gas.

   This may occur at both anode and cathode.

2. The discharged ions react with each other or break up, e.g :

   At anode $2\,OH = H_2O + \frac{1}{2}\,O_2$,
   At anode $\begin{matrix} COO \\ | \\ COO \end{matrix} = 2\,CO_2$,
   At anode $2\,CH_3COO = 2\,CO_2 + C_2H_6$.

   This is very characteristic at the anode, particularly of organic anic

3. The discharged ions react with the solvent, e.g.:

   At cathode $Na + H_2O = NaOH + \frac{1}{2}\,H_2$,
   At anode $SO_4 + H_2O = H_2SO_4 + \frac{1}{2}\,O_2$.

4. The discharged ions react with the solute, e.g.:

   At cathode $8\,H + 2\,H_2SO_4 = H_2S + 5\,H_2O$,
   At cathode $K + KAg(CN)_2 = Ag + 2\,KCN$.

5. Discharged ions react with the electrode, e.g.:

   At cathode $4\,H + PbO_2 = Pb + 2\,H_2O$,
   At anode $2\,Cl + Cu = CuCl_2$.

Digitized by Google

Which of the above reactions is most likely to occur in any given case depends some extent upon, (a) current density; (b) temperature; (c) concentration the solution.

In general, it may be said that at the cathode a reduction takes place, while the anode oxidation (in its general sense) occurs. The intensity of these tions depends upon the electrode potential at which the reaction takes ce. This can be varied by the use of different electrode materials (thereby easing the overvoltage). The efficiency of certain secondary reactions has been found to depend upon the nature of the electrode (catalytic action). e efficacy of electrolytic reduction and oxidation in organic chemistry where e intensity of the reaction must be carefully regulated likewise rests on the ese factors.

Passivity. — A metal is said to assume the "passive" state when it comports lf towards acids like a noble metal, i.e., becomes insoluble. Iron affords a ry striking example of this phenomenon, although it is exhibited by other tals as well. Thus, if dipped in strong nitric acid, or if anodically polarized, becomes passive. Several explanations have been advanced to account for the nomenon, one being that it is due to an invisible film of oxide on the surface, d another that the surface assumes a condition in virtue of which the velocity f reaction between it and the surrounding solution is infinitely slow. For mmé of theories see *Trans. Am. Elec. Chem. Soc.*, *29*, 217, 1916.

Alternating-current Electrolysis. — The decomposition of an electrolyte, d the solution of metal electrodes by electrolysis, can be effected under certain nditions by an alternating current as well as by a direct current. The chief termining factors are the velocity with which the chemical reaction takes ce and the periodicity of the alternating current.

THEORY OF SOLUTIONS. — To understand the theory of the various nomena described above, a knowledge of the theory of solutions is necessary.

Osmotic Pressure. — The present theory is based upon Van't Hoff's thermodynamic and experimental investigations published in 1887. When a substance is brought into contact with a second substance in which it is more or less luble, it dissolves in virtue of a force (the nature of which is imperfectly derstood), which is called its "solution tension" or "solution pressure." If the solute is present in excess, the process of solution continues until the lution becomes saturated, i.e., until equilibrium is established between the lute and solution, such that the solution pressure of the former is just balanced by an opposing pressure created within the solution which tends to cause the dissolved substance to separate out. This pressure is called the osmotic pressure of the solution. Under these conditions there are just as many molecules of solute passing into solution as separate out of the solution during any interval of time. A clearer conception of the osmotic pressure of a solution, as above defined, may be obtained from the following considerations.

Semi-permeable Membranes. — If a solution be placed at the bottom of a cylinder and carefully covered with a layer of pure solvent, the process of diffusion will begin at once and continue until a homogeneous dilute solution is formed. If the experiment be repeated with the single modification, that the pure solvent is separated from the solution by a piston consisting of a semi-permeable diaphragm which will permit the solvent to pass freely through it in either direction, but which will not allow the solute to pass through, the process of diffusion will take place as before, provided the piston is movable. Thus the piston will be forced back by the osmotic pressure of the solution while the solvent passes freely through it thereby diluting the solution. Membranes possessing the property of semi-permeability are not only theoretically con-

Digitized by Google

ceivable but may actually be prepared. Such a membrane is forme precipitate of copper ferrocyanide deposited within the walls of an porous cell when copper sulphate and potassium ferrocyanide solu allowed to diffuse into the cell from within and without respective membrane is permeable to water, but impermeable to sugar and ma organic and inorganic substances, such as the copper and potassium s which it is formed. Most membranes, in fact, possess the property permeability to a limited degree.

Measurement of Osmotic Pressure. — To prevent the pisto forced up by the diffusing solution, a downward pressure P must be a it equal to that exerted upon it from below by the solution. The m of P is, therefore, a measure of the osmotic pressure of the solution. experimental difficulties, it is impracticable to measure osmotic pre precisely the manner just described, but by slightly modifying the arra of the apparatus it may readily be done. Thus, if the solution is con a closed vessel, A, Fig. 3, the walls of which are made semi-permeabl positing a membrane of copper ferrocyanide within the pores of the cell, and this be immersed in the solvent B, the osmotic pressure will be exerted as before against the membrane from within. If the latter could stretch like a rubber balloon, it would do so as the solution became diluted; being, however, restrained by the material of the walls of the cell on and in which it is deposited from doing this, dilution of the solution can take place only by the solvent passing through the fixed membrane into the solution cell. This it will do unless the cell A is hermetically sealed. If an open manometer M of small bore be inserted in the top of A, the solvent as it passes into the cell will cause the solution to rise gradually in M until the hydrostatic pressure thus produced prevents further entrance of solvent. When equilibrium is established, the hydrostatic pressure gives a measure of the osmotic pressure of the solution then existing in the cell. As the entrance of an appreciable amount of solvent into the cell reduces the concentration of the solution, the pressure thus measured is less than that of the original solution; hence for quantitative work an open mano replaced by a closed mercury manometer.

Laws of Osmotic Pressure in Non-electrolytic Solutions. — By ratus similar in principle to that just described the following laws ha verified. They hold for dilute aqueous solutions of many organic sul such as sugar, and for many solutions in organic solvents, all of which po common property of being non-electrolytes.

1. The osmotic pressure of a solution is directly proportional to its tration (and therefore inversely proportional to the volume in which mass of the solute is dissolved).

2. It is directly proportional to the absolute temperature.

3. It is independent of the nature of the solute, being a function the number of mols of substance dissolved in unit volume of solution.

4. The numerical magnitude of the osmotic pressure p of one mo substance dissolved in a volume v of solution at the absolute temperat identical with the gaseous pressure exerted by one mol of a perfect ga temperature T and occupying the same volume v.

The gas laws are therefore not only directly applicable to solutions, numerical value of the gas constant R is the same for each. Thus the o laws of Boyle and Gay-Lussac for gases have the same form for solutions,

$$pv = RT,$$

Digitized by Google

re p = the osmotic pressure, v = the volume of the solution containing one l of solute, and T = the absolute temperature.

The accompanying le gives the numeri- value of $\overline{R}$ when the ious quantities are ex- ssed in the units des- ated. In heat units

$$\overline{R} = 1.985 \frac{\text{calories}}{\text{deg. cent.}}.$$

Abs. pressure p	Volume v	Abs. temp. T	Gas constant $\overline{R}$
Atmospheres	Liters	Deg. cent.	0.0821
Grams per sq. cm.	Cu. cm.	Deg. cent.	84,800
Dynes per sq. cm.	Cu. cm.	Deg. cent.	0.83161×10^8

When applied to con- trated solutions of non-electrolytes the above laws suffer deviations analo- us to those which they exhibit when applied to highly compressed gases.

Osmotic Pressure in Electrolytic Solutions. — The first of the above laws r non-electrolytic solutions applies to electrolytic solutions only within nar- limits, while the third and fourth laws fail absolutely. The osmotic pres- e of this class of solutions is much greater than the equation $pv = \overline{R}T$ would ad one to expect. Thus, a 0.1 normal sodium chloride solution has an motic pressure 1.9 times as great as that which it should have on the basis of above formula. A potassium sulphate solution containing 0.1 gram-equiva- lent per liter has an osmotic pressure 2.3 times as great as that calculated. o bring these results within the scope of the gas-law formula, Van't Hoff mposed the empirical equation $pv = i\overline{R}T$, where i is a constant having the alue unity for non-electrolytes and a value greater than unity for electrolytes.

THE DISSOCIATION THEORY. — Arrhenius, in 1887, gave the first atisfactory explanation of the anomalous behavior of electrolytes, which show ot only abnormally high osmotic pressures, but also abnormally high boiling points and abnormally low vapor pressures and freezing points. On thermo- dynamic principles these phenomena can all be shown to be proportional to the total number of molecular complexes per unit volume and entirely independent of their chemical constitution. Abnormally high osmotic pressures may there- fore be explained on the assumption that each molecule, when dissolved, exists in a more or less dissociated condition, i.e., at any given instant there are in the solution more discrete particles or complexes than there would be if each mole- cule remained continuously intact. The ions are not supposed to be per- manently separated, but a continuous process of dissociation and combination is assumed to be going on all the time. If the further assumption be made that the dissolved substance is electrolytically active only during that fraction of time while it exists in a dissociated or ionized state, in other words, that dis- sociated molecules are alone capable of being acted upon by electric forces, the connection between electrolytes and solutions showing deviations from the gas laws is explained.

On the assumptions of this theory, sodium chloride, NaCl, in aqueous solution is partially dissociated or ionized according to the equation, $NaCl \rightleftarrows \overset{+}{Na} + \overset{-}{Cl}$, and therefore at any instant there are present in the solution not only sodium- chloride molecules, but also positively charged sodium ions and an equal number of negatively charged chlorine ions, the number of which at any instant depends upon the average fraction of a second during which the molecules are dis- sociated or "ionized." If the salt were "completely, i.e., 100 per cent ionized" there would be no molecules, as such, present in the solution, but instead twice the number of ions as there were molecules originally dissolved. Hence the osmotic pressure of such a solution would be twice as great as that calculated

Digitized by Google

from the equation $pv = RT$; in equation $pv = iRT$, i would be equ
Again, if a given volume of solution contains one mol of potassium
K_2SO_4, which is 75 per cent ionized according to the equation
$K_2SO_4 \rightleftarrows 2K^+ + SO_4^=$, then at any instant there will be $1 - 0.75 = 0.25$ mol
molecules, 0.75 mol of $SO_4^=$ ions, and $2 \times 0.75 = 1.50$ mol of K^+ ions p
the solution, or $0.25 + 0.75 + 1.50 = 2.5$ molecular complexes for ever
sulphate dissolved; hence $i = 2.5$.

Although the nature of the ions resulting from the ionization of aci
and salts is now known to be more complicated in many cases than ass
such simple ionization reactions as the above, owing to their hydration
tion with molecules of the solvent, still the above hypothesis of Arrhe
proved the most fruitful conception which has been introduced into c
during the last thirty-five years and it remains to-day, modified in the
recent research, the best working hypothesis with which to interpret ele
phenomena in aqueous solutions. It is a natural sequel to the free io
of Clausius which in turn displaced the old chain theory of Grotthuss.

THEORY OF ELECTROLYTIC CONDUCTION. — The extern
of a current flowing through an electrolyte cannot be distinguished fr
produced by a current of the same strength conducted by a metal. T
magnetic effect of a current flowing through a helical glass tube fil
electrolyte is the same as that produced by the same current flowing
an equivalent circuit of an equal number of turns of copper wire. A
may be induced in a closed ring of electrolyte just as in a ring of metal.
Law and Joule's Law hold for conduction in electrolytes as well as in
The mechanism of the conduction in the two cases, however, is very d
as shown by the phenomena produced at the junction of two conductor
of which the conduction is metallic or "electronic" and in the other of
is electrolytic or "ionic."

Migration of Ions. — Electrical conduction, both metallic and elec
is believed to be a convection phenomenon. In the case of electroly
duction there is much evidence to indicate that the convection consist
transport of electrically charged ions through the electrolyte, both w
against the direction in which the current is assumed to flow. Simul
convection of anions and cations in opposite directions may not only
visible to the eye but their velocities may also be directly measured.
assumption that the ions are the carriers of charges, the motion of whi
stitutes the current, the "velocity of migration" can also be calculat
conductivity measurements and the experimentally determined "t
ratios" (*see below*).

Velocity of Migration. — In Table VII are given the results o
measurements of the migration velocity of various ions and also the ca
velocities, both expressed in centimeters per second and for a potential
of one volt per centimeter.

The velocities are directly proportional to the potential gradient. T
increase rapidly with the temperature. They vary but slightly with t
centration of the solution if the concentration is not too great, and fo
solutions may be regarded as practically constant.

From the table it is seen that hydrogen migrates with the maximum
Hydroxyl OH^- has the next greatest velocity. The high velocity of the h
ion explains the fact that aqueous solutions of the mineral acids are as
the best electrolytic conductors, and the high velocity of the hydro
accounts for the relatively good conductivity of the inorganic bases.

able VIII contains the generally accepted values of the transport ratios for more common ions. These numbers vary but slightly with the temature. They tend to approach the value 0.5 with increasing temperature, as the temperature rises both ions of a given electrolyte tend to conduct al per cents of the current. With increasing dilution the transport ratios good electrolytes approach constant limiting values; these are practically ned in solutions whose concentration is 0.01 gram-equivalent per liter.

lation between Velocity of Migration and Transport Ratios. — On the mption that the ions are the carriers of the charges the motion of which stitutes the electric current, and on the further assumption that the moving s do not carry along with them different quantities of the solvent, the ratio the velocity u_a of the anions to the velocity u_c of the cations in any ition must be equal to the ratio of the transport ratios $n_a = c/(a+c)$ and $= a/(a+c)$ of the anions and cations respectively, i.e.,

$$\frac{u_a}{u_c} = \frac{n_a}{n_c} = \frac{c}{a}.$$

e transport ratios n_a and n_c may be determined experimentally as described ve and by the use of this relation the *relative* velocities of migration may compared with the ratio calculated from the direct determination of the ities u_a and u_c. See Washburn's *Principles of Physical Chemistry*.

Hydration or Solvation of Ions. — The above relation between the ities of migration and the transport ratios has been found to hold y approximately in a number of instances. The probable explanation this lack of agreement between theory and experiment is that the nges in concentration at the two electrodes are due not only to the migra- n velocities of the ions, but also to the fact that the ions carry along with ain molecules of the solvent, the amount of solvent carried by the anions d cations being different. This "hydration" or "solvation" of the ions has ently been proved by direct eriment (*Washburn, Zeit. für ys. Chem., Vol. 66, p. 513,*). by adding to the solution an ifferent substance upon which e electric current produces no igratory effect (e.g., sugar or ifinose). See also Lewis, J., *Am. em. Soc., Vol. 32, p. 862, 1910.*

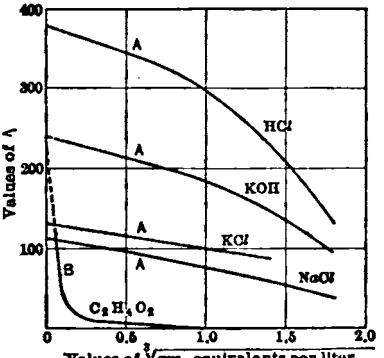

Fig. 4.

Conductance of Electrolytes. — (*See also article on Resistance and Conductance.*) While no simple relations have been found to hold between the *specific* conductances of different electrolytic solutions, very important results follow at once from a comparison of their *equivalent* conductances.

Table IX shows the relation between the equivalent conductance Λ and the concentration m in gram-equivalents per liter for some typical aqueous solutions. In Fig. 4 certain of these data are shown graphically. From a study of these results the following important conclusions may be drawn.

1. The Equivalent Conductance of a Solution Increases Dilution of the Solution Increases and Approaches a Limiting M Value. — The maximum equivalent conductance, usually denoted by Λ is different for different solutions. It may be found graphically for g trolytes (giving curves of the form A, Fig. 4), by extrapolating the curv senting the observed data until it cuts the ordinate of zero concer This method fails however for weak electrolytes such as acetic acid, see C

2. Independent Migration of Ions. Ionic Mobilities. — Th uct of the equivalent conductance of any solution at infinite dilution the transport ratio of either of the ions forming the electrolyte is a for that ion and independent of the nature of the electrolyte. That is n_a and n_c the transport ratios of the anions and cations respectively, the $l_a = n_a\Lambda_\infty$ is a constant irrespective of the nature of the electrolyte this anion forms a part; similarly $l_c = n_c\Lambda_\infty$ is a constant for the cat spective of the nature of the electrolyte of which it forms a part. For e the product $n_c\Lambda_\infty$ for the potassium ion is a constant whether the sol one of potassium chloride, potassium bromide, potassium sulphate, etc. constants l_a and l_c are called the "mobilities" or "ionic conductivities ions. This relation was discovered by F. Kohlrausch in 1876 and state law of the independent migration of ions.

light of the dissociation theory is simple. On this theory, the value o
determined by three factors, any one of which, if zero, will make $\Lambda_\phi = 0$.
are:

1. The fraction of the total number of molecules in one gram-equiv
the solute which are dissociated at any instant. This fraction, called t
gree of ionization" or "ionization coefficient," is usually denoted by
subscript ϕ indicating the dilution to which it refers.

2. The average velocities with which the ions migrate while free. Let
u_a be these velocities, in centimeters per second, for the cations and
respectively, for a potential gradient of one volt per centimeter.

3. The charge carried by the ions. This is fixed, since one equivalent
of every ion carries with it $F = 96{,}540$ coulombs.

If a volume ϕ of the solution containing one gram-equiv. of the so
imagined placed between two parallel plate electrodes 1 cm. apart,
e.m.f. of one volt be applied, the quantity of electricity conducted acr
electrolyte in one second, i.e., the current, will be equal to the equivale
ductance Λ_ϕ (definition of Λ_ϕ). The current is also equal to the total q
of electricity conducted by the cations plus that conducted by the anions

$$\Lambda_\phi = \gamma_\phi F u_a + \gamma_\phi F u_c = \gamma_\phi F (u_a + u_c).$$

The experimental fact that for many electrolytes at infinite dilution
equal to the sum of two constants l_a and l_c (the mobilities of the ions
depend only on the nature of the ions, indicates that the velocity of mi
u_a or u_c of any given ion depends only upon the nature of the ion a
upon the electrolyte of which it forms a part, and that the degree of ion
at infinite dilution is the same for all such solutions; there is much evid
indicate that this is practically 100 per cent (*see below*).

Degree of Ionization. — The fact that Λ_ϕ increases with the
may be due either to the velocities u_a and u_c or to γ_ϕ increasing w
dilution, or to both causes combined; F is a constant. In concentrate
tions both the velocities and the degree of ionization undoubtedly decr
the concentration increases. For dilute solutions, however, there is consi
evidence to show that the frictional resistance opposed to the motion of t
changes but slightly with increasing dilution, and hence the values of the
tion velocities in such solutions may be regarded as nearly constant.
be assumed, and also that the *nature* of the ions remains unchanged, i.
u_c and u_a at the dilution ϕ are practically the same as at infinite d
$\phi = \infty$, then the observed increase in Λ_ϕ with the dilution must be du
increase in γ_ϕ. On these assumptions, the solute becomes more and mo
ized as the dilution increases, and at infinitely great dilution all the mole
the solute are continuously dissociated or ionized, i.e., as ϕ approaches i
γ approaches unity.

Hence for $\phi = \infty$, $\Lambda_\infty = F (u_c + u_a)$, and therefore

$$\frac{\Lambda_\phi}{\Lambda_\infty} = \frac{\gamma_\phi F (u_c + u_a)}{F (u_c + u_a)} = \gamma_\phi.$$

This relation affords the simplest way of determining the coefficient of
tion γ_ϕ of an electrolyte, namely, finding the ratio of its equivalent co
ance at dilution ϕ to its maximum conductance at infinite dilution. T
assumptions mentioned above should not be lost sight of when applyi
formula. In general, the viscosity of the solution must be corrected for
at great dilutions. See Washburn and Clark, *Jour. Am. Chem. Soc.*, 38

dicates that 1 gram-equivalent of $H_2SO_4 = \frac{1}{2}$ mol.

f Migration of Ions. — From a knowledge of velocity of migration may be easily computed iation theory. Thus for aqueous solutions at onization may be assumed complete, $l_c = Fu_c$ $u_a = \frac{l_a}{F}$. From Table X we have for the chlorine ion $l_{Cl} = 65.5$; therefore the velocity per centimeter with which these ions migrate $\frac{\text{cm.}}{\text{sec.}}$ and $\frac{65.5}{96,540} = 0.000677 \frac{\text{cm.}}{\text{sec.}}$ respectively. ionization must be taken into account. The tained in this way. For the relation of veloc- henomena see Nernst's *Theoretical Chemistry*.

on Degree of Ionization. — It has been on of a solution has relatively little effect on migrate, except at high concentrations. Hence nt conductance with the dilution ϕ, see *Fig. 4*, change in the degree of ionization. It can be t the ionization coefficient γ of a binary elec- ution ϕ or concentration η according to the

$$= K \quad \text{or} \quad \frac{\eta\gamma^2}{1-\gamma} = K,$$

"the equilibrium constant of the ionization ture and pressure. This formula, known as exactly only for weak electrolytes, i.e., those organic acids, and which give rise to dilution or good electrolytes, giving curves of the type A wholly satisfactory explanation for this given. *(See discussion in address by James*

Walker, British Association Meeting, 1911. Also G. N. Lewis, Zeit. f. Chem., 70, 216, 1910.) Instead of obeying the above law, curves of the satisfy an exponential equation of the form

$$\frac{(\eta\gamma)^n}{\eta(1-\gamma)} = \text{constant},$$

in which n is a constant depending upon the electrolyte and having between 1.40 and 1.56. Other "dilution laws" have also been prop Kohlrausch, Van't Hoff, Rudolphi, Kraus, Bray, and Bates.

Effect of Temperature on Ionization. — The per cent to whic stance is ionized in solution may increase or decrease with the temp The sign and magnitude of the effect depend upon whether the io reaction is accompanied by an absorption or evolution of heat. Sul which dissociate with evolution of heat become less ionized with in temperature; substances which dissociate with absorption of heat becor ionized with rising temperature. Highly dissociated substances like chloride, hydrochloric acid, etc., belong to the former class. Water very slightly ionized belongs to the latter class. In general a variation perature from 0° to 100° C. produces a change in ionization of only a cent. Recent investigations by Noyes carried out at temperatures up to have confirmed these predictions of theory. The effect of temperatu may be computed through its effect on K by means of Van't Hoff's dynamic relation

$$\frac{d \log K}{dt} = \frac{Q}{RT^2},$$

where K is the above equilibrium constant of the ionization reaction, Q t of the corresponding reaction, R the gas constant and T the absolute te ture to which the values of K and Q refer. For derivation of this equa Nernst's *Theoretical Chemistry*.

Negative Temperature Coefficients of Electrical Conductivity. fact that certain electrolytes, e.g., a phosphoric-acid solution, may negative temperature coefficient is readily explained in terms of the relations. If the increase in the velocity of migration of the ions wit temperature is more than offset by a diminution in the average number ions, resulting from a decrease in ionization, the conductivity of the solut diminish. By combining solutions having positive and negative temp coefficients in suitable proportions, electrolytes have been prepared whi nearly a zero temperature coefficient over quite a range of temperatur following mixture, proposed by Manganini, has this property: 121 gran nite, 41 grams boracic acid, 0.06 gram potassium chloride dissolved in s water to make one liter. Its specific conductance at 18° C. is $\kappa =$ Such a solution is well adapted for a liquid resistance just as manganine adapted for resistance coils.

Conductivity of Fused Electrolytes. — In Table XII are given the conductance (κ) and the equivalent conductance (Λ) of several typica salts at their respective melting points; also for comparison the equ conductance of these salts in infinitely dilute aqueous solutions at 18° will be seen that the values of the specific conductance (κ) of the salts respective melting points are much greater than the values of the conductance of the same salts in normal aqueous solutions. On th hand, if the volume ϕ occupied by one gram-equivalent of the salts fused state is determined by specific gravity measurements and the equ conductance Λ computed ($\Lambda = \phi\kappa$), it will be seen that these values

) the maximum equivalent conductance Λ_∞ of the same salt in aqueous tions. Thus the conducting power of one equivalent of fused sodium te at 305° C. is less than when the same weight of salt is dissolved in one ure liters of water.

LE XII. — SPECIFIC AND EQUIVALENT CONDUCTANCE OF TYPICAL FUSED SALTS AT THEIR MELTING POINTS

Salt	Temperature, melting point, °C.	Specific conductance, κ	Equivalent conductance, Λ	Λ_∞ at 18° C. in aqueous solution
KNO_3	305	0.9510	42.15	105.2

NO_3	215	0.3676	18.09	109.3

lectrical conduction in fusions is wholly electrolytic it is probable that it ermined by the same three factors which determine the conductance of tions, and that the equivalent conductance may be expressed by an equa- of the general form

$$\Lambda = \gamma F (u_c + u_a).$$

yet, however, all attempts to measure the velocity with which ions migrate used salts have led to no satisfactory or conclusive results. Hittorf's transnce ratios cannot be determined as in solutions, since in a pure fused salt ncentration differences do not occur at the electrodes. Only indirect estimates the value of γ have been possible. The evidence thus far obtained, however, nts to a high rather than to a low state of ionization in molten salts. For a mé of the present status of this question see Goodwin, *Trans. Am. Electroem. Soc., 1912.*

The equivalent conductance of fused salts increases in general from 1 to 1½ r cent per degree centigrade. As the increase has been found in a number of es to be almost identical with the increase in the fluidity of one equivalent ight of the fused mass, it is probable that the velocity of migration of the ions reases in this proportion. The ionization of fused salts is certainly not a ict of temperature, as in the case of gases; there is evidence, in fact, that ionization of some fused salts may decrease with increasing temperature as does in their aqueous solutions.

THEORY OF CONTACT POTENTIALS. — In the case of liquid-liquid actions and metal-liquid junctions a satisfactory theory, based on the dissociation theory and the theory of solutions, has been worked out.

Theory of Liquid-liquid Potentials. — Nernst (*Zeit. für Phys. Chem., 4, 129, 1889*) was the first to show that in the case of electrolytes a difference potential necessarily arises between two solutions in contact which gradually nishes, until the solutions are completely mixed. The general theory, rked out by Planck (*Ann. der Physik, Vol. 40, page 561, 1890*) is complicated. leads, however, to simple formulæ in the following special cases.

Case I. — The junction is between two dilute solutions of the *same solute at different concentrations* c_1 and c_2, both ions of the solute having the valency n:

for example, c_1-HCl — c_2-HCl or c_1-$ZnSO_4$ — c_2-$ZnSO_4$. The potential tween solutions 1 and 2 is given by the equation

$$e = \frac{RT}{nF}\frac{l_c - l_a}{l_c + l_a}\log_e \frac{c_1}{c_2}$$
$$= \frac{0.000198}{n} T \frac{l_c - l_a}{l_c + l_a} \log_{10} \frac{c_1}{c_2} \text{ volts},$$

where R = the gas constant; T = absolute temperature; F = the Far 96,540 coulombs; n = valence of ions; l_c and l_a the mobilities of the and anions, respectively; and c_1 and c_2 the concentrations (or, more the corresponding osmotic pressures) of the ions in the two solutions respe

It follows from this formula that the potential at a liquid junction app zero if the electrolyte is composed of two ions which migrate with near velocities, and increases as the difference in their velocities increases. K^+ and Cl^- ions have nearly identical mobilities, and hence between any lutions of potassium chloride there exists only a very small potential dif For a concentration ratio of 10 to 1 the potential difference at 18° C. 0.0004 volt. This theory also explains why liquid-liquid potentials ar est between acids or between alkali solutions, for hydrogen and hydro possess relatively great mobilities.

Case II. — The liquid junction is between solutions of two *different* each containing two ions of the same valence n and at the *same concer* Here again the process of diffusion gives rise to potential difference solution 1 and solution 2, the value of which may be computed by the

$$e = \frac{RT}{nF}\log_e \frac{l_{c_2} + l_{a_1}}{l_{c_1} + l_{a_2}}$$
$$= \frac{0.000198\ T}{n} \log_{10} \frac{l_{c_2} + l_{a_1}}{l_{c_1} + l_{a_2}} \text{ volts},$$

where l_{c_1}, l_{a_1} and l_{c_2}, l_{a_2} are the mobilities or migration velocities of the and anions in the two solutions respectively. The above formulæ as the general formula for mixed electrolytes have been satisfactorily veri experiment.

For most recent work see *Trans. Faraday Soc. Vol. 8, p. 86, 1912.*

Theory of Metal-liquid Potentials. — By extending the concep the process of solution of solids in liquids to the case of metals, which p solution only as positively charged ions, Nernst (*Zeit. f. Phys. Chem., 1889*) developed an osmotic theory of metal-liquid potentials. This to all kinds of electrodes which are reversible in the thermodynamic se which from an experimental standpoint are non-polarizable. For a reversible electrodes Nernst has shown that the potential from metal to may be expressed by the relation

$$e = \frac{RT}{nF}\log_e \frac{P_M}{p}$$
$$= \frac{0.000198}{n} T \log_{10} \frac{P_M}{p} \text{ volts},$$

where again R is the gas constant, T the absolute temperature, n the val the metal ions, F the Faraday, p the partial osmotic pressure of the met present in the solution and P_M an integration constant characteristic fo metal, which depends upon the temperature and solvent, but is independ the nature of the solute.

Digitized by Google

Electrolytic Solution Pressure. — The constant P_M in the above for- la is called the "electrolytic solution pressure of the metal M." Since $e = 0$ n $P_M = p$, the electrolytic solution pressure P_M is sometimes regarded as al to the osmotic pressure of the metal ions which would be just sufficient to ent the metal electrode from dissolving or passing into the ionic form, in ch case there would be no development of a potential difference at the metal- id junction due to this cause. Hence the numerical value of P_M for a given al and solvent may be considered as a measure of the tendency for the metal ssolve in the solvent, i.e., to pass from the metallic to the ionic form. Thus alkali and alkali-earth metals, which pass readily into the form of ions, e a very high electrolytic solution pressure, while the noble metals like gold, er and platinum have a very low solution pressure. From this point of view electrolytic solution pressure of a metal may be taken as a measure of its ce in the electrochemical series. The only method thus far proposed for luating the value of P_M is by computation from Nernst's formula for electrode tentials given above. The value to be assigned to e depends upon the experi- ital determination of the "absolute" difference in potential (*see next para- aph*) between the electrode and the solution with which it is in contact. At sent there is some question as to whether the actual difference of potential ween the electrode and solution may not be partially due to the phenome- of selective absorption of the ions, which is not taken into account in the e formula. For this reason the values of P_M frequently computed from measured electrode potentials are open to question. See Le Blanc's *Lehrbuch Elektrochemie, pages 230–235;* Lehfeld, *Phil. Mag. 48, 430, 1899.*

Absolute Electrode Potentials. — On the assumption that the poten- difference between a metal and a solution is zero when the surface tension the metal is a maximum and that this condition is fulfilled in "dropping ctrodes," or may be obtained in a properly adjusted Lippmann capillary ctrometer, the absolute potential rise from the solution to the mercury in the rmal calomel electrode has been found to be $e = 0.5600 + 0.0006(t - 18°\ C.)$ lt. It is in terms of this value for the normal calomel electrode that "abso- e" electrode potentials have been expressed. On account of the uncertainty taching to the interpretation of this value it is better for the present to adopt arbitrary value zero as the potential drop at the calomel electrode.

ELECTRODYNAMOMETERS. — (*See also Ammeters; Balan rent; Wattmeters.*) One of the most reliable and accurate laborator ments for current and power measurements, particularly a-c. measu is the electrodynamometer.

This instrument depends upon the action of one circuit carrying upon another carrying the same current (*see Electricity and Magnetis ciples of*). The working parts of the instrument consist of two coils, and the other movable.

SIEMENS ELECTRODYNAMOMETER. — The simplest form o dynamometer is that devised by Siemens, shown diagrammatically i The coils are arranged at right angles to one another as shown, the he representing the fixed coil and the light lines representing the movable coil. The force of attraction or repulsion is proportional to the current in the fixed coil times the current in the moving coil, and consequently if the same current flows in the two coils, the deflection is proportional to the *square* of the current. This force is balanced by the torsion of a spring. By turning the torsion head at the top of the instrument the coils are kept at right angles. The torsional force is proportional to the angle D through which the head is turned; hence the current is

Fig. 1. Dyna

$$I = K\sqrt{D},$$

where K is a constant which is obtained by sending a known current the instrument. When arranged with separate binding posts for the or fixed coil and for the potential or swinging coil, as shown in Fig. 2, th ment may be used as a wattmeter for either direct-current or alternating-current power measurements. The power in watts is then

$$P = K^2 R_1 D,$$

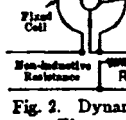

Fig. 2. Dynar Wattmet

where K has the same value as before, and R_1 is the total resistance of the potential circuit, including the coil and external resistance R. This power includes the loss in the potential circuit, which is V^2/R_1, where V is the impressed voltage; this correction is usually small.

Uses of Siemens Electrodynamometer. — The instrument may brated on direct current and may be used to measure either direct or alt current or power, since when properly designed its readings are inde of frequency and wave form. High-grade standard wattmeters suit the precise calibration of commercial indicating wattmeter or watt-hou on alternating current and non-unity power-factor circuits are made electrodynamometer principle (*see Wattmeters*).

Design of Siemens Electrodynamometer. — The movable coil is suspended by a silk thread. Attached to the coil, at the point of sus is a spiral spring, the other end of which is attached to a movabl This collar carries a pointer which moves over a scale and denotes the torsion of the spring. A second pointer is rigidly attached to the mova and registers with a fixed mark on the scale, when the fixed and mova are at right angles. The current is led in and out of the movable coil mercury cups.

Dynamometers and wattmeters for use with alternating current should little metal used in their construction as is practical, as eddy currents set up in the metal parts that will influence the coil system and change

nt of the instrument. The case and supporting frames should therefore be insulating material.

Range of Siemens Electrodynamometer. — Commercial instruments of h type for measuring currents are not suitable for measuring currents of less n 0.02 ampere. Precision wattmeters (q.v.) built on the same principle may sed to measure power of the order of 1,000,000 watts on unity power factor.

Sources of Error. — The interaction of the earth's magnetic field and the ent in the movable coil may be appreciable when the instrument is used r direct-current measurement unless the movable coil is perpendicular to the rth's field. This action may be detected by sending a direct current through e *movable coil only;* any deflection will be due to the earth's field.

When the instrument is used to measure alternating currents the earth's ld has no effect. However, eddy currents induced in the various parts of e windings or case, or in neighboring conductors, may produce a disturbing fluence. This may be tested by sending an alternating current through e *movable coil only*, the other coil being open; any deflection will be due to dy currents. The "zero" position of the pointer should also be such that ere is no mutual induction between the two coils when in the "zero" position. is can be tested by short-circuiting one coil and sending an alternating current ough the other; any deflection will be due to mutual induction.

The instrument can be used for measuring the power input to circuits of low wer factor only when the self induction of each coil and of the external so-lled "non-inductive" resistance (*see Fig. 2*) is negligible (*see Fleming, Hand-ok of the Electrical Laboratory and Testing Room*).

Degree of Precision. — When properly calibrated and properly used the adings of a good Siemens electrodynamometer may be relied upon as accurate within 1/10 per cent for a full-scale deflection. The smaller the deflection the ss the percentage accuracy.

Rowland Electrodynamometer. — This instrument is identical in principle th a Siemens electrodynamometer, except that instead of noting the angle hrough which a torsion head must be turned, the moving coil is allowed to flect and the deflection is noted by means of a telescope and scale. Its ief application is for measuring small alternating currents and small amounts f power in alternating-current circuits. It is seldom used except in special vestigations requiring a high degree of precision or for the measurement of lternating quantities of small magnitude; e.g., alternating currents of the der of 0.1 ampere or power of from 0.01 to 1 watt. Its uses are fully described Rowland's "Physical Papers," Johns Hopkins Press, Baltimore, 1902.

Irwin Astatic Electrodynamometer. — This instrument has two fixed cir-lar coaxial coils of the same diameter through which the current circulates in pposite directions, producing a field which is directed radially outward. The ovable element is suspended by a wire or silk fibre and consists of two semi-ircular coils mounted on a thin disc of mica, the current in each being in oppo-ite directions. Any effect which may be due to a non-uniform stray field is educed by the fact that the movable coils are close together.

COSTS (Pre-war prices). — A simple Siemens electrodynamometer suitable for measuring currents of from 0.025 to 5 amperes costs about $75. A Rowland electrodynamometer with shunt box costs about $450. An Irwin astatic gal-vanometer costs (in 1920) about $150.

ELECTROLYSIS OF UNDERGROUND STRUCTURES.

also Electrochemical Processes, Industrial; Electrochemistry, Principles of

following discussion will be limited to the electrolysis of underground str
that is, to the corrosion of metal work in the earth, due to the action
currents from the grounded rails of electric railroads.

The track rails of electric railways practically always form part of the
circuit feeding the cars. As these rails are either laid in the ground or on
on the ground, and as the ground is a partial conductor, some of the cur
leave the rails and flow in the ground. If pipes, lead-sheathed cables
tural foundations happen to be in the ground near the railway, part of t
current from the rails will enter these underground structures and flo
them, leaving them at some other point to return to the station bus.
current is direct, the underground structure from which current leaves
the earth, becomes the anode of an electrolytic cell, the earth containing
trolyte. This anode corrodes, due to the liberation of acids from the sa
tained in the earth. Occasionally the cathode, or underground struct
which current enters from the earth, is liable to corrosion by secondary
In the case of railways using alternating current for distribution, t
currents are usually a large proportion of the total current, but t
trolytic effects are negligible. (See J. L. R. Hayden, *Trans. A.I.E.E.*,
p. 221.)

In the case of direct-current railways, it is therefore desirable to con
current to the track rails as far as practicable. This may be done b
taining the rail bonds in a high degree of efficiency and by keeping d
voltage drop in the rails by means of insulated negative feeders, as descr
G. I. Rhodes, *Trans. A.I.E.E., Vol. 26, p. 247, 1907.*

While such means will assist materially in mitigating electrolysis t
it is often necessary to take special steps to protect underground st
without relying upon the railway companies to confine their current
rails.

MINIMUM VOLTAGE TO PRODUCE ELECTROLYSIS. conduction of current through moist ground is almost entirely elect
ordinary conduction being almost negligible. Electrolytic corrosion
whenever current flows from metal into the ground, regardless of w
difference of potential may exist between different parts of the circuit.
that current may flow, however, it is in general necessary that the diffe
potential between anode and cathode exceeds the algebraic sum of the
of combination and separation of the compounds involved in the elec
process. An iron anode in a soil containing iron salts in solution will be a
when the e.m.f. is infinitesimal.

CORROSION EFFICIENCY AND PASSIVITY. — When an current is passed through an electrolyte, the mass of the anode dissolved
calculated theoretically by Faraday's law (see index). In practice this
may be exceeded, or the reverse. The term "coefficient of corrosi
"corrosion efficiency" is used to designate the ratio of the actual to th
retical mass of the anode dissolved. The corrosion efficiency is usually l
100 per cent owing to the occurrence of secondary reactions. Thus
rosion of iron, which primarily occurs by the formation of ferrous salts,
theoretically occur at the rate of 1.045 grams per ampere-hour, but in
the rate may be anywhere from zero to forty per cent more than the the
value. In the case of iron in soil, without protection, the corrosion effic
practically independent of the temperature over a range from 0° C. to
It is also independent of the kind of iron, whether wrought iron,

Digitized by Google

machined cast iron. The efficiency is greater the lower the current density, varying from 20 to 140 per cent for a range of current densities between 5.0 and 365 milliamperes per square centimeter. It is greater with increasing moisture content up to saturation of the soil. Data on steel encased in concrete are given below, under "Protection of Steel by Concrete."

DISTRIBUTION OF EARTH CURRENTS. — The distribution of stray currents in the earth depends not only upon the resistance of the earth but also upon the resistance and distribution of the conducting structures in the earth.

Earth Resistance. — As the earth conducts electrolytically, its specific resistance can be calculated from the concentration of the salt solutions it contains. Such calculations are, however, generally useless, as, even with moderate specific conductance, the extent of the current path in the earth is so great that its resistance is very low, except near the electrodes. The effect of the electrodes is to concentrate the current streams into limited areas, thereby increasing the effective resistance of the earth. It is, therefore, obvious that the resistance of the earth depends more upon the electrode area than anything else.

The resistance of the earth is low when the electrodes consist of considerable lengths of track rails. This is particularly noticeable in the case of single phase lines, due to the skin effect and inductance of the rails. Thus J. Dalziel and J. Sayers (Inst. Civil Engineers, London, 1909) found that, on the Midland Railway, the current did not continue along the rails for any considerable length, but within a few hundred yards of the car sank gradually into the earth to re-enter the ballast at a very short distance from the power station. I. F. Parshall found that on a line eight miles long, the earth-return current was 60 per cent of the total. Probably the most exact data of this kind are those due to A. W. Copley (*Trans. A.I.E.E., Vol. 27, p. 1171, 1908*) who stated that on the New York, New Haven & Hartford Railroad, before the adoption of the three-wire system, the percentage of current in the earth was 25 per cent on the four-track sections and 60 per cent on the single-track sections.

Electrolytic Zone. — When a drop of potential occurs in a track rail, the current spreads out from it into the soil in much the same way that the leakage lines of magnetic force from a long electromagnet spread out into the air; that is, almost the entire leakage current is confined to a limited zone of the earth, the extent of this zone depending upon a complicated function of both the potential gradient and the total drop in the rails themselves. The stream lines of the current will tend to crowd into a pipe or cable sheath (on account of its low resistance) if such conductor is within this zone, but this tendency rapidly diminishes as the distance between the conductor and the rails increases. Compare with the tendency of an iron bar to become magnetized when placed in the leakage field of an electromagnet; the induced magnetization rapidly diminishes as the distance of the bar from the magnet is increased. Conductors at a comparatively short distance from the rails are, therefore, not liable to electrolysis unless the difference of potential between them and the rails is large or the leakage path of the current from the rails to the conductors is of low resistance. Thus in England, where the drop in the grounded return is limited to a total of seven volts, Messrs. Cunliffe found experimentally that the electrolytic zone is confined to within three feet of the track. The voltage drop under this rule is taken as the mean between the average and the momentary maximum values during a 15 to 30 minute period of a schedule run, at the time of maximum traffic, exclusive of exceptional occasions.

Digitized by Google

STRUCTURES AFFECTED BY CORROSION. — Stray curr
set up corrosion of the rails, rail spikes, cross-bonds, steel columns, etc.,
which they escape into the earth, and they can set up corrosion of gas a
pipes, cable sheaths, building structures, etc., which they may enter a
in their course through the earth. The protection of the former class
ials is entirely the concern of the railroad company which originates t
currents; not so with the latter class, which is often of great concer
municipalities or public-service corporations which own them. Ele
surveys should, therefore, be made with a clear understanding of whic
property is under suspicion of danger. As a rule, electrolysis is most
tive to the grounded metal of the railroads; foreign pipes, cable shea
being affected in comparatively rare instances. Of all properties foreig
railroads, the thin sheaths of telephone cables are most susceptible to ele
corrosion.

Destruction of Concrete by Electrolysis.— Some experimenters ha
that where iron imbedded in concrete becomes an anode, not only is
corroded but the concrete also is cracked. This action is due to the
stress set up by the increase of volume which the iron suffers when it
to an oxide or salt. The current has no direct effect upon the concre
anode even when sufficiently strong to liberate chlorine from the brine
impregnate it. (C. E. Magnusson, *Trans. A.I.E.E., June, 1911.*)
cathode, however, the concrete becomes softened and loses its bond
electrode. See papers by E. B. Rosa, B. McCallum and A. S. Pete
Assn. of Cement Users, 1912, and abstracted in *Eng. News, Vol. 68, p. 11*
No action, however, occurs on concrete through which current flows, e
the electrodes.

ELECTROLYTIC SURVEYS. — An electrolytic survey is an in
tion made to determine the condition of grounded metallic structures
soil in which they are imbedded and of their electrical conditions with the view of ascertaining what conditions tending to produce damage, may exist.

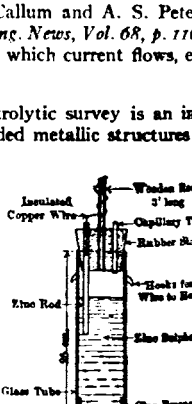

Fig. 1.

Potential Readings. — Random readings between rails and pipes give no quantitative information about electrolytic conditions. As a matter of fact, a difference of potential between a pipe and rail at any point is often greater the less the stray currents at that point. To illustrate this, we may assume a pipe to be outside the electrolytic zone and, therefore, safe from electrolytic corrosion. If, at any point, the rail is at the same potential as the pipe, the potential of the rail at every other point will differ from the pipe. Also, if the part of the rail which is at the potential of the pipe happens to be at some distance from the power
the pipe will be positive to the rail at all points between the earthe
and the power station. Hence the fact that the pipe is positive to
does not indicate that it is subject to electrolysis. A more importan
tration is the case of a pipe carrying little current itself but conne
some distant pipe which is carrying considerable current. In such a
pipe may be highly electropositive to the rails and yet be quite i
of electrolytic tendencies. These illustrations are merely specific cases

Digitized by Google

general principle that potential readings are useless unless taken with reference to the resistance of the earth between rails and conductors, which in turn depends upon the direction and distribution of the current stream lines. The potential difference between the structure tested and earth affords more complete information than can be secured from any other practicable class of observations. For this purpose, it is necessary to use a non-polarizable electrode such as that shown in Fig. 1. The zinc sulphate paste shown therein is made by adding saturated zinc sulphate solution to the zinc sulphate crystals until the mixture has attained a semi-fluid condition. The Bureau of Standards is developing improved types of electrodes.

Measurement of Leakage Current in Grounded Return System. — The columns and foundations of elevated structures and subways, rail spikes, bare negative cables and bonds are the parts most likely to be attacked electrolytically.

In the case of the elevated railways of New York City, after about nine years' operation with the steel structure a part of the return system, it was found necessary to remove all metallic connections in the Borough of Manhattan between the track rails and structure and to install negative feeder cables to compensate for the conductivity thereby sacrificed.

The corrosion of rail spikes, while happily rare, is a matter of such grave concern to the railroads and public that it should be carefully watched for. It occurs when ties are old and water-logged or when improperly treated with preservative. Timber is ordinarily classed with the non-conductors, because, when dry and well-seasoned, it has a high dielectric strength and practically infinite resistance. When green or moist, however, it becomes an electric conductor of comparatively low resistance. The resistance along the grain is much less than across it, and porous woods, such as oak, are better conductors than the non-porous woods such as pine. The conductivity of wood is due primarily to the presence in its pores of electrolytes formed from the salts found in natural timber, from preservatives and from salts originating from coal fumes or ashes. The flow of current, from the rails and spikes into the ties, fills the pores of the wood with iron salts, which add to the electrolytic conductivity and permit the leakage of more current. The effect is, therefore, cumulative, the leakage current increasing until the pores of the wood are completely saturated with electrolyte. Cases have been known where spikes were rotted more than half way through and where the rail flanges were badly corroded. Ties creosoted by the hollow-cell process, which leaves the fibers empty, are particularly likely to acquire high electrolytic conductivity. Red oak treated with zinc chloride is also a bad tie from the electrolytic point of view.

Columns of elevated railroads, subways, passenger stations, etc., are best tested for electrolytic trouble by means of a sensitive galvanometer used in the following way. Iron clamps with pointed tips are fastened to the column at points four or five feet apart, care being taken that the points penetrate the paint and make metallic contact with the steel. Wires are run from these clamps to a galvanometer and the deflection noted. The galvanometer having been calibrated, this gives the drop of potential in the column. The cross-sectional area of the column being known, its resistance may be calculated from the known resistivity of steel (usually 11 times that of copper). The potential drop, divided by the resistance, gives the flow of current in the column. Knowing the direction of flow, its amount and the efficiency of corrosion, the actual damage being done by electrolysis may be calculated as a definite weight of metal per annum. This method is being pursued with great success on the Electric Zone of the New York Central Railroad, the galvanometer employed

being a Queen & Co.'s E-8010 with tube E-8011, a calibration resist a tripod. A deflection of one scale division is equivalent to about volt. Considering an average column with a resistance of 0.000,004 a 4-foot length, a deflection of one scale division corresponds to three-f an ampere. Where the columns are to be encased in concrete, permar ing terminals should be provided, preferably in the form of small i screwed into the steel and ending flush with the concrete.

Measurement of Leakage Current in Pipes, Cable Sheaths, etc not uncommon to find potential readings taken between different sy pipes, without regard to the location of the connections, the results being as differences of potential between those systems of pipes. The poter pipe system, however, may vary from point to point, and consequer readings have no significance unless the points between which the difference is measured are specified. The significance of potential between specific points is that they afford an indication of the potent ent normal to the tracks and thereby help to determine the electroly

Making use of all possible connections to the pipe, the potential d between these points and the anode end of the grounded system s determined as described below and the limits of the "electrolytic zone tained by noting where the potential gradient in the pipe becomes n For this purpose, water hydrants and water pipes constitute the best tion points.

Potential readings between points on the same pipe line or cable sh sometimes made the basis of potential curves showing the drop in the sheath. Such potential curves may be very significant when taken fr sheaths, but are of little use for pipes on account of the variable joint r of the latter. Thus in case of a cable sheath of uniform resistance a entire length tested, where the potential curve is flat, the sheath c current; when it is a straight sloping line, the sheath carries current giving current to or taking current from the earth; where it changes current is either entering or leaving the sheath.

Hering's Method. — The current in a pipe may also be mea the following method. (*C. Hering, Trans. A.I.E.E., June, 1912.*) damental principle is as follows. Let *P*, Fig. 2, be a part of an und pipe which has been uncovered and through which an unknown current *I* is flowing. Let *D* be a sensitive galvanometer, millivoltmeter or any other suitable form of detector; there should preferably be no variable resistance like an unbonded pipe joint between the two contact points. Let *A* be an ammeter, *B* a few battery cells and *R* an adjustable resistance; the shunt circuit containing them is c as shown, anywhere outside of the points of application of the voltage the farther away the better; they may even be on the other side of a

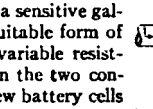

Fig. 2

To find the current flowing in the pipe adjust the resistance *R* until zero; then the current due to the battery *B* will be exactly equal and to the current in the pipe. Hence the reading of the ammeter *A* current in the pipe.

If *D* is a galvanometer with proportionate deflections, instead of a tector, then by taking a deflection immediately after the shunt circuit opened a reading proportionate to the drop of voltage for that curren obtained. The instrument *D* is thereby calibrated to read the pipe directly and can be used for this purpose thereafter; the test with th current is therefore merely of the nature of a preliminary calibration, be carried out only once for each station.

Instead of attempting to adjust the current in the shunt to bring th

The above formula is based upon the following assumptions:

(1) That the drop in the rails V is not affected by the insertion of t

(2) That the area over which the current from the pip or sheath e earth is short. For proof of formula, see *Elect. World, 1910, Vol. 35,*

MITIGATION OF ELECTROLYSIS.—Where stray currents are able, electrolysis may be mitigated by the use of drainage bonds, insul electric shielding.

Protection from Electrolysis by Drainage Bonds. — Bonds are useful for testing purposes; they may be applied permanently to re earth currents. There are certain effects, however, which may render inadvisable.

1. If one piping system is connected to the rails or bus, a difference of will be established between it and all other underground metallic struct it will, therefore, attract current from the latter and expose them to ele danger. A bonded piping system thus becomes a part of the trolle circuit and the owner may become a party to whatever damage may the other structures.

2. A considerable current in a gas pipe is a serious fire hazard and cable sheath is a menace to continuity of service.

3. Electrolysis is promoted at all imperfect joints and connections.

4. In the case of power cables, the sheath currents may be great enou unduly to the heating of the cables.

In spite of these objections bonds are very largely used to prote sheaths from corrosion. To be most effective, the sheath should be c to the negative bus by an insulated cable and the bus itself should be c to the track rails by insulated cables only.

Protection of Steel by Concrete. — The conductivity of concrete upon its porosity and wetness. Tests have shown that when wet the resistance may be as low as 20 or 30 ohms per yard cube and when dry, as 2000 ohms. When the potential gradient in the concrete around exceeds about 2 volts per centimeter, the temperature rises and the of iron is usually so rapid as to cause the concrete to crack open. At temperatures, the efficiency of corrosion of iron in concrete is low, b

number of insulating joints. It is found that where a pipe line is laid
joint insulated, the line has such a high electrical resistance that
able current flows, although considerable potential gradient may e
earth parallel to the pipe line. Insulating joints in cable sheath
found to afford an effective means of preventing electrolysis.

Protection by Shielding. — Underground structures have been
from electrolysis by connecting to the structure an auxiliary metallic
located so as to cause the current to flow to earth from the auxiliary
The shielding conductor must be so placed as to prevent the current fr
the structure to be protected, or at least, to cause its magnitude to
reduced.

Protection by Booster. — It is often proposed to render groun
work electronegative to the rail return by means of a booster, but such
are seldom carried into execution on account of the expense they inv

A scheme adopted with success at Karlsruhe, Germany, involves th
booster which does not have to carry the main current and which is
comparatively small. At places where there is danger for gas pipes
pipes, electrodes are placed in the earth in the neighborhood of the
these electrodes are connected to the positive pole of a low-voltage ge
storage battery, while the pipe to be protected is itself connected
negative pole. In this way electric current is forced to enter the pip
earth so that anodic destruction of the pipe is impossible. The power
tion is said to be insignificant. (Geppert & Liese, *Elek., Kraftb. Bahne*
1912.)

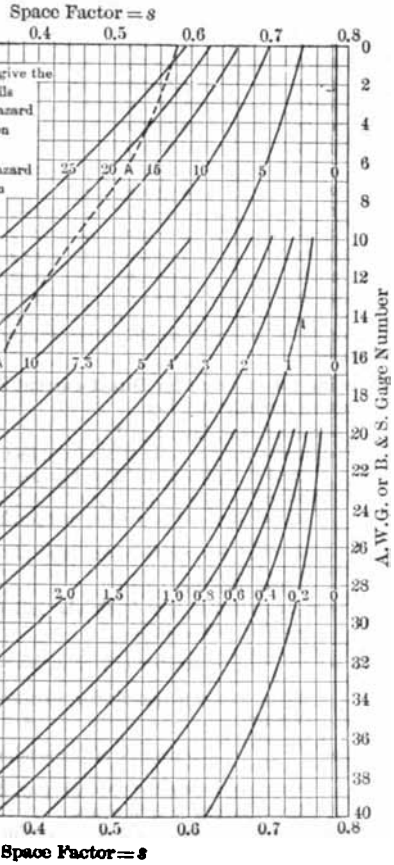
As a rough approximation a solenoid winding should be so designed t
average power developed will not exceed 0.5 watt per square inch of ra
surface for an open winding, and will not exceed 0.7 watt per square
radiating surface for an iron-clad solenoid. In figuring the radiating
of an open winding, the surface of the hole through the solenoid is not ir
and the end surfaces are included only when the solenoid is short. By t
ating surface in the case of an iron-clad solenoid is meant the surface
winding which is in contact with the iron. A radiation of 0.5 watt per
inch and 0.7 watt per square inch for an open and an iron-clad winding
tively corresponds roughly to an average temperature rise of approx
60° C.; for other rates of radiation the temperature rise will be approx
proportional to the watts per square inch radiated.

For short-time service, i.e., when the solenoid is energized only for sho
vals with long intervals between the applications of power, the thermal c
of the solenoid will permit of a greater dissipation of energy in the
without overheating it.

**Space Factors; Round Versus Square Wire; Layer Versus Hap
Windings.** — By the space factor of a winding is meant the ratio of th
occupied by the conductors to the total space occupied by the conduct
insulation on the conductors and the voids between conductors. Th
factor for strips and square wires is greater than for round wires, but s
square wires are not extensively used in small sizes because of the ir
amount of insulation required for a given section of conductor, and be
the tendency of such wires to twist in winding so that they lie upon their
instead of upon their faces. However, for conductors of larger secti
No. 10 B. & S. gauge, square wire is often used.

In winding wires larger than No. 18 B. & S. it always pays to wind the
fully in smooth layers ("layer" wound), but for smaller sizes used f
solenoids (as distinguished from iron-clad solenoids) the gain in spac
does not as a rule warrant this care and the wires are wound in a mor
haphazard fashion ("haphazard" wound). For iron-clad solenoids, h
a layer winding is always used, for economy of material requires that th
ing space be kept as small as possible. The dotted curves A and B i
for haphazard windings are taken from an article by F. A. Willard (*Ele
1906, Vol. 47, p. 823*).

Round wires are sometimes so wound that the wires of one layer li
hollows between the wires of the layer underneath; the wires in this
said to be embedded. Objections to this procedure, however, are th
layer must be started from the same end and the insulation on the wires
tightly compressed and therefore is less effective; in most instances t
labor and the diminution of insulating quality offset the small gain i
factor, which seldom exceeds 3 per cent.



The space factor s for a layer winding of round wire without embedd
making no allowance for extra insulation between layers is

$$s = \frac{\pi}{4}\left(\frac{d}{d+2t}\right)^2,$$

where d is the diameter of the conductor and t the thickness of in
Values of s for various sizes of wire and various thickness of insulation a

Winding Calculations for Direct-current Solenoids. — Round solic are assumed throughout. Let

s = space factor, from Fig. 1.

k = ratio of specific resistance of conductor used to that of standa nealed copper at 20° C. For copper of 100 per cent conduc at 20° C., $k = 1$; for copper of any other per cent conductivit C per cent, at any other temperature, say t° C.,

$$k = \frac{100}{C} + 0.004\,(t - 20).$$ See also *Wires and Cables, Bar Wires, Resistor.*

A = cross section of wire in circular mils (= square of diameter in sandths of an inch).

$n = \frac{1{,}270{,}000\,s}{A}$ = number of conductors per square inch, the squar being taken perpendicular to the direction in which the w wound.

$\rho = \frac{1{,}100{,}000\,sk}{A^2}$ = resistance of the winding per cubic inch of the wi space, excluding the space, if any, occupied by extra insulatic tween layers; ρ is in ohms.

$w = 0.271\,s + 0.040$ = weight of the winding (copper and cotton insul per cubic inch of the winding space, exclusive of the space, i occupied by extra insulation between layers; w is in pounds.*

E = impressed volts.

(NI) = ampere-turns, where N is the total number of turns and I the cu in amperes.

* This formula also holds approximately for other kinds of insulation and for alloy resistance wires. Calling g_c the specific gravity of the conductor and specific gravity of the insulation, the exact formula is

$$w = 0.0362\,(g_c - g_i)\,s + 0.0284\,g_i.$$

Underhill gives g_i as 1.6 for asbestos, 1.4 for cotton, and 1.0 for silk.

p = allowable watts per square inch of radiating surface (may be taken approximately as 0.5 for open and 0.7 for iron-clad solenoids, see above).

S = radiating surface, in square inches, calculated as described above under *Temperature Rise of Winding*.

l = mean length of turn in inches (see Fig. 2 for a simple solenoid).

T = depth of winding space in ipches (see Fig. 2), excluding the space occupied by the extra insulation, if any, between layers.

L = length of winding space in inches (see Fig. 2).

$V = LTl$ = volume of winding space in cubic inches, excluding space occupied by the extra insulation, if any, between layers.

The problem is usually to find the size of wire and necessary winding space for a coil which will give, without overheating, a required number of ampere-turns (NI) at a given impressed voltage E. The diameter of the core or spool is also usually known, or at least must not exceed certain fairly well-defined limits, depending upon the service for which it is to be used. The procedure is then to assume a reasonable value for the mean length of turn l. The size of wire is then immediately fixed by the relation

$$A = \frac{kl\,(NI)}{1.16\,E}. \tag{2}$$

From Fig. 1 the corresponding size of wire (A. W. G. or B. & S. gage) and the corresponding space factor s may then be found.

The volume V and radiating surface S of the coil must then satisfy the relation

$$\frac{LTS}{l} = \frac{k\,(NI)^2}{1{,}470{,}000\,ps}. \tag{3}$$

The length L and depth T of the winding space must be so chosen that this relation will be satisfied; as a rule this can be done only by cut and try. Note that changing the depth T of the winding space will also change the mean length of turn l, unless the diameter of the core or spool is so altered as to keep l constant. The cross section of the wire varies directly as l, as shown by equation (2), and therefore the value of the space factor s to be used in (3) will depend upon l, but only to a slight extent except in the case of very small wires.

Having determined the cross section of the wire (A), the mean length of turn l and the dimensions (L and T) of the winding space so that both (2) and (3) are satisfied, the total number of turns in the winding will be

$$N = nLT = \frac{1{,}270{,}000\,sLT}{A}, \tag{4}$$

and the current is then equal to the given number of ampere-turns divided by N and the total length of wire is equal to Nl.

The total resistance R and total weight W (including insulation) of the wire may then be found directly from a wire table, or may be calculated from the formulas

$$R = \rho V = \frac{klN}{1.16\,A} = \frac{1{,}100{,}000\,skLTl}{A^2}, \tag{5}$$

$$W = wV = (0.271\,s + 0.040)\,LTl. \tag{6}$$

See note at bottom of preceding page regarding w.

Calculation of Open Solenoid of Circular Cross Section. — case of a coil wound on a spool of diameter D, see Fig. 2, the mean le turn is $l = \pi (D + T)$. Assuming that the outside cylindrical surface of the winding is the only radiating surface, which is only approximately true, as pointed out above, $S = \pi (D + 2T)L$. Whence, putting

$$Q = \frac{k(NI)^2}{1{,}470{,}000\ ps}, \qquad (7)$$

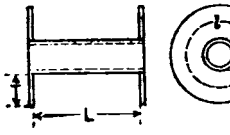

Fig. 2.

the required length of coil for a given diameter of core D and depth of w T is

$$L = \sqrt{\frac{(D+T)Q}{(D+2T)T}}.$$

When L is given instead of T, then the required depth of winding is

$$T = \frac{1}{4}\left[\left(\frac{Q}{L^2} - D\right) + \sqrt{\left(\frac{Q}{L^2} - D\right)^2 + \frac{8QD}{L^2}}\right].$$

In either case, the number of turns, total resistance, weight, etc, are fo described above for the general case.

Example. — Required to design an open solenoid 10 inches lo having an internal diameter of 1.5 inches, to give 12,000 ampere-turns volts, the heat developed not to exceed 0.5 watt per square inch of ra surface (taken as the outside cylindrical surface of the coil). Assume length of turn equal to 10 inches, then from (2) the required cross sectio wire, assuming copper at 70° C., is $A = 1130$ cir. mils. From Fig. 1 th factor is then $s = 0.62$, assuming single cotton-covered wire with 2-mil tion wound in layers. From (7) the value of Q is then $Q = 380$, when (9) the required depth of winding is $T = 2.36$ inches. The actual mean of turn is then $l = 12.1$ inches which substituted in (2) gives for the cr tion of the wire required, $A = 1368$. This wire section gives a space fac Fig. 1, of $s = 0.63$, which agrees practically with the value $s = 0.62$ used The nearest commercial size of wire is No. 19 B. & S., having a cross se 1288 cir. mils. If this size of wire is used the actual ampere-turns will b 11,300. From (4) the total number of turns will then be $N = 14{,}700$, a (5) the total resistance will be $R = 143$ ohms. The current is then amperes. The total weight of the winding is then from (6),

$$W = 60 \text{ pounds.}$$

creases again, reaching a value of about 0.6 of the maximum pull w plunger is even with the top of the coil. The approximate pull var shown in the diagram, Fig. 2; of course the actual variation is a smoot such as shown by curve *A* in Fig. 6.

Calculation of Pull of Simple Solenoid. — The calculation of the ex of such a magnet is very complicated, being dependent not only upon the turns, but also upon the shape of the coil, the size and length of the plu the induction in same. For practical purposes the maximum pull, w plunger is at least as long as the coil, can be represented by the formul

$$P_1 = \frac{cANI}{l_0} \qquad \text{pounds,}$$

where c = the pull in pounds per square inch per ampere-turn per coil length,
A = the area of the cross-section of plunger, in square inches,
I = the current in the coil, in amperes,
N = the number of turns in the coil,
l_0 = the length of the coil, in inches.

It has been found by the author that c varies between 9×10^{-6} and 10.5 when the plunger is *magnetically saturated*. For practical purposes suf close results for a *saturated* plunger are obtained if c is taken equal t The formula shows that the maximum pull for a *saturated* plunger is proportional to the current, which makes this type of magnet especially for relays and instruments which should be very sensitive. When density in the plunger is well below the knee of the *B–H* curve, the varies almost directly as the ampere-turns, and the maximum pull, th varies approximately as the square of the ampere-turns.

The pull at any point in the stroke for a *saturated* plunger may expressed by the formula

$$P_1 = \frac{10^{-6} ANI}{l_0} \cdot k \qquad \text{pounds,}$$

where k is a factor which gives the ratio of the pull at any point of the s the maximum pull; Fig. 2 gives the approximate value of k at variou of the stroke.

IRON-CLAD ELECTROMAGNET WITH FLAT-END PLUNG

The simple solenoid is a very inefficient type of magnet, because a la centage of the reluctance of the magnetic path is found in the long air path outside the coil. Therefore, the plunger magnet is modified by putting an iron return circuit around the outside of the coil, thus reducing considerably the reluctance of the path and increasing the work which can be obtained with a certain amount of power, and with a certain expenditure of energy in the coil. Fig. 3 shows this type of "iron-clad" magnet. In its highest position the plunger strikes against the frame, so that in reality the magnet represented is a special form of magnet with stop, which is described below. If it is desired to have the pull decrease towards the end of the stroke, a hole similar to the one on the lower end is drilled in the upper end of the frame, and the permitted to protrude through it.

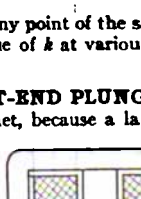

Fig. 3.

Digitized by Google

Use of Stop to Increase Pull. — The total pull on a plunger depends on the total number of flux lines which pass through it. For a given number of ampere-turns the total number of flux lines may be increased by decreasing the reluctance of the magnetic circuit. This reluctance may be still further reduced by using a ring or stop in the upper part of the solenoid of such a length that the air-gap is central to the coil for the maximum travel which is required. This form is shown in Fig. 4.

Pull of Stop on Plunger; "Air-gap Pull." — The pull P_2 between the stop and plunger may be expressed by the formula

$$P_2 = \frac{B^2 A}{72 \times 10^6} \quad \text{pounds,} \qquad (3)$$

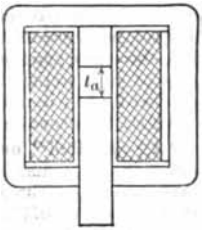

Fig. 4.

where B is the flux density in the air-gap * perpendicular to the end surface of the plunger, in lines (maxwells) per square inch, and A the area of the end of the plunger, in square inches (*see Electricity and Magnetism, Principles of*). The value of B may be calculated from the ampere-turns of the coil and the dimensions of the magnetic circuit in the same manner as the flux due to the field coils of a generator is calculated; see *Generators, Direct-current*. Or, neglecting leakage and the reluctance of the iron part of the path, B may be calculated approximately from the formula

$$B = \frac{3.19\,NI}{l_a} \quad \text{lines per sq. in.,} \qquad (4)$$

where NI is the total ampere-turns of the coil and l_a is the length of the air-gap in inches. Combining (3) and (4) gives

$$P_2 = 1.4 \times 10^{-7} A \left(\frac{NI}{l_a}\right)^2 \quad \text{pounds.} \qquad (5)$$

This pull of the stop on the plunger is usually referred to as the "air-gap pull." The actual variation of this air-gap pull with the length of the air-gap, for a particular magnet, is shown in curve *B*, Fig. 6.

Total Pull of Iron-clad Solenoid with Stop. — The total pull of the iron-clad solenoid with stop may be looked upon as due to two components, the solenoid effect P_1 given by equation (2) and the pull P_2 between stop and plunger given by equation (5); hence the total pull is

$$P = 10^{-7} ANI \left(\frac{k}{l_a} + \frac{1.4 \times 10^{-6} NI}{l_a^2}\right) \quad \text{pounds.} \qquad (6)$$

When the air-gap is short and at the center of the solenoid $k = 1$. The variation of this total pull with length of air-gap for a particular electromagnet is shown in curve *C*, Fig. 6.

IRON-CLAD SOLENOID WITH CONED PLUNGER. — It will be noted that for a given air-gap pull P_2, the ampere-turns required are directly

* Strictly, B in this formula is the actual air-gap flux density less the flux density which would be produced by the solenoid were there no iron whatever in its magnetic circuit. This correction, however, is smaller than the probable error in calculating B and may therefore be neglected.

Digitized by Google

proportional to the length of the air-gap. If, therefore, for the same length of the path for the magnetic lines through the air-gap can be the pull for the same ampere-turns will be increased, or if the pull res stant the ampere-turns to obtain it can be decreased. This is accom coning the end of the plunger, as shown in Fig. 5. For such a magnet should not be much in excess of the plunger diameter, as the leakage considerably with longer strokes, and this defeats the object of the coning. As the induction in the iron plunger is greater than the induction in the air-gap, there is a limit to the practicable value which may be given to the cone angle; this limit is about reached for cast iron for a cone angle of 28° and for cast steel for a cone angle of 19 degrees.

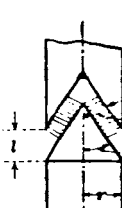

Fig. 5.

"Air-gap Pull" on Coned Plunger. — In the following it is assumed for simplicity's sake that a uniform flux at right angle to and distributed over the entire surface of the cones passes between plunger and plug. This is not strictly correct, especially for long strokes and the pull calculation is therefore only approximately correct.

Let

l = length of stroke, in inches,

A = total cross-section of plunger, in square inches, = πr^2 whe radius of the plunger, see Fig. 5,

α = angle of the cone, in degrees, see Fig. 5,

NI = total ampere-turns of coil.

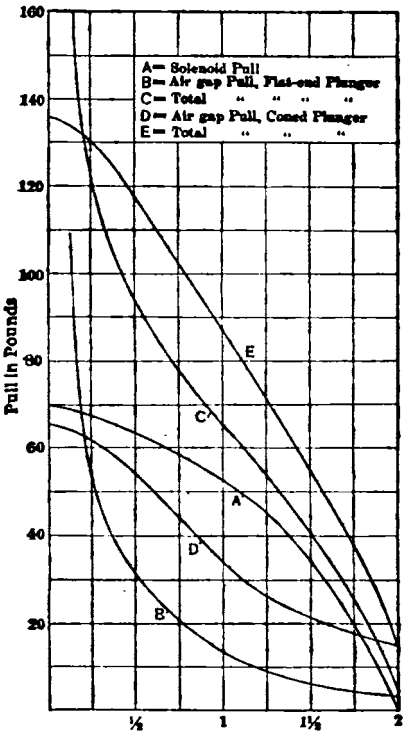
Then the flux density in the plunger is

$$B_i = \frac{3.19\,NI}{l \sin^2 \alpha} \qquad \text{lines per sq. in.}$$

and the air-gap pull in the direction of the stroke is

$$P_2 = 1.4 \times 10^{-7} A \left(\frac{NI}{l \sin \alpha}\right)^2 \qquad \text{pounds.}$$

The solenoid pull, as found by experiment, is practically the same as end plunger, equation (1). Whence the total pull on the coned plunge



$$P = 10^{-8} ANI \left(\frac{1}{l_s} + \frac{1.4 \times 10^{-8} NI}{l^2 \sin^2 \alpha}\right) \qquad \text{pounds,}$$

where l_s is the length of the solenoid winding assuming the gap at the the solenoid ($k = 1$).

Note that $l \sin \alpha = l_a$ is the "effective" length of the air-gap, i.e., th perpendicular to the surface of the cone. Hence, comparing with equa it is seen that the pull on a coned plunger for the same effective air-g same as on a flat-end plunger, but the length of the stroke is increase ratio of $\frac{1}{\sin \alpha}$. Comparing equation (7) with equation (4), it is seen advantage is gained by increasing the flux density in the plunger square of $\frac{1}{\sin \alpha}$. For small air-gaps, therefore, the coned plunger becon rated much more quickly for the same current than does the flat-end

Digitized by Google

the leakage and the reluctance of the iron part of the path produces an iable effect, causing the pull to become almost constant for small air- instead of increasing as shown by the approximate equation (9). This is clearly shown by the curves *D* and *E* in Fig. 6.

Pull Curves of D-C. Magnet. — Length of solenoid 3 inches; internal diameter of solenoid 1¾ inches; external diameter 2¾ inches; diameter of plunger 1¼ inches; angle of cone 20°; stop projects 1 inch inside coil; number of turns 300; current 57 amperes.

HORSESHOE-TYPE ELECTROMAGNETS. — Another type of electromagnet which is used quite extensively is the horseshoe-type electromagnet, shown in its simplest form in Fig. 7. This magnet is not suitable for very long strokes, because the leakage increases very rapidly with increasing distance between armature and poles. The total pull on the "armature" *K* of such a magnet, neglecting the leakage, may be expressed approximately by the relation

$$P = 2.8 \times 10^{-7} A \left(\frac{NI}{2 l_a + l'} \right)^2 \quad \text{pounds,} \qquad (10)$$

where A = cross-section of each pole, in square inches, NI = total ampere-turns, l_a = length of each air-gap in inches, and l' = length of air-gap equivalent to the

reluctance of the iron. This last depends on the permeability and di of the iron part of the circuit; calling l_1 the mean length of this iron ci μ its permeability, and assuming the mean cross-section of this path to be the same as the cross-section A of each pole, then $l' = l_1/\mu$. A more exact calculation of the pull may be made by calculating, as for a generator field (*see Generators, Direct-current*), the ampere-turns required to establish a given flux density of B lines per square inch in the gap, and then applying equation (3) to determine the pull.

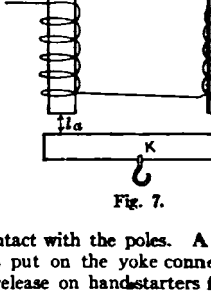


Fig. 7.

Applications of Horseshoe Type. — This type of electromagnet is frequently used where it is only desired to hold a weight after the armature has come into contact with the poles. A form of this magnet whereby the winding is put on the yoke conne two poles is used extensively as a no-voltage release on handstarters f current motors (*see Starters, Motors*).

Lifting Magnets for Handling Magnetic Materials. — Various horseshoe electromagnets are used for lifting magnetic material. F long pieces, such as pipes and rails, the magnet may be designed with a large distance between the poles, with the winding on the yoke; th usually referred to as the "bi-polar" type. For lifting shorter piece plates, slabs, billets, etc., a magnet with a relatively short distance b.e poles is better. This is readily secured by making the magnet with pole carrying the winding, with the second pole surrounding the wi central pole. Accordingly as the magnet has a rectangular or circu section it is called a "rectangular" or "concentric" magnet.

The concentric magnet is used for the greatest variety of purpos frequently referred to as a "general duty magnet." This type of especially suited for lifting pig iron, billets, skull-crackers, scrap, magnetic material of high reluctance.

In all types of lifting magnets the voids inside the coil winding a filled with impregnating material which also serves to make the magn proof.

Magnetic Disc Brakes. — A similar magnet is used for mag brakes. The magnet is usually mounted on the end plate of the moto tracts a disc-shaped armature which operates against a spring. Whe is under the influence of the spring pressure and the magnet deene presses against a series of stationary and movable discs, the latter b nected with the motor shaft, and causes friction between these par tends to retard and stop the motor. The movement of the armature disc brakes is very small, being of the order of ¼ inch.

Magnetic Clutches. — Of similar construction are magnetic In this case the magnet is mounted on the end of the shaft of the driving whereas the armature, which consists of a circular ring, mounted to means of a somewhat flexible connection, is connected with the driven When the magnet is energized the disc is attracted and takes part in tion, thereby driving the second shaft. A pair of collector rings are to convey the current from the stationary wires to the rotating magnet. case also the movement of the armature is very slight. In order to brake release quickly a non-magnetic material is often provided bet magnet and the armature which prevents sticking, due to residual mag

according to a sine curve when the current is sinusoidal. The avera
ive pull is one-half of the maximum pull. Whenever the pull is
the load, there is a tendency for the plunger to move away from the
this causes rattling or humming of the magnet. This humming may
come in different ways, one method being to use a "shading coil,"
below.

Polyphase Electromagnets. — It can be shown that if three ma
used and each is supplied with current from one phase of a three-phas
or if two magnets are used and each is supplied with current from one p
two-phase source, then the resultant pull will be constant at any mom
if the plungers are rigidly connected there will then be no chatteri
most common form of three-phase magnet is shown in Fig. 9. This
of a core having three poles and a plunger of similar construction. C
pole there is wound a coil which is supplied from one of the three
the circuit. There are various modifications of the polyphase mag
their general principle is the same. In calculating the total pull, th
each pole is figured separately and the several pulls, which are equa
another, are combined vectorially, since they differ in time phase (
nating Currents).

**Calculation of Pull of Single-phase Electromagnets, or of On
of Polyphase Electromagnets.** — The formulas for pull given above f
current electromagnets also hold for alternating-current magnets, provided I is taken as the effective value of the current, B as the effective value of the flux density and P as the average or effective value of the pull.

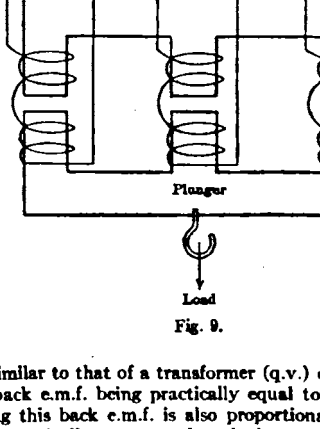

Fig. 9.

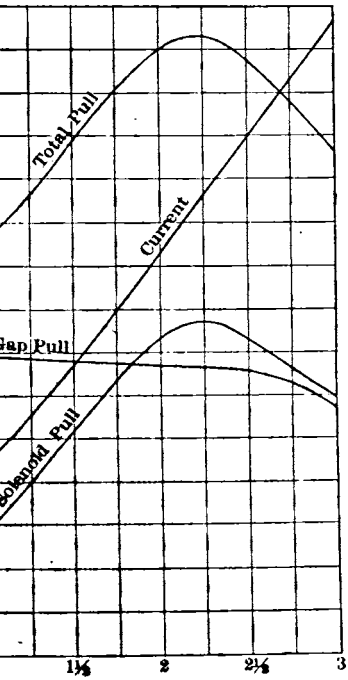
In contrast to the d-c. electromagnet, the flux in an a-c. electromagnet for a given impressed e.m.f. is approximately constant irrespective of the length of the air-gap. This is due to the fact that the opposition to the flow of current through the winding is due almost entirely to the back e.m.f., due to the alternation of the flux, and only to a very small extent to the resistance of the winding, the action in this respect being similar to that of a transformer (q.v.) tion motor (*see Motors*). The back e.m.f. being practically equal to pressed e.m.f., the flux producing this back e.m.f. is also proportion impressed e.m.f., and is therefore practically constant when the impress is constant.



Since the flux remains practically constant, the current I, as may from equation (4), must vary approximately proportionally to the leng air-gap l_a; this proportionality holds only approximately, since equa neglects the magnetic leakage and the reluctance of the iron part of the circuit. The actual variation of the current with the length of the air-g particular a-c. electromagnet is shown in Fig. 10.

Using the same notation as used above for d-c. electromagnets and in putting E = effective value of impressed voltage per phase, and f = fr of impressed voltage in cycles per second, the current taken by each

stop and plunger. It will be noted that the current is roughly proport the air-gap. The solenoid pull reaches a maximum at an air-gap of ab inches and then falls again approximately proportional to the air-gap; gap pull is constant over a wide range of the travel. The result is a t curve which has a maximum at approximately 2¼ inches and which dro an air-gap of approximately ¾ inch is reached, and from there on it i again, due to the increase of the air-gap pull, the latter being caused diminution of the leakage flux as the air-gap decreases.

Limiting Flux Density and Losses in A-C. Electromagnets. — A must be paid to the fact that the iron losses, similar to those of the tran increase with the flux density and therefore the design must be such t flux density is not too high. The flux density in the iron in the case o end plunger, from equation (4), which neglects the magnetic leaka reluctance of the iron part of the magnetic path, is

$$B = \frac{1.6 \times 10^7 E}{fNA} \quad \text{maxwells per sq. in.}$$

and in the case of a coned plunger, under the same assumptions, from e (7), is

$$B = \frac{1.6 \times 10^7 E}{fNA \sin \alpha} \quad \text{maxwells per sq. in.}$$

where α is the cone angle, see Fig. 5.

These relations are approximate only. The magnetizing componen exciting current, and from it the flux density can be more accurately ca by the methods employed in the design of transformers or induction See *Transformers* and *Motors, Polyphase Induction*.

The iron and copper losses can also be calculated by similar methods, a these losses the energy component of the exciting current can be dete The total current and power factor of the electromagnet can then be d

Shading Coil for Single-phase Electromagnets. — The humming o phase magnets may be greatly reduced by introducing a so-called " coil" in the pole face. This shading coil is nothing more than a short-c secondary winding, consisting of one or more turns, which encloses only the total flux passing through the plunger. Due to the leakage reactance of this turn, the current induced in it is out of phase with the inducing flux, so that at the moment when the inducing flux, due to the main winding, is zero, there still remains a flux due to the current in the shading coil, which flux produces a pull. The result is that the combined pull from the main flux and the shading coil flux never becomes zero. Fig. 11 shows the arrangement of the shading coil. This coil is mounted in the plunger or in the plug close to the pole face, in order to reduce the length of the path for the magnetic lines which are interlinked with the shading coil. Naturally the shading coil has no effect with long air-gaps, and it is therefore imperative that a good magnetic contact be obtained when the plunger is in the sealed position to get the greatest possible effect of the shading coil.

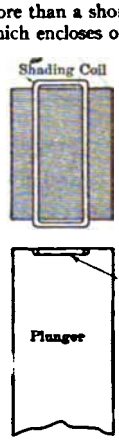

Fig. 11. Shading

Incidentally the shading coil also increases considerably the maximum pull for a given impressed e.m.f., as the maximum pull is also due to the com-

an example, a plunger magnet without shading pull of zero and a maximum pull of 28 pounds, he shading coil, a minimum pull of 18 pounds unds.

ELECTROMETERS. — (*See also Electrodynamometers; Voltmeters.*) An electrometer is primarily an instrument for measuring differences, but under certain conditions may also be used as a watt the latter case it is usually called an electrostatic wattmeter. The of the instrument is due to the attraction or repulsion of electrostati It may be used for either direct- or alternating-current measurements

There are a great variety of forms of electrometers. On account o required in its use, the ordinary quadrant electrometer is seldom except for laboratory purposes, but various modifications of the ele provided with pointer and scale so as to be direct reading are used cially for high voltage measurements. Such instruments are known static voltmeters; for description see article on *Voltmeters*.

Electrometer versus Galvanometer or Electrodynamomete advantage of the electrometer over the galvanometer or electrodynam that it takes no current when used for constant (d-c.) voltage meas Due to its electrostatic capacity, however, it does take a certain a charge which should always be allowed for if the capacity of the ele is appreciable compared with any other capacity which affects its Also, when used for a-c. measurements, the charging current take electrometer should be allowed for, if this charging current is ap This charging current is usually considerably less than would be tak electrodynamometer of the same degree of sensitiveness.

KELVIN QUADRANT ELECTROMETER (Fig. 1). — Two br rants a and a' are connected together and two quadrants b and b nected together and these respective pairs are well insulated from one another. The "needle" n (a light aluminum vane) is suspended by a silk, silvered quartz or other fiber and insulated from the quadrants.

Fig. 1. Electro

A light aluminum vane v is suspended from the needle by a fine conducting wire and dips into a conducting solution, usually 60 per cent sulphuric acid, which serves as a means of connecting the needle to any external source of p.d. or to the ground. If a conducting suspension is used this may be employed to connect the needle to the external source of potential. The sulphuric acid also keeps the air dry in the case containing the quadrants, and the motion of the vane in the acid damps the vibrations of the needle. The suspension carries a mirror m by means of which the deflectio needle may be read.

Formulas for Quadrant Electrometer. — In order to obtain a line calibration curve the needle must be properly shaped and must pended midway (vertically) between the two quadrants and must hav metrical zero position with respect to the two quadrants. Under these c when the two pairs of quadrants are charged to potentials V_a and V_b needle to the potential V_n above any fixed potential, say that of the the angular deflection is

$$D = \frac{1}{K}(V_a - V_b)\left(V_n - \frac{V_a + V_b}{2}\right),$$

where K is a factor, which is practically a constant. The value and c of the factor K should be determined by calibration.

There are three ways of using the instrument, as indicated in the

, V the p.d. to be measured, a and b the two pairs

$$V = E \pm \sqrt{E^2 - 2KD}. \quad (\textit{See footnote.})$$

$$V = \frac{KD}{E}$$

$$V = \sqrt{2KD}.$$

very small amounts of power, of the order of 1 watt, when the volt
this power is 5000 volts or more. It therefore serves as a very conveni
of measuring the power loss in small samples of insulating materia
voltages. See paper by E. H. Rayner, *Jour. Inst. Elec. Eng.*, 1912, V

The connections used by Rayner are shown in Fig. 4. R is a non
resistance. The needle of the electrometer is connected to the middl
the high-tension winding of the transformer. *On the assumption that*
ing current of the electrometer and the difference in phase between V and
neglected, the power supplied to the load is

$$P = \frac{2K}{R} D,$$

where K is the instrument constant and D the deflection. The ran
instrument as thus used depends upon the value of R, the higher R t
the amount of power which may be read.

However, the higher the value of R the greater the phase differenc
E and V if the load current is out of phase with V, and therefore for sm
measurements when the load has a low power factor *e.g.*, when it is a
an allowance must be made for this difference in phase angle. Also,
charging current of the electrometer is comparable in magnitude wit
current a correction must also be applied on this account. These c
are discussed in detail in Rayner's paper.

This action is usually spoken of as a bombardment, or collision, althou not necessary to assume that the free electron actually hits the atom.

6. When an electron is expelled from an atom the atom manifests th erties of a positively charged body.

7. In every substance there exists in addition to the electrons wi atoms a certain number of "free" electrons, i.e., electrons which can mo in the inter-atomic spaces; these free electrons may also pass from stance to another. Under certain conditions, e.g., in a gas at ordina sures, a free electron may attach to itself one or more atoms or molecul

Properties of the Positive Particle. — Experiment also justifies the ing assumptions regarding the positively charged particles:

1. The smallest positive charge that it has been found possible to pr numerically equal to that of an electron, viz., 4.9×10^{-10} c.g.s. elec units.

2. The smallest possible positive charge is always associated with a having a mass of the same order of magnitude as that of an atom, th being never less than that of a hydrogen atom.

3. The positively charged particle may be looked upon as an atom fro one or more electrons have been expelled; its mass therefore depends u nature of the atom. A "free" positively charged particle may also a itself one or more neutral atoms or molecules.

Relation between Electrons and Ions. — The term "ion" is reserved to designate any charged body having a mass of the order of ma of that of a molecule or atom. In this sense an electron is not an ion, positively charged particle is an ion. If, however, the electron becomes a to an atom or molecule, then this combination forms an ion. In the cas discharge of electricity through gases at low pressure, the electron, alth is not attached to an atom or molecule, is sometimes called an ion. *Electrochemistry, Principles of.*

APPLICATIONS OF THE ELECTRON THEORY. — All of t going conclusions have received ample experimental verification. The phe which have presented the most important evidence are the cathode ra condensation of water drops on free electrons, the emission of electro metals at high temperatures, and from certain metals under the influ ultra violet light, and the properties of radio-active substances. Fr mass of evidence it is now certain that the atoms of all substances con or more electrons; that many of the common properties of matter are with the numbers and arrangements of the electrons in the atoms; t neutral atoms may lose or gain electrons and so become charged ions; t electron may be separated from an atom and its independent existence s and that in all substances there are always present a certain number of fr trons in motion among the molecules and atoms due to their mutual c in accordance with the kinetic theory of matter; it appears probable t theory governs also the motion of the free electron.

The electron theory has led to simple explanations of many of the el and optical properties of matter, and the study of the properties of elect a number of useful applications in the field of electrical engineering. S the more striking results in both fields are briefly described in the fo paragraphs.

Electron Emission from Hot Bodies (Thermionic Discharge.) *also Radio Communication.*) When a metal is heated to a high tempera a high vacuum it gives off electrons freely. This fact was first stu Richardson. Langmuir by improvements in methods of obtaining hig

Fleming valve and kenotron. If a third electrode, in mesh or grid placed between the cathode and anode, very small potentials on the cause wide variations in the potential gradient at the surface of the and so cause wide changes in the value of the electron discharge. Th has proved of immense value as a relay for magnifying radio signals phonic speech, as exemplified in the audion and thermionic amplifi same principle is used in larger tubes for generating sustained oscilla rents for radio transmission, as exemplified in the pliotron. At pres rectifying and generating tubes are limited to small current capac *Radio Communication*) owing to difficulties of tube construction.

Cathode Rays. — When an electric discharge is passing in a vacu at a certain value of the pressure of the gas contained in the tube it i that a greenish phosphorescence occurs on the walls of the tube. B solid bodies in the tube it is found that the phosphorescence is due to s proceeding in straight lines perpendicularly from the surface of the catho name "cathode rays" has been given to this agent which produces t phorescence. These rays are deflected by both electric and magnetic f communicate a negative electric charge to an insulated conductor "rays" consist of a rapidly moving stream of electrons. The amou deflection of the rays, under the action of magnetic and electrostatic fi be calculated on the assumptions of the electron theory, and a comp the calculated with the observed deflections shows the two to be in clo ment.

The cathode rays give rise to X-rays when they strike a target obstacle. The use of a hot cathode with a focusing negative shield for r the velocities of emission has led to great improvements in X-ray tubes to further knowledge of the X-rays (see *X-rays*). In this way it is po obtain X-rays of single values of frequency and these by interference have led to important evidence as to the molecular structure of matter

Kanalstrahlen. — If the cathode of a tube producing cathode ray forated, faint luminous streaks are seen to proceed through these perfor a direction opposite to that of the cathode rays. The name "kanals has been given to this phenomenon (the German name is very generally in English). These rays are also deflected by both electric and magne but to a lesser extent and in relatively the opposite direction from the c of cathode rays, and communicate a *positive* charge to an insulated co

In terms of the electron theory these rays are positively charged *ion* culations from actual measurements, making this assumption, show charge carried by each of these ions is numerically equal to that of an and that the mass of each ion is never less than the mass of a hydrog but may be greater, depending upon the nature of the gas and the pr the tube. That is, the cathode particle is an electron traveling in one and the kanalstrahlen particle is what is left of the atom which has electron, traveling in the opposite direction.

Electrical and Thermal Conductivity. — One of the fundamental tions of the electron theory is that in conductors there are many electro are free to move about among the molecules besides those electron fixed positions of equilibrium. It is likely that these electrons are no the same ones; the molecules are probably continually gaining an electrons. It is reasonable to assume that the more free electrons (on age) in a body the better electrical conductor it is. According to th theory of matter, the molecules of all substances not at the absolut temperature are in a state of ceaseless agitation; if the assumption that the *free* electrons share in the motion of the molecules, then the n

al the more rapidly will kinetic energy be communi-
o neighboring ones, that is, the better conductor of

ey can travel before colliding with other molecules

Digitized by Google

or ions. In the case of a gas the "mean free path" is relatively lar greater the less the density.

The ions present in a gas may therefore acquire, under the action of a field, a very considerable velocity. When one of these rapidly mo comes very close to a molecule of the gas it exercises a large force of on the electrons in the molecule and may thereby expel one or more from the atom. The electric field therefore causes a large increase in ber of ions present in the gas and consequently the conductivity of largely increased.

Townsend has explained spark-over in terms of this theory. So lo current is due only to the free electrons originally present and those c collision the current for a given voltage cannot continue indefinitely. the voltage is high enough to give ionizing velocities to the positive io cumulative generation of both positive ions and negative electron giving an indefinite increase of current, i.e., a spark-over.

Efforts have also been made to explain the arc, but these are not co satisfying. The hot cathode is essential for the arc, and its tempe probably due to the bombardment of the positive ions.

Theory of the Corona. — (*See also article on Corona.*) The electr strongest at the surface of a transmission wire, and stronger the sm radius. Thus with increasing voltage, ionization sets in first at the This results in conductivity of the surrounding air or gas, causing an in the effective diameter of the wire to a point where the decreasing field is just balanced by the electric strength of the air. The law o formation on a clean round wire in air is, very closely:

$$E = 33\,\delta\left(1 + \frac{0.26}{\sqrt{\delta r}}\right),$$

where E is the surface electric intensity in kilovolts per cm., δ the relativ of the air, and r the radius of the wire in cm.

Townsend has given an explanation of the above law in terms of th of ionization by collision. Corona is a spark phenomenon. The infl the radius of the conductor is satisfactorily shown, but the explanatio influence of the density of the air depends on experiments made at very pressures and is not so clear. The law of the power loss between tran lines, due to corona, has not been explained.

The above law of corona formation is obeyed with great consta accuracy when clean round wires are used. This fact, together with th form of the law has led to the suggestion of the use of corona as a s and a means of measurement of high voltage (*Whitehead*).

Optical Phenomena. — A number of otherwise obscure optical phe are satisfactorily explained in terms of the ionization theory, on the ass that in general there exist in a given molecule one or more electrical sy electrons capable of vibrating at different frequencies. In this way it is to explain the change of refractive index with the wave length, selective tion, emission and reflection, the Zeeman effect, the Faraday effect, a optical phenomena.

MASS OF THE ELECTRON. — Since to account for the various c facts noted above it is necessary to assume that a moving electron pro magnetic field (which assumption is in accord with the experimental f a moving charged body of finite dimensions produces a magnetic field), it that the total energy of motion of an electron is

$$W = \tfrac{1}{2} m_0 v^2 + W_e.$$

oogle

presents the energy which would be required to give
it had no electric charge whatever, and W_e is the energy

g electrodes are grounded for reasons of convenience m of precipitator, for example, consists of a grounded s of which is placed a wire connected to a source of direct power.

rying the suspended liquid or solid particles which are ween the discharge and collecting electrodes. During spended matter are charged and are driven away from nd over to the collecting electrodes upon which they other gases are unaffected and pass on out of the pre-

ne most effective precipitating action is obtained when etween the electrodes is sufficient to produce a glow the discharge electrodes (*see Corona*), and when the harged negatively rather than positively.

in a precipitator depends upon the size and type of he gap distance between the discharge and collecting ature and other characteristics of the gas being treated. n between the velocity of the gases through the pre- f the path between the electrodes. In other words, the e influence of the electric field for a suitable period of tisfactory removal of these particles from the gases. depends to a considerable extent upon the character pitated. If the particles are fluffy in character, light, d, a longer time will be required than if they are rela- of a liquid or sticky nature.

on to use for collecting electrodes pipes ranging from and from 6 to 15 feet in length, and gas velocities from If the collected material is liquid in nature it will f the collecting electrodes and will drop into a suitable e purpose beneath the precipitator. In such cases the ng. If the collected material is dry or at all sticky in ary to dislodge it from the collecting electrodes by lly the cleaning is accomplished by striking or rapping ates, whereupon the material falls into hoppers placed In some cases it is also necessary to clean the dis-

Digitized by Google

charge electrodes occasionally, and when such a condition is anticipate sion is also made for rapping the framework which supports the high te discharge electrodes.

The power consumption of an electrical precipitator is governed by the of electrodes and their length, type and size, as well as by the characte the gas to be cleaned, as regards temperature, conductivity, etc. Th consumption is in no cases excessive and is usually quite small. Th consumption of energy is from 1 to 2 kilowatt-hours per 100,000 cu of gas.

Typical Installations. — The Cottrell Processes are in use for the of suspended particles from the gases given off by sintering machines, re tory furnaces, lead and copper converters and blast furnaces, drying, and calcining kilns, electric furnaces, and gas producers. They are al for cleaning the hot gases from furnaces burning pyrites or other sulphur materials in sulphuric acid manufacturing plants, and for the remova mist from the gases given off by sulphuric acid concentrators, nitratin pickling vats, etc. They have been applied also for cleaning gases f blast furnaces and the recovery from such gases of potash, manganese a valuable materials.

At Garfield, Utah, 200,000 cubic feet of gas per minute coming from converters are treated for the recovery of material containing lead bismuth, etc.

At Duluth, Minnesota, 5000 cubic feet per minute of producer gas is in a Cottrell precipitator having twenty-five collecting electrode tu 10 inches in diameter and 12 feet in length, the suspended particles of t gases being completely removed so that the gas is readily available engine use.

At the plant of the Davison Chemical Company at Baltimore, M 30,000 cubic feet of gas per minute coming from sulphuric acid concentra treated by the Cottrell processes, with the recovery of over 20 tons pe 40° Bé. sulphuric acid.

At the Washoe smelter of the Anaconda Copper Company, at An Montana, Cottrell precipitators are being installed to handle all of t going to the main smelter stack, amounting to some 3,000,000 cubic minute. The Cottrell Processes will also be used at this plant for the tion and recovery of arsenic from the flue dust recovered in the main p tion installation.

At the plant of the Security Cement and Lime Company at Hag Maryland, the gases from four cement kilns are treated, recovering mately 20 tons per day of dust containing from 8 to 10 per cent water K_2O.

At the plant of the International Smelting Company at Miami, Arizo Cottrell installations are in service collecting and recovering suspended from the gases from four Wedge roasters used as driers and from three converters.

They must insure a smooth acceleration, afford positive speed contr widely varying loads, bring the elevator quickly, but smoothly, to a from high to low speeds, regardless of load. Accurate stops at the must be made and devices should be provided to protect against sla overtravel, overloads, failure of voltage, etc. Controllers may be of magnet type, the semi-magnet type or the mechanically operated type speed passenger elevators running from about 100 to 600 feet per mi practically always installed with full-magnet controllers.

Direct-current Control Equipment. — With a direct-curren ment the car is started by moving the car switch or car-controller handl to the full on position. This releases the solenoid brake, after which t starts with full field strength and with resistance in the armature circui the motor has started, the contactors on the contactor panel automati out the dynamic brake resistance, the armature resistance and the se (if used), when the motor reaches its normal speed. Current relays current taken during the acceleration to a predetermined value. An circuit breaker is provided which opens the circuit, while running, in abnormal current would tend to flow. This overload circuit breaker is interlocked with the car switch in such a way that should the motor be by the action of the circuit breaker relay, this can be reset from the car b moving the control lever to the off position. The control equipment is arranged to give two speeds — one, a range of from rest up to the norm of the motor, secured by cutting out the armature resistance step by ste higher range, up to twice normal speed, secured by inserting resistan shunt field of the motor.

In stopping, the controller handle can be brought back to the secon giving half speed, and then to the first point, which introduces the resis series with the armature and shunts the armature with the dynam resistance which is relatively low. In this way it is possible to give a sl ing speed of about 25 per cent of the normal speed and which does not v much with the load in the car. Moving the control handle to the off stops the car. It causes the motor to be disconnected from the circui same time applying the solenoid brake, which is actuated by a spring or The coil of the dynamic brake is connected to the motor armature so t circuit is kept closed in stopping until the motor comes practically to r the braking effect of the current generated in this local circuit is avai assist the mechanical brake.

Limit switches actuated by the elevator winding drum are provided the elevator at predetermined limits of travel. In addition to these, ov switches are also ordinarily provided in the elevator hatchway as a precaution. These switches are arranged to open the control circuit travel of the car. The first-named switches are generally connected after the car has been automatically stopped at either limit of travel, it is for the operator to start the car in the reverse direction only. When th way-limit switches open, it is, however, generally impossible for the ope reverse the car without first going to the elevator machine, thus insurin tion to the cause which made it necessary for the hatchway-limit sw operate the car.

An auxiliary switch which will automatically stop the motor in case t slackens from any cause, such as the breaking of the cable or the catchin cage, is also generally provided. It is mounted on one side of the windin and operated by a cross arm extending across the drum. Should the c come slack the movement of the cross arm will serve to trip the switch, the control system and stopping the elevator. The slack-cable switch

ENDOSMOSE OR ELECTRIC OSMOSIS. — (*See also E istry, Principles of.*) If a current is passed along a film of water insulating surface, the water will be attracted to the negative Similarly an electric current flowing through a porous partition, o opening, filled with conducting liquid, causes a flow of the liquid t partition or opening. This phenomenon is known as endosmose osmosis. While various physicists have offered explanations of thi enon, none have received general acceptance.

The quantity of a given liquid which is carried through a given p phragm in a definite time varies directly with the current strength a pendent of the area and thickness of the diaphragm. The quantity the nature of the solution, being greater with liquids of high specific and high specific capacity. The direction of flow is generally from negative electrode, but under certain conditions the flow may be posite direction.

Applications of Endosmose. — Endosmose may be utilized water from wet substances. Thus if a wooden box be equipped forated metallic plates at opposite ends and be filled with wet tur rent circulated through the turf from one end to the other, wate out of the perforations of the cathode plate. Endosmose is utili ning processes to accelerate the passage of tanning fluids through and efforts are being made to utilize it for drying peat, extractin similar purposes.

Endosmose of Negative Feeders. — If electric conductors cove saturated braid or a number of such braids be made the cathode of a and say 110 volts applied between anode and cathode, the braid will few minutes and the blisters will finally burst, grounding the condu water. The same action goes on at lower voltages at a proportiona rate, but with equal certainty. No action is observable if the wire be anode instead of the cathode. The same phenomenon is said to be with rubber insulation, but the writer has tried several samples of American compounds made with 30 per cent of Para rubber and ol signs of endosmose after subjecting them for a week to a press volts. C. H. Wordingham (*Elec. Engineer, London, Vol. 26, 1900, p.* however, that certain makes of rubber insulation are porous and enter and eventually destroy the whole of the rubber on the neg ductors. For this reason insulation of low specific resistance shoul used on negative feeders. For the same reason it is not practicable t a negative contact rail on electric railways, below earth potent insulators soon become saturated with moisture and thereby be ductors. Thus S. B. Fortenbaugh, relating the experience of the ways in London, says:

1. That the difference of potential between the positive conductor is always normally considerably greater than the potential existing be negative conductor and earth.

2. That a reversal of polarity is always instantly accompanied by able increase in the normal leakage current between the positive an conductor.

3. The insulation of the negative conductor to earth cannot be i maintained.

Effect of Endosmose on Insulation Measurements. — Wh wires having insulation of low specific resistance, endosmose may fur the resistance if the wire is negative to the water bath.

EQUATIONS. — (*See also Complex Numbers; Errors of Observation; rithms; Vectors.*) The subjects treated in this article are

Quadratic Equation
Cubic Equation
Simultaneous Equations
Determinants for solving simultaneous equations
Equations of Common Curves
Differential Equations

QUADRATIC EQUATION. — The solution of

$$ax^2 + bx + c = 0$$

is $$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} = -\frac{b}{2a}\left[1 \pm \sqrt{1 - \frac{4ac}{b^2}}\right]$$

CUBIC EQUATION. — The solution of the general cubic equation form

$$ax^3 + 3bx^2 + 3cx + d = 0$$

is obtained as follows: Put

$$y = ax + b$$
$$H = b^2 - ac$$
$$G = a^2d - 3abc + 2b^3$$

then (1) becomes

$$y^3 - 3Hy + G = 0.$$

The nature of the roots of this equation depends upon the algebraic sig and the relative numerical magnitudes of G and H.

Case I. H positive and G numerically less than $2H\sqrt{H}$. (G r either positive or negative.) Put

$$\phi = \frac{1}{3}\sin^{-1}\left[\frac{G}{2H\sqrt{H}}\right]$$

then the three roots of (2) are

$$y_1 = 2\sqrt{H}\sin\phi$$
$$y_2 = 2\sqrt{H}\sin(\phi + 120)$$
$$y_3 = 2\sqrt{H}\sin(\phi - 120)$$

and all three roots are real.

Case II. H positive and G numerically greater than $2H\sqrt{H}$. Put

$$u = \frac{1}{3}\cosh^{-1}\left[\frac{\pm G}{2H\sqrt{H}}\right]$$

the plus sign to be used when G is positive, the negative sign when G is n thus making $\cosh 3u$ positive in either case.

Then the three roots of (2) are

$$y_1 = \mp 2\sqrt{H}\cosh u$$
$$y_2 = \pm\sqrt{H}\cosh u + \sqrt{-3H}\sinh u$$
$$y_3 = \pm\sqrt{H}\cosh u - \sqrt{-3H}\sinh u$$

ed when G is positive, the lower when G is negative.
e is real, the other two being complex quantities. See
tities and *Hyperbolic Functions*.

and G any value. Put

$$u = \frac{1}{3}\sinh^{-1}\left[\frac{\mp G}{2H\sqrt{-H}}\right]$$

used when G is positive, the positive sign when G is
h $3u$ positive in either case. Then the three roots of

$$= \mp 2\sqrt{-H}\sinh u$$
$$= \pm\sqrt{-H}\sinh u + \sqrt{3H}\cosh u \qquad (5)$$
$$= \pm\sqrt{-H}\sinh u - \sqrt{3H}\cosh u$$

when G is positive, the lower sign when G is negative.
is real, the other two complex quantities.
the sum of the three roots is zero. Also, in the special
the angle ϕ is 30°, and therefore from (3) the three
$-2\sqrt{H}$; this also follows from (4).

$$y^3 - 6y + 2 = 0.$$

$G = 2$ and is less than $2H\sqrt{H}$.

$$\phi = \frac{1}{3}\sin^{-1}\left[\frac{2}{4\sqrt{2}}\right] = 6.90°$$

0.3399; $y_2 = 2.2618$; $y_3 = -2.6018$.

$$y^3 - 3y + 4 = 0.$$

$G = 4$ and is greater than $2H\sqrt{H}$.

$$u = \frac{1}{3}\cosh^{-1} 2 = 0.439$$

$= 1.098 + 0.785\sqrt{-1}$; $y_3 = 1.098 - 0.785\sqrt{-1}$.

$$y^3 + 6y + 2 = 0.$$

$= -2$ and $G = 2$

$$= \frac{1}{3}\sinh^{-1}\frac{-2}{-4\sqrt{2}} = 0.1155$$

$= -0.3275$

$= 0.1638 + 2.467\sqrt{-1}$

$= 0.1638 - 2.467\sqrt{-1}$

QUATIONS. — Given n independent equations in
uations fix the values of each of the n unknowns.
nultaneous equations in x, y and z, say, solve each of

Digitized by Google

the three equations for x in terms of y and z. Equating these three for x gives two equations in y and z. Solving each of these two equat y in terms of z and equating these two values of y gives a single equat The solution of this last equation then gives the value of z. Then su this value of z in either of the equations in y and z, and solve for y substitute these values of y and z in any one of the original equations a for x.

Determinants. — In the case of linear simultaneous equations (i.e x, y and z occur only to the first power), the equations may be solved b minants. This method is a considerable time saver when the numbe knowns is greater than three, but when the number of unknowns is less the straight substitution method is preferable.

The determinant of a set of simultaneous equations is formed by the equations one below the other with the same unknown in the same position in each. The block of numbers forming the coefficients of knowns is called the determinant. For example, the determinant of th tions

$$\begin{aligned} w + x + y + z &= 6 \\ w + \quad\; y + 3z &= 4 \\ w + 2x + 3y \quad\; &= 1 \\ w + 3x + \quad\; z &= 3 \end{aligned}$$

is

$$D = \begin{vmatrix} 1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 3 \\ 1 & 2 & 3 & 0 \\ 1 & 3 & 0 & 1 \end{vmatrix}$$

The values of any one of the unknowns, say y, is found by writing a determinant, D_y, exactly like the determinant D, except that the constant ing the right-hand members of these equations are substituted for the coe of y in the determinant, that is

$$D_y = \begin{vmatrix} 1 & 1 & 6 & 1 \\ 1 & 0 & 4 & 3 \\ 1 & 2 & 1 & 0 \\ 1 & 3 & 3 & 1 \end{vmatrix}$$

Then

$$y = \frac{D_y}{D}$$

and similarly for the other unknowns.

The value of any determinant is found by making use of the followin

(1) If a determinant has two equal rows or columns, it is equal to ze

(2) To any row or column one may add or subtract any number of tin other row or column without altering the value of the determinant.

(3) To multiply any row or column by a number is the same as mult the determinant by that number.

(4) If all the terms in a row or column except one are zero, the deter reduces to one of a lower order which may be obtained by striking out t and column which intersect at the term in question, and multiplying th by that term, changing the sign of this term, however, if it is removed odd number of terms from the principal diagonal. ilateral

$kx - 1\Big]$

he length of arc

rbolic Functions.

$+\theta$).

ATIONS. — Differential equations of the following eory of alternating and transient currents.
used: $\epsilon = 2.7183 \ldots$ = base of natural system riables. A, ϕ, γ, and θ are integration constants. n constants.

$$\frac{dy}{dx} = ay. \qquad (1)$$

$$y = A\epsilon^{ax}.$$

$$\frac{dy}{dx} + ay = 0. \qquad (2)$$

$$y = A\epsilon^{-ax}.$$

$$\frac{dy}{dx} + ay = b. \qquad (3)$$

$$y = \frac{b}{a}\left[1 - A\epsilon^{-ax}\right].$$

$$\frac{d^2y}{dx^2} = -a^2y. \qquad (4)$$

$$y = A \sin (ax + \phi).$$

$$\frac{d^2y}{dx^2} = a^2y. \qquad (5)$$

$$y = A \sinh (ax + \phi).$$

Digitized by Google

$$\frac{d^2y}{dx^2} + 2u\frac{dy}{dx} + (u^2 + a^2)\,y = 0.$$

Solution:

Case I. a^2 positive: —	$y = Ae^{-ux}\sin(ax + \phi)$.
Case II. a^2 negative: —	$y = Ae^{-ux}\sinh(ax + \phi)$.
Case III. $a^2 = 0$: —	$y = A(x + \phi)\,e^{-ux}$.

$$\frac{d^2y}{dx^2} + 2u\frac{dy}{dx} + (u^2 + a^2)\,y = B\sin(\omega x + \theta).$$

The complete solution of this equation consists of the solution of N the term

$$\left(\frac{B\sin\delta}{2u\omega}\right)\sin(\omega x + \theta - \delta),$$

where

$$\delta = \tan^{-1}\frac{2u\omega}{a^2 + u^2 - \omega^2}.$$

For each additional sine term added to the right-hand member of tion, there will be a corresponding term of the same form as (a) in the

---

$$\frac{d^ny}{dx^n} + a_{n-1}\frac{d^{n-1}y}{dx^{n-1}} + \ldots a_1\frac{dy}{dx} + a_0y = B\sin(\omega x + \theta).$$

Solution:

$$y = A_1e^{m_1x} + A_2e^{m_2x} + \ldots A_ne^{m_nx} + KB\sin(\omega x + \theta + \delta),$$

where m_1, m_2, etc., are the n roots of the equation

$$m^n + a_{n-1}m^{n-1} + \ldots a_1m + a_0 = 0,$$

and K and δ are found by substituting the $KB\sin(\omega x + \theta + \delta)$ by its given differential equation and equating the coefficients of $\sin(\omega x$ - $\cos(\omega x + \theta)$ respectively on the two sides of the resulting equation the second member of the differential equation is a constant, B, the sin the solution becomes simply $\frac{B}{a_0}$.

Note that all of the preceding equations are merely special cases of th equation (8).

$$\frac{d^2y}{dx^2} + 2u\frac{dy}{dx} + (u^2 - q^2)\,y = \frac{1}{c^2}\frac{d^2y}{dx^2}.$$

The complete solution of this equation contains an infinite number of the form

$$y = e^{-(u-s)x}[A_1e^{mx}\sin(\omega x + nz + \phi_1) + A_2e^{-mx}\sin(\omega x - nz + \phi_2)]$$

where A_1, ϕ_1, A_2, ϕ_2 and two of the four constants ω, s, m and n are in constants (fixed by the terminal conditions). The values of m and n of ω and s are

$$m = c\sqrt{ab}\cos\frac{\eta + \epsilon}{2},$$

$$n = c\sqrt{ab}\sin\frac{\eta + \epsilon}{2},$$

Digitized by Google

$$\epsilon = \tan^{-1}\left(\frac{\omega}{s+q}\right),$$

$$\eta = \tan^{-1}\left(\frac{\omega}{s-q}\right).$$

s of m and n are

$$\omega = \frac{\sqrt{FG}}{c}\cos\frac{\alpha+\beta}{2},$$

$$s = \frac{\sqrt{FG}}{c}\sin\frac{\alpha+\beta}{2},$$

$$\alpha = \tan^{-1}\left(\frac{m}{n+cq}\right),$$

$$\beta = \tan^{-1}\left(\frac{m}{n-cq}\right).$$

) may also be written as a series of terms of the

$$\epsilon^{-(u-s)z}\sin(\omega x+\phi+\mu), \qquad \text{(b)}$$

$\cosh 2(nz+\gamma)+\cos 2(nz+\theta)$,

$z+\gamma)\tan(nz+\theta)$,

gration constants, and the relations between the are the same as above.

o, the solution of equation (9) is

$$[f_1(\omega x+nz)+f_2(\omega x-nz)], \qquad \text{(c)}$$

itrary functions and ω and n are connected by the

$$\frac{\omega}{n}=\frac{1}{c}.$$

$$\frac{d^2y}{dx^2}+\frac{1}{x}\frac{dy}{dx}=4a^2y. \qquad (10)$$

$$+\frac{(ax)^4}{2^2}+\frac{(ax)^6}{(3!)^2}+\frac{(ax)^8}{(4!)^2}+\ldots\Big]. \qquad \text{(a)}$$

ergent for all values of x, but for $ax>1$ the more convenient and sufficiently accurate.

$$+\frac{3^2}{2\,(16\,ax)^2}+\frac{3^2.5^2}{3!\,(16\,ax)^3}+\frac{3^2.5^2.7^2}{4!\,(16\,ax)^4}\Big]. \qquad \text{(b)}$$

Digitized by Google

ERRORS OF OBSERVATION. — When a quantity is measure possible accuracy many times in succession, the numbers expressing t are found to differ by amounts, which, although generally small, are oc considerable in comparison with the quantity measured. Though th ences may be decreased by improved methods, better instruments skill, they can never be entirely removed. They are known as the observation. The following formulas, which are derived from the Least Squares, apply to such errors and not to errors which can be e by correcting mistakes of the observer or defects of instruments or m observation. *That is, they apply only to errors which may be either negative, the chance of a positive error occurring being exactly the same as of a negative error occurring.*

Weighted Observations. — Sometimes in spite of the care with servations are taken, there are reasons for believing that some obs are better than others. In this case the observations are given "weights" or numbers expressing their relative practical worth. A observation is an observation multiplied by its weight.

PROBABLE VALUE OF SEVERAL OBSERVATIONS. — probable value of a quantity which is observed directly several ti equal care is the arithmetical mean of the measurements.

Example. — The length of a room (in feet) is measured ten t the following results:

20.05	20.06	19.98	19.99	20.00
20.07	20.01	20.05	19.95	19.98

The arithmetical mean of these lengths is 20.01 feet, which is accord probable length of the room.

The most probable value of a quantity which is observed direct times, but where the observations have different weights, is equal to t the weighted observations divided by the sum of the weights.

Example. — In the above example if the fourth and fifth obs are twice as reliable as the others, and the seventh three times as reli most probable value would be the sum of 20.05, 20.06, 19.98, (19 (20.00 × 2), 20.07, (20.01 × 3), 20.05, 19.95 and 19.98, divided by 14, equal to 20.01, which happens in this instance to agree with the un average.

PROBABLE ERROR OF ANY ONE OF SEVERAL OB TIONS. — The probable error of a number of direct observations m equal care is found by the following formula:

$$r = 0.6745 \sqrt{\frac{\Sigma v^2}{n-1}},$$

where

n = number of observations.
r = probable error of a single observation.
v = residual found by subtracting the arithmetical mean fr measurement.

Example.—In the example cited above, $n = 10$. The value the order of the observations given above are as follows:

+ 0.04	+ 0.05	− 0.03	− 0.02	− 0.01
+ 0.06	0	+ 0.04	− 0.06	− 0.03

Digitized by Google

whose probable errors are r_1 and r_2 respectively. Then the error in Z i

$$\sqrt{z_1^2 r_2^2 + z_2^2 r_1^2}.$$

Let Z be any function of the independently observed quantities z_1,
whose probable errors are r_1, r_2, r_3, etc. Then the probable error in Z i

$$\sqrt{\left(\frac{dZ}{dz_1}\right)^2 r_1^2 + \left(\frac{dZ}{dz_2}\right)^2 r_2^2 + \left(\frac{dZ}{dz_3}\right)^2 r_3^2 + \text{etc.}}$$

METHOD OF LEAST SQUARES. — A set of simultaneous
containing more equations than unknowns cannot have any exact solut
the superfluous equations are deducible from the others. They may,
have a most probable solution which is such that the sum of the errors
after corrections for the deduced values of the unknowns shall be a
This result is obtained as shown in the following example:

$$\begin{aligned} s - t + 2u &= 3, \\ 3s + 2t - 5u &= 5, \\ 4s + t + 4u &= 21, \\ -s + 3t + 3u &= 14. \end{aligned}$$

The coefficients of s are 1, 3, 4 and -1. Multiplying by these co

$$\begin{aligned} s - t + 2u &= 3, \\ 9s + 6t - 15u &= 15, \\ 16s + 4t + 16u &= 84, \\ s - 3t - 3u &= -14. \end{aligned}$$

Add these equations and obtain $27s + 6t = 88$.

The coefficients of t are -1, 2, 1 and 3. Multiply the original equ
these coefficients.

$$\begin{aligned} -s + t - 2u &= -3, \\ 6s + 4t - 10u &= 10, \\ 4s + t + 4u &= 21, \\ -3s + 9t + 9u &= 42. \end{aligned}$$

Add these equations and obtain $6s + 15t + u = 70$.

The coefficients of u are 2, -5, 4 and 3. Multiply the original
by these coefficients.

$$\begin{aligned} 2s - 2t + 4u &= 6, \\ -15s - 10t + 25u &= -25, \\ 16s + 4t + 16u &= 84, \\ -3s + 9t + 9u &= 42. \end{aligned}$$

Add these equations and obtain $t + 54u = 107$.

The equations

$$\begin{aligned} 27s + 6t &= 88, \\ 6s + 15t + u &= 70, \\ t + 54u &= 107, \end{aligned}$$

are then solved in the ordinary way, the solution being

$$s = 2.47, \quad t = 3.56, \quad \text{and} \quad u = 1.92.$$

A more complete table is given in the *Smithsonian Mathematical Tab*
Hyperbolic Functions (No. 1871), by G. F. Becker and C. E. Van Orstra
Washington, 1909. Semi-exponentials, i.e., values of $\frac{1}{2}e^x$ and $\log_{10}\frac{1}{2}e^x$,
iven in *Tables of Complex Hyperbolic and Circular Functions*, by A. E. K
elly, Cambridge, Mass., 1914.

FACTORIALS. — The multiple product represented by

$$n\,(n-1)\,(n-2)\,\ldots\,3\times 2\times 1$$

called "n factorial," and is represented either by the symbol $n!$ or $\underline{n}$. Th
llowing table gives the value of $n!$ up to $n = 10$.

$1! = 1.$	$6! = 720.$
$2! = 2.$	$7! = 5040.$
$3! = 6.$	$8! = 40320.$
$4! = 24.$	$9! = 362880.$
$5! = 120.$	$10! = 3628800.$

and Compressors; Draft, Mechanical.) For ven- nd for producing mechanical draft, two kinds of l the centrifugal fan.

reversed, that is, driven by power applied to the r in large volume at low pressure, and it is then are in common use for blowing air into or out of tilation. Usually they consist simply of a rapidly r more nearly flat blades slightly inclined to the s these blades are given various curved forms for efficiency of the fan.

older form of centrifugal fan is that of a paddle ng from four to twelve radial arms, to which are planes. In modified forms the blades are bent ference to the direction of rotation, from an axial l fans up to 25 feet diameter and 10 feet width n of mines, and in many cases without an external asing is used, with a tangential discharge outlet, inlets, concentric with the shaft, one on each side nodification of the centrifugal fan known as the n, the number of blades is increased to from 30 to made relatively very long, axially, and narrow, o width being as much as 9 to 1; they are made ge tipped forward in the direction of rotation and e casing and the radial distance of the vanes from ed. The pressure produced by centrifugal fans e of the speed of the tips of the blades and with the es a maximum commercially of about 1 pound per s of centrifugal or multivane fans. Much higher obtained from special forms of fans built on the *see Blowers and Compressors*).

-In the article on *Blowers and Compressors* is l" work done by a blowing machine. Since an a pressure of more than 1 per cent of normal atmos- n the volume and static pressure of the air as it gibly small in comparison with the initial volume a for the theoretical horse power reduces to

$$\frac{}{000}\left[\frac{dQ^3}{2g\,(60A)^2}+144\,p_s Q\right],$$

pressure at discharge over the initial static pres- square inch,

ear velocity $V_a = \frac{Q}{A}$ feet per minute to the air.

called the "velocity" pressure.

Digitized by Google

Useful or "Air Horse Power" of the fan may then be written

$$P = \frac{(p_v + p_s)\,Q}{229}.$$

The total pressure $p_v + p_s$ developed by the fan is called the "imp "dynamic" pressure. The pressures developed by a fan are usually e in inches of water column; hence putting H_v and H_s for the correspondi of water column required to balance p_v and p_s, the above formulas beco

$$H_v = 0.832 \times 10^{-4} \frac{d\,Q^2}{A^2},$$

$$P = \frac{(H_v + H_s)\,Q}{6360}.$$

When the discharge outlet is restricted (e.g., by partially closing the d valve), the cross section A refers to the area of the discharge pipe betw restriction and the fan, not to the cross section of the restricted openin

Actual Horse Power. — The actual horse power required to drive is equal to the value given by the last formula divided by the efficienc fan efficiency depends not only upon the design of the fan, but also u relative values of the velocity and static pressures. The maximum effi a centrifugal fan ranges from 40 to 70 per cent. The maximum efficienc fans usually ranges from 30 to 40 per cent. The table below, taken fro published by F. R. Still of the American Blower Co., in the *Jour. E Eng.*, 1902, is fairly representative of the performance of ordinary st centrifugal fans. For a given type of fan and given ratio of velocity within the casing on the outlet side to the static pressure, there is a fi tion between the linear velocity $V_a = \frac{Q}{A}$ of the air within the casing on let side and the peripheral velocity V_f of the fan; the ratio $\frac{V_a}{V_f}$, as ca from Still's curves, is also given in the table below.

$\frac{H_v}{H_s}$	Efficiency	$\frac{V_a}{V_f}$	$\frac{H_v}{H_s}$	Efficiency
0.00	0.00	0.00	0.4	0.38
0.05	0.30	0.22	0.5	0.37
0.10	0.43	0.30	1.0	0.32
0.15	0.43	0.35	1.5	0.30
0.20	0.42	0.39	2.0	0.28
0.30	0.41	0.42	∞	0.22

More recent fans of the multivane or "Sirocco" type, when prope portioned, have given efficiencies of 60 per cent and upwards.

THE VOLUME OF AIR DISCHARGED per minute is $Q = V_a$ V_a is the linear velocity of the air in feet per minute. When the speed constant and the outlet pipe is partially closed, the linear velocity o through the full cross section A of the outlet decreases and the power

meter. Using the latter figure, we have $D = \sqrt{3}\, A$.
able given above a rough estimate of the dimensions
may be made. For example, 20,000 cubic feet of
to be discharged against a static head of 1 inch of
approximate dimensions and speed of the fan and
te horse power required? The size of fan and the
depend upon the linear velocity of the air through
locity the smaller the fan and the greater the horse
s as defined above we have $Q = 20{,}000$, $H_s = 1$,
alue of the linear velocity V_a is 2000 feet per minute.
$= 2.74$, $H_v = 0.255$, $\frac{H_v}{H_s} = 0.255$, $\frac{V_a}{V_f} = 0.41$, $V_f =$
0.415, H.P. = 9.6. That is, the diameter of the
5 feet 6 inches, its width 2 feet 9 inches, its speed
wer will be required to operate it. If V_a is taken as
the required diameter will be approximately 3 feet
11 inches, its speed 650 r.p.m., and 20 horse power
t.
iving at the size of fan is extremely rough at best;
reader is referred to manufacturers' catalogues.

R FANS. — The following memoranda are intended
ations. See also article on *Blowers* and article on

n and service for which it is to be used. Rating,
under specified conditions of test. Whether exhaust
d. Whether fixed or oscillating. Details of motor,
quency, phases and voltage.

See also Motors, Industrial Applications of.) The
es as the speed rises and unless some sort of shutter-
ill be fully loaded when it comes up to speed. Shut-
starting conditions should be carefully considered-
r is intended for driving the fan. As the torque
usually small, a motor with low-resistance starting
out requiring a very heavy current. To keep the

current down, however, a low tap on the starting compensator mus and an intermediate step may be very desirable.

Fig. 1 shows the starting-torque curve of a shuttered centrifugal fan to full speed, and also a speed-torque and a speed-current curve of a sy motor with a squirrel-cage starting winding of fairly low resistance plotted for 50, 70 and 100 per cent of normal voltage. If the motor is started from the 50 per cent tap of the compensator it will bring the fan to about 80 per cent of full speed. If the motor is then thrown over to the full-line voltage it may exert an excessive torque, and the current, as shown by the current curve, will rise to a very high value. If an intermediate tap is provided — say a 70 per cent tap — the torque exerted will be less but still enough to bring the motor to about 95 per cent of synchronous speed and the current will be much less. Application of the field would then pull the machine into step after which it could be thrown over to the line with a very little rush of current. For a variable-speed service the synchronous motor is of course not suitable and a varying-speed brush-shifting motor or a phase-wound induction motor must be used.

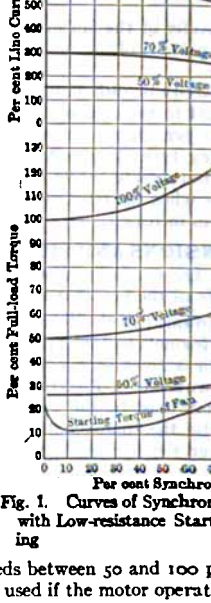

Fig. 1. Curves of Synchron with Low-resistance Start ing

For direct-current installations shunt motors are preferred, the speed adjustment being accomplished either by field control, armature control or a combination of the two. Field control is generally used where the motor operates for long intervals at speeds between 50 and 100 p maximum speed; the combination control is used if the motor operat intervals at speeds between 75 and 100 per cent of maximum speed, a sionally required to operate at speeds below 75 per cent; and armatu is used advantageously for motors operating at long intervals near but where occasionally a lower speed is required. Ventilating fans o the best applications for armature control because the torque a decreases with the cube of the speed.

With very large mine fans, having a high inertia, the time required f ation is comparatively long — one minute or more — and this must be when the starting resistances are selected. Starting resistances f driving such large fans should therefore as a rule be of a larger size t ordinarily be the case.

TERS AND PURIFIERS. — (*See also Boilers; ctric.*) Impurities in the water supplied to a boiler ion of scale on the heating surface of the boiler, re- iler efficiency and overheating and consequent weak- lates; (2) the corrosion and consequent weakening (3) an increase in the amount of suspended moisture m from boiler to engine. Sulphates of lime and silica, iron and aluminum and suspended matter are purities. Acids, organic matter, magnesium chloride sion, while priming is induced by the presence of rbonate and other alkalies.

the feed water of various chemicals, as, for example, le-forming impurities may be changed into harmless between the impurities and the "boiler compounds" dhesion of the scale to the heating surfaces may be tion into the feed water or boiler of such substances led matter, such as sand, mud, insoluble organic inated by mechanical filtration or by allowing the tanks. Organic impurities usually float on top of is making steam and may be blown out through a cipitated matter may be ejected by frequent blowing rm a crust. Scale, when it has once formed, can be the tubes with some form of scraper. Very hard be softened so as to be more easily scraped, by dis- ntity, say 50 to 100 pounds, of caustic soda in the it at atmospheric pressure for from 12 to 24 hours. nagnesia, two of the chief scale-forming impurities, ly precipitated by raising the temperature of the g point for a pressure of about 60 pounds absolute).

EHEATING FEED WATER. — Although the heat- g or settling of the feed water results in the elimina- purities, the primary object of preheating the feed l consumption. The heat required to raise the tem- ed water 11° F. is approximately 1 per cent of the nvert the water into saturated steam at ordinary y 11° F. the temperature of the feed water is raised which would otherwise be wasted, a saving of approx- e effected in the amount of coal required. Let H = the given pressure, h_0 = heat of the water entering water leaving the heater, then the saving, expressed t that would be required by a boiler without a super-

$$S = 100 \frac{h - h_0}{H - h_0}.$$

may be taken from steam tables (*see Steam*). This ing in fuel, provided the boiler efficiency is the same water heater. However, if the boiler is overdriven, ater heater will effect a greater saving than that given n the work to be done by the boiler is reduced the ncrease.

ATER HEATERS. — The heat used for preheating ived: (1) from the exhaust steam; (2) from the flue

Digitized by Google

gases, in which case the heater is usually called a "fuel economizer" live steam taken directly from the boilers, in which case the primar of the heater is to purify the feed water, and it is therefore usuall "live-steam purifier." The heat may be transmitted from the ste water either (1) by allowing the steam to mingle with the wate up its heat by condensation, or (2) by passing the water and stea separate chambers arranged so that the heat is conducted to the wat the walls of the chambers. These two types of heaters are referred tively as "open" and "closed" heaters. Closed heaters may be eit water-tube or steam-tube type; in the former the steam surround tubes through which the water is passed, while in the latter the stean through a set of tubes surrounded by water. A closed heater in steam pressure is less than atmospheric is called a "vacuum" or " heater; such heaters are frequently used in the exhaust of condensin "Atmospheric" or "secondary" heaters are those in which the stea is that corresponding to the back pressure of the engines or pumps. in which the steam pressure is the same as that in the boiler is called a " heater.

Open Heaters. — The essential parts of an open heater are: (1) a taining (2) a set of trays or pans to catch the scale-forming elen cipitated from the water; (3) a filter to take out suspended impur (4) an oil separator to extract the oil from the steam before it superheater.

Dimensions. — C. L. Hubbard (*Practical Engineer, Jan. 1, 1* the following:

Exhaust heaters should be proportioned according to the quality of to be used, the size being increased with the amount of mud or sca ing properties which the water contains, regardless of the quantity o be heated. The general proportions of an open heater will depend upon the arrangement of the trays or pans, but an approximation o of shell for a cylindrical heater is as follows: $A = H + aL$; $L = H$ which A = sectional area of shell in square feet; L = length of shell feet; H = total weight of water to be heated per hour divided by t of steam used per horse power per hour by the engine; $a = 2.15$ for ve water, 6.0 for slightly muddy water, and 8.0 for clear water.

The pan or tray surface varies according to the quality of the wate regards the amount of mud and the scale-making ingredients. Th in square feet for each 1000 pounds of water heated per hour may be follows, for the vertical and horizontal types respectively:

Very bad water	8.5 an
Medium muddy water	6 an
Clear and little scale	2 an

The space between the pans is made not less than 0.1 of the rectangular and 0.25 of the diameter for round pans. Under ordinar stances it is not customary to use more than six pans in a tier, in obtain a low velocity over each pan. The size of the storage or settling in the horizontal type varies from 0.25 to 0.4 of the volume of the shell ing on the quality of the water; 0.33 is about the average. In th vertical heaters, this varies from 0.4 to 0.6 of the volume of the shell occupy from 10 to 15 per cent of the volume of the shell in the horizo and from 15 to 20 per cent in the vertical.

Temperature Elevation of Feed Water. — Let H = tota steam in B.t.u. above 32° F. at the pressure of the steam in the hea

ter entering the heater; F = final temperature of K = ratio of weight of exhaust steam condensed ight of the feed water per hour; then, neglecting

$$= \frac{I + K(H + 32)}{1 + K}.$$

. *Hepburn, Power, April, 1902.*) Let W = pounds ft. of heating surface between steam and water; n; I = initial temperature of the water; F = final = B.t.u. transmitted per sq. ft. per hr. per deg. ween the steam and the water; then

$$= \frac{2.30\,W}{U} \log_{10} \frac{T_s - I}{T_s - F}.$$

according to the condition of the surface and with d also depends upon whether the heater is of the pe. Gebhardt gives the following values of U: ers, 250 for plain copper or brass tubes and 300 for er velocity of 50 feet per minute; for single-flow plain brass with a water velocity of 12.5 feet per eaters, 300 for copper tubes with a water velocity team-tube heaters, 120 for iron tubes.

ode number of the box, is caused to revolve, thus making
it in accordance with the code. These makes and breaks
f the relay at headquarters and by means of a local
s the alarm at headquarters. As many gongs as may be
ted by the same relay, these being placed in the engine-
or wherever else it is desired to give the alarm.

—The placing of a number of boxes on the same circuit
bility of confusion, due to two or more boxes being pulled
lled "interference." A box which makes no provision
is called an "interfering box." A common type of box,
fering box," is so arranged that if two or more boxes on
pulled at once the signal of the first box to be started
thout interference from the others, but the signals of the
smitted. In a later development, and one that is largely
is such that if any number of boxes up to four on the
ltaneously pulled, no interference and no loss of signals
box securing possession of the line in succession, the
g their turn, so that the signals of all the boxes will be
onfusion. These are called "non-interference succession

In fire departments which have a number of engine and
s, it is customary to establish a single fire-alarm head-
box circuits center. From this headquarters other cir-
circuits," extend to the apparatus houses. An alarm
rcuit may be transmitted to the gong circuits either man-

Digitized by Google

Manual Systems. — In manual systems the box alarm is received
quarters and then is set up on a transmitter, which, when started, a
cally repeats the alarm over the desired gong circuits. The manual
this operation may consist in placing a disc, notched on its periphery t
with the desired box number, in the transmitter, and then starting the
ism, the notches on the disc effecting the desired makes and break
gong circuits. This method is employed in the fire-alarm systen
Borough of Manhattan, New York.

Another manual method of transmission is to set up the desired box nu
a dial transmitter, which, when set in motion, transmits the alarm to
circuits. Still another method is to actually re-transmit the box numbe
ally by means of a Morse key.

Automatic Systems. — In these the relays at headquarters, w
operated by the box circuits, automatically perform the making and
of the gong circuits, and thus re-transmit the box alarm to the gong
This is advantageous in point of time saving, but has certain obje
features in removing all discretionary power from the operators at head

Confusion in Fire-alarm Nomenclature. — Considerable c
exists in the nomenclature of the fire-alarm art in various parts of t
try. For instance, the term "automatic system," instead of applyin
automatic re-transmission of the alarm at fire headquarters, is freque
plied to those systems where the original alarm is automatically se
the operation of a thermostat in a building under the influence of unc

FLYWHEELS FOR LOAD EQUALIZATION. — (*See also Motors, Industrial Application of; Steel Mills, Electric Drive of.*) There methods in general use for equalizing a fluctuating load, the storage and the flywheel. The former is mostly used in connection with a ce vice where the peaks are of considerable duration and for which se flywheel is entirely unsuitable. For short fluctuating loads, such as service, mine hoists, etc., the flywheel is particularly suitable, and it applied either to the driving motor direct or to an intermediate moto tor equalizing set, depending on the operating conditions.

Selection of Flywheel. — The problem of selecting a flywheel for service is not an easy one, and each case must be treated separately. Th problem is to determine what effect a flywheel will have on smoothing load fluctuations; what effect it will have on the motor and supply whether a flywheel is warranted; and what size flywheel will result in r economy.

Flywheel Effect. — The effectiveness of a flywheel, rotating at a given of revolutions per minute, in equalizing the load, depends not only weight but also upon the square of its radius of gyration (q.v.). The p the weight of a flywheel by the square of its radius of gyration is common the "flywheel effect"; it is proportional to the moment of inertia of the A factor which limits the usefulness of a given flywheel is the allowable in speed, as the energy which a flywheel is able to give up is proportion difference between the squares of the initial and final speeds. Another be considered is the fact that a flywheel is not an inexhaustible source o The time during which it can supply a certain number of horse-power i and it can, with a given drop of speed, only supply a given number power seconds. A certain flywheel, for example, may easily take care amounting to 100 per cent overload for one second, but it may be en adequate to handle a 50 per cent overload lasting for five seconds.

Induction Motor with Flywheel. — Let the motor at any instant oping a torque T, and let the opposing torque of the load at this insta

Then $T = T_1 + \frac{I}{32.2}\frac{dw}{dt}$, where I is the moment of inertia of all the r

parts and w their angular velocity. In the case of an induction motor th T is practically proportional to the slip (*see Motors, Induction*). By maki this relation and the above equation the following working formula i deduced for the change in the torque developed by an induction moto interval during which the opposing torque of the load remains constant

T_0 = torque, in pound-feet, developed by motor at a given instant.
T = torque, in pound-feet, developed by motor *t seconds later.*
T_1 = opposing torque, in pound-feet, due to the load, *assumed constan*

FREQUENCY CHANGERS.— (*See also Generators; Motor Motors.*) Frequency changers are motor-generator sets in which bot are designed for operation with alternating current, but for two d quencies, thus a 25-cycle motor may drive a 60-cycle generator. Th for three general classes of work which may be typified as follows:

(a) To supply 60-cycle current for lighting from a 25-cycle po The 60-cycle current is much more satisfactory for lighting than is current.

(b) To supply 25- or 15-cycle current for single phase railway fr 60-cycle power system.

(c) To tie together two large power stations which started indepen different frequencies and as a result of growth and changed economi or ownership, find it desirable to be able to exchange energy either of evening up the demand or to meet the emergency of an accident erators of one of them. Most of the large power stations in a given ne even when owned by different corporations, are tied together to help out in case of trouble in one of them. For this type of service it that the frequency changers be "reversible," that is, either mach the driving motor.

While several types have been proposed and discussed on pape types have attained, or are likely to attain, any great commercial These are the "Induction-synchronous" and the "Synchronous-sy types. The former is not ordinarily reversible while the latter is re

INDUCTION-SYNCHRONOUS TYPE. — An induction m connected to a synchronous alternating-current generator (either sin three-phase at either end or any combination thereof) may be d choosing a suitable relation between the number of poles on each receive power at any frequency and deliver power at any other Thus a 10-pole motor operating on a 25-cycle circuit driving a 24-pol at 300 r.p.m. will deliver approximately 60 cycles. This combinati disadvantage that an increasing load causes decreasing speed an decreasing frequency in the load circuit. This can be taken care cases by choosing a ratio of poles which will give a nominal ratio of cycles for instance, and by added resistance in the secondary of th motor, regulate the speed at all loads so that the generator gives Where the secondary system or load is an independent circuit wit generators there is no objection to allowing the frequency to vary sli the nominal value.

If there are to be two frequency changers in parallel supplying t adjustment of the division of load may be accomplished either designing the resistances of the secondary of the two induction mot they have the same slip, or by having an adjustable resistance co these secondary circuits of the motors. The great advantage of the synchronous type is that, due to the characteristics of the inductio variation of one or two per cent in the frequency of either of the two s not cause a serious overload on the set, as is the case with the sy synchronous type.

SYNCHRONOUS-SYNCHRONOUS TYPE. — This consists chronous motor driving a synchronous alternating-current gener constant speed characteristic of a synchronous motor makes it p suited as the driving motor of a frequency changer, as this insures ratio of frequencies irrespective of the load on the set.

Such sets are more generally used than any other type, particular

Digitized by Google

whose frequencies are fixed by the presence of other
considerable variation in the frequency of one system
erload on the set and may cause it to pull out of step.
ble that the capacity of the set be not too small in
of the system. The synchronous motor usually has
cage winding in its pole faces in order to assure good
duce hunting (*see Motors, Synchronous*). This type
will transfer energy either way between the systems
he reversal of the flow of energy is accomplished by
ry armatures in its cradle as described under parallel

ous-synchronous set may operate properly in parallel
rtionately with other synchronous apparatus on the
motor and generator are respectively connected, the
otor and generator must be carefully chosen. Thus
ycles per second, the highest speed which allows an
quency is 300 rev. per min., and this requires 10 poles
d 24 poles on the 60-cycle machine.
pensive sets it is frequently the custom to use a speed
4-pole machine on the 25-cycle circuit and a 10-pole
5 cycles for the other circuit. All the other machines
then operate at 62.5 cycles. Other combinations of
us combinations of frequencies can be readily calcu-
al relation between poles, speed and frequency; see
rent, and attached tables. High-speed sets with
ause they are smaller and less expensive for a given
nerator set must be provided with direct current for
n a direct-connected exciter or from a special exciter

Synchronous Sets. — The parallel operation of two
nvolves certain complicated considerations. In the
he load depends not only upon the voltage regulation
constituting a set, but upon the mechanical position
haft. Two sets built apparently the same may not
cause of inaccuracy in the placing of the key-ways,
it is customary to mount the stationary member of
ovable in a cradle, so that the angular phase position
e stationary armature) with respect to the base, may
to be operated in parallel are loaded, and the station-
ne is rotated in the cradle until the load on the two

ncy Changers. — The synchronizing of such sets is
plicated conditions must be satisfied. The theory is
ssed at length in a paper by J. B. Taylor on *Parallel*
., *Vol. 25, p. 113*, from which the attached table is
uirement is that it is necessary to synchronize not
upply circuit, but also the generator with its load
otor has been synchronized properly, it may be found
egrees out of phase with the load circuit. To bring
is necessary to cause the motor to "slip" one or more
generator comes into proper phase; this can be done
motor one or more times depending upon the number
nd on the motor. The necessity for more than one
hat with a large number of poles on both motor and

Digitized by Google

generator there are only a few combinations in which the poles of the
the generator of one set match up with the poles of motor and ge
another set. Thus with a 10-pole motor and 24-pole generator (the
mon arrangement) when the motor slips one pole or 180 electrical deg
circuit, the generator slips $\frac{5}{12} \times 180$ or 432 electrical degrees of its
is necessary to make the motor slip 5 poles or 5×180 degrees to mak
erator slip the first even multiple of 360, that is $5 \times 432 = 2160$ o
degrees. In this case it might be necessary to make the motor slip 4 p
getting the right combination. Five reversals would reproduce the ori
ditions and, after that, more reversals would repeat the cycle of pos
binations. The table shows the possible combinations for various
used sets.

In practice, this difficulty is overcome by the use of a special syn
indicator (*see Synchronizers*) having two hands on the same dial; one h
the phase relation of each member of the set with respect to its particul
circuit. It is necessary to synchronize the set when both hands are
stationary but point to the zero position. If only the motor were
synchronized it would be found that both hands were stationary,
hand pointing to zero but the generator hand pointing to some other

FREQUENCY INDICATORS. — The frequency of the current by a generator may be determined directly from its speed, N revolut minute, and number of poles p, from the formula

$$f = \frac{Np}{120}.$$

The same formula also applies to a synchronous motor, N and p being and number of poles of the motor. The speed may be measured by a r counter and stop watch or by means of a tachometer, or speed indicat latter may be calibrated to read the frequency directly for a given gen motor.

By the term Frequency Indicator or Meter is to be understood an ins the indications of which are determined directly by the frequency of t connected to its windings, as distinguished from an electrical Tacho Speed Indicator which generally consists of a D.C. Voltmeter opera permanent field generator, the scale being calibrated to read "cycle permanent field generator, or so-called magneto, is directly driven from of the A.C. generator, the frequency of which it is desired to measure in

INDICATING FREQUENCY METERS. — Indicating frequenc are made in a variety of types, the most common being (1) the moving moving-coil type, (2) the induction type, and (3) those operating on ciple of the mechanical resonance of an iron reed acted upon by the field produced by a current from the given source.

Other types, less common, consist of a synchronous motor with an att for indicating its speed on a scale which is calibrated in frequency.

A wave meter is a type of frequency meter used for measuring radio fre which are much higher in value than the frequencies used in power wo description, see *Wave Meters*.

Moving-vane Type of Frequency Indicator. — A common form quency indicator of this type consists of a moving vane, with pointer att mounted that it is acted upon by two coils set at right angles to each oth coil is connected in series with a non-inductive resistance and the other with a comparatively large inductance. The vane tends to set itself in t tion of the resultant field due to the currents in two coils, there being trolling spring, and consequently for a fixed ratio of these currents the va up a definite position irrespective of the values of these currents. circuits are so connected to the source of supply that when the volta the mains varies, the voltages across the two circuits of the instrum proportionally to each other, and therefore the position of the vane and is unaffected by voltage variations. An increase in the frequency, decreases the current through the inductive circuit relative to that thr non-inductive circuit, and consequently causes a deflection of the v pointer; similarly a decrease in the frequency increases the current thr inductive circuit, producing a deflection in the opposite direction. Th ance and inductance of each circuit is so adjusted that for the stand quency, e.g., 60 cycles, the pointer stands in the middle of the scale. instrument is suitable for a range of frequency generally from about 25 below, to 25 per cent above normal frequency.

Effect of Wave Form. — Such instruments are affected to a ve extent by the wave form of the voltage on the mains to which they are co

This is readily understood by considering that wave forms differing fro sine are the equivalent to a superimposed higher frequency harmoni affects the frequency meter in the same way as would a higher frequenc

umerous expedients have been devised to overcome
ibinations of resistive and inductive circuits, and by
ble resistance in series with the inductance, this resist-
nd with the wave form on which the instrument is to

Frequency Indicator. — This type is similar to the
that two moving coils, rigidly fastened together, con-
t and the stationary element is a single coil.

Frequency Indicator. — A form of instrument of
nsitiveness is greatly increased, is described by *Pratt*
E., 1912, Vol. 31, p. 1505. The two moving coils or
in series with suitable resistances, inductances and
hat the two circuits are nearly in electrical resonance
with the impressed frequency. A 6-inch deflection of
of the instrument is readily obtained for a change of
ycles per second, and by changing the constants of the
n can also be obtained for a change of frequency from
. This instrument shows only a trace of variation due

Vibrating-reed Type of Frequency Indicator. — In these instru series of vibrating reeds is provided, each tuned to vibrate at a frequenc sponding to a certain number of cycles per second, or sometimes the t done for differences as small as ¼ cycle per second or less. Some arra is provided by means of which the frequency of the alternating circuit municated to these vibrating reeds. In one arrangement all of the r mounted on a common support which is vibrated by a single electr through which the alternating current whose frequency is to be measure In another arrangement the reeds are attached to a rigid support but structed of magnetic materials and acted on by one or more electro directly. These instruments are quite accurate in service if the voltag varied beyond that for which the instruments are intended, in which wrong reed may be made responsive.

The frequency of modern power circuits varies but little and the rate tion is slow. Thus the pointers of the usual frequency meters are g either at rest or moving very slowly, introducing a personal element of c the part of the observer as to operativeness. The argument in favo vibrating reed frequency meter is that the indicator is in motion cor showing that the instrument is operating. On the other hand, frequency indicating by means of pointers and graduated dials in the same way meters and ammeters, are generally preferred, being more easily read.

Miscellaneous Indicators. — Graphic recording frequency meters on the same principles and have movements similar to those of movi moving coil, or induction-indicating instruments, to which are added cloc paper charts and pens for recording the frequency variations at different

Cycle counters can be considered as a variety of frequency meters a not intended primarily to measure frequency. They consist of a cloc the escapement of which is controlled by a vibrator oscillated by an magnet connected to an alternating current circuit. The dials oper the clock train indicate the number of alternations elapsed or occurrir connected to the circuit. Conversely, if allowed to be connected to an cuit of unknown frequency for a fixed length of time, as for example, 10 s the frequency may be determined. The principal use of cycle counte timing relays, etc., instead of using stop watches, as much greater acc possible than with the stop watch. The frequency of the circuit sh either known or can be readily determined by operating the cycle count period of time which can be readily measured by ordinary means, suc seconds. Then, intervals of time as short as 1 cycle can be readily m within an error equal to 1 alternation, which is obviously an impossibili stop watches. By the use of cycle counters, chronographs or oscillogra avoided for timing purposes, unless time intervals within an error of le one alternation are to be determined.

COST OF FREQUENCY INDICATORS. — Switchboard fr meters of the moving-vane induction or moving-coil type (not tuned), co $45 to $65. The tuned, or electrical resonance, switchboard type cost fr to $85. Vibrating-reed frequency indicators for switchboard service co $35 to $95; portable indicators of this type cost from $110 to $125 included in both cases. The various types are made for standard freque 25, 40 and 60 cycles per second and for circuits of 110 or 220 volts. Fo voltages potential transformers should be used.

FRICTION DRIVE. — (*Adapted from paper by W. F. M. Go*
A.S.M.E., 1907.) A friction drive consists of a fibrous or somewha
driving wheel working in rolling contact with a metallic driven wh
a drive may consist of a pair of plain cylinder wheels mounted upo
shafts, or a pair of beveled wheels, or of any other arrangement
serve in the transmission of motion by rolling contact.

Suitable fibrous materials for the driving wheel are straw fiber, lea
tarred fiber, sulphite fiber, or leather; suitable materials for the dri
are iron, aluminum and type metal. See also P. L. Weston, *Magn*
band Drive, El. Rev. 81, p. 383, Oct. 19, 1917.

Crushing Strength and Safe Load for Fiber Wheels. — The
strength of each fibrous material, as determined by finding the lo
which the wheel failed before 15,000 revolutions had been made, is
the following table, together with the safe working load, taken as one

Material	Crushing load, lb. per in. width	Sa lb.
Straw fiber.....	750	
Leather fiber.....	1200	
Tarred fiber.....	1200	
Sulphite fiber.....	700	
Leather.....	750	

Coefficient of Friction. — The coefficients of friction between the various fibrous materials and the three metals are given in the table below, these being maximum values, corresponding to a slip of about 2 per cent. The friction at constant slip was found to be practically independent of the pressure between the limits of 150 and 400 pounds per inch width of face in contact.

Horse-power Transmitted. — Goss gives the following formula
maximum horse-power which can be safely transmitted by a friction d

$$P = \frac{\pi d}{12} \times \frac{WPN \times 0.6f}{33{,}000} = kdWN,$$

in which d = diameter of driving wheel in inches, W = width of face
P = safe working pressure in pounds per inch of width, N = revolu
minute, f = coefficient of friction, 0.6 a factor for the decrease of the
in service and for the loss in journal friction, k a coefficient including
the numerical constants.

COEFFICIENTS OF FRICTION AND HORSE-POWER OF FRI
DRIVES

S. — The analyses of the solid fuels given above
Wood when freshly felled contains on an average
ure, varying with different species. After eight to
e open air, the moisture is reduced to 20 or 25 per
greater dryness, it will, on exposure to the atmos-
n, and the percentage it will then contain will vary
ss of the air; that is, wood is hygroscopic.
be surface moisture, received from rain while being
d which may be dried out on exposure to the atmos-
ure, contained inside of the lumps, which cannot be

Digitized by Google

dried out without subjecting the coal for some time to a temperatu
ably above 212° F. The anthracite, the semi-bituminous coals an
minous coals of the Appalachian coal field seldom contain hygroscop
in excess of 1 or 2 per cent, but it is a characteristic of the western
coals and lignites that the hygroscopic moisture is much higher; th
Illinois coals it is as high as 14 per cent. When this moisture is dr
coal will again absorb it on being exposed to the atmosphere. So
contain as much as 40 per cent moisture.

ULTIMATE ANALYSES OF VARIOUS FUELS. — Typic
analyses of various fuels together with the percentage of ash are g
the analyses are for fuels from which all moisture has been expelled

	C	H	O	N	S
Wood	50	6	41	1	..
Peat	59	6	30	1	..
Lignite	69	5	16	1	1
Bituminous coal	76	5	10	1	1
Semi-bituminous coal	86.5	4.5	3	1	0.
Semi-anthracite	78.5	3.5	2	1	2
Anthracite	77	2.5	2	1	1
Charcoal	82	2	..	1	..
Coke	89	..	..	..	1
Petroleum (Texas)	84.5	11	3	..	1.
Natural gas	70	25	1	4	..

In the progression from wood to anthracite, the chief change in ch
stitution, as shown in the above table, is a decrease in the oxygen from
to 2 per cent. The hydrogen also decreases, but less rapidly. In all t
of coal, the ash is exceedingly variable, ranging from as low as 2 per
25 per cent or more. Coals high in ash are usually also high in sul
ash and sulphur may be removed to a considerable extent by c
washing.

AIR REQUIRED FOR COMBUSTION. — The theoretical w
A required for complete combustion of 1 lb. of fuel may be deter
the formula,

$$A = 0.115\,C + 0.346\left(H - \frac{O}{8}\right) + 0.043\,S,$$

where C, H, O and S are the percentages (by weight) of carbon,
oxygen and sulphur in the fuel. This gives about 12 lb. of air pe
combustible. In the best boiler practice, the weight of air required is
20 lb. per pound of coal, but in actual practice, the air supplied vari
much wider limits. See article on *Boilers*.

COAL. — **The proximate analysis** of coal is made by separatin
by successive heatings at different temperatures, into moisture, volat
fixed carbon and ash. For the determination of moisture, a r
sample, say 2 ounces or 60 grams, should be taken, crushed to ab
size, and heated for two hours to 140° C. (284° F.) or until the coa
decrease in weight. If a finely crushed small sample is taken, m
moisture may be lost by air-drying while crushing and weighing

Digitized by Google

constituents, a sample of about 1 gram of finely
or an hour at 105° C. (221° F.) and weighed, then
covered crucible until all the volatile matter is
ith a blast lamp to a white heat, the cover being
carbon is burned away, leaving the ash, which is
d be reported as in the example below, the per-
weight.

	Moist coal	Dry coal	Combustible
.....	10.0	.....	.....
.....	30.0	33.33	57.14
.....	40.0	44.45	42.86
.....	20.0	22.22	.....
	100.0	100.0	100.0

Proper sampling of coal is difficult. So much
be properly done. For instructions in this field,
Mines and Reports of Committee D-5, A.S.T.M.

The percentages of fixed carbon and volatile mat-
sh a means of classifying different kinds of coal.
ows:

	Fixed carbon	Volatile matter	Heating value per lb. of combustible, B.t.u.
....	97 to 90	3 to 10	14,600 to 15,000
....	90 to 85	10 to 15	14,700 to 15,500

imilar to anthracite, but is less hard, less shiny
t can usually be distinguished by its tendency to
thracite does not.

al is softer than semi-anthracite. The combustible
coals is very uniform in composition. The volatile
22 per cent of the combustible matter. Such fuels

Digitized by Google

are usually low in moisture, ash and sulphur and rank among the best st coals in the world.

The ash content runs from 3 to 8 per cent and for the higher grade heating value is in the neighborhood of 14,500 B.t.u. or better, per po dry coal.

Bituminous coal is also a soft coal. It is distinguished by hig centage of volatile matter, which causes it to give off dense volumes of when heated. It requires careful firing and furnaces especially adapte to prevent smoke. There is a wide variation in its physical properties.

Sub-bituminous coal is commonly known as "black lignite." generally black and shining, closely resembling bituminous coal, "weathers" or disintegrates more rapidly on exposure and lacks the pri structure of bituminous coal. Its calorific value is generally less than bituminous coal.

Lignite, or "brown coal," is intermediate between coal and pe usually has a woody structure and is distinctly brown in color, even on fracture. It carries a higher percentage of moisture than any other c coals, its mine samples showing from 30 to 40 per cent of moisture. fragile and rapidly splits into fine pieces upon exposure to air.

The following analyses of representative coals of the six classes are gi Prof. N. W. Lord:

Class 1. Anthracite Culm. Penn.
Class 2. Semi-anthracite. Arkansas.
Class 3. Semi-bituminous. W. Va.
Class 4(*a*). Bituminous coking. Connellsville, Pa.
Class 4(*b*). Bituminous non-coking. Hocking Valley, Ohio.
Class 5. Sub-bituminous. Wyoming, black lignite.
Class 6. Lignite. Texas.

— The heating value of coal depends on its percent-
nd on the heating value per pound of that com-
in different districts and bears a relation to the
r as shown by the above table.
tile matter is less than 40 per cent of the combustible,
of combustible may be approximately determined
means of the following table. When the volatile
ent, the figures in the table may have a plus or minus
cent, since the coals high in volatile matter differ
xygen.

Volatile matter, per cent of combustible	Heating value, B.t.u. per pound of combustible	Volatile matter, per cent of combustible	Heating value, B.t.u. per pound of combustible
28	15,660	43	14,220
32	15,480	45	13,860
37	15,120	47	13,320
40	14,760	49	12,420

und of combustible of all the semi-bituminous coals,
cent of volatile matter in the combustible, is within
u. per pound. This is within the limits of error of
sis or of calorimetric determination.

Digitized by Google

The heating value of any coal may also be calculated from t analysis by means of Dulong's formula,

$$\text{B.t.u. per pound} = 146\,C + 620\left(H - \frac{O}{8}\right) + 40\,S,$$

in which C, H, O and S are respectively the percentages by weig hydrogen, oxygen and sulphur. The probable error of this formula 2 per cent for any coal containing less than 40 per cent volatile m combustible. For coals higher in volatile matter, the error is somet When the percentages are expressed as percentages of the various the *combustible*, the formula gives the B.t.u. per pound of combus the percentages are percentages of the various elements in a give **coal**, the formula gives the B.t.u. per pound of coal, which is, of cour the B.t.u. per pound of combustible in proportion to the per cent and ash present. In general, if K be the per cent of combustible sample, and H the heating value per pound of combustible, the he per pound of coal is $\frac{KH}{100}$.

For the direct determination of the heating value of coal or othe a bomb calorimeter, in which the fuel is burned in an atmosphere of oxygen, is the most accurate instrument. (*See Calorimeters, Fuel.*)

Average Heating Values. — The following figures give t commercial heating values of the principal power plant fuels, otl and gas.

	B.t.u
Anthracite	11
Semi-anthracite	
Semi-bituminous coal	14
Bituminous	11
Lignite (as fired)	
Lignite (dry)	
Coke	
Charcoal	11
Peat (as fired)	4
Peat (dry)	5
Wood (dry)	6
Bagasse (45 to 55 per cent water)	
Tan bark (65 per cent water)	
Tan bark (dry)	6
Straw	5

The Commercial Value of a Coal is not always in direct p its heating value. Excessive moisture causes a reduction in its ter combustion, which reduction, in steam boiler practice, decreases th excessive ash tends to obstruct the draft and thus cause imperfect High percentages of volatile matter tend to cause smoke and soot, the use of special furnaces.

Specifications for Coal. — For the reasons just stated, contracts chase of coal on specifications of quality should penalize excess of m and volatile matter above certain stated percentages. For a full d purchase of coal by specification and specifications used by the U see latest Bulletins of the U. S. Bureau of Mines relating to this subj specifications are as follows:

Digitized by Google

l-anthracite. — **The standard is a coal containing** not over 2 per cent moisture and not over 10 per 5 per cent on the price will be given for each per 5 per cent up to and including 15 per cent, and a e price will be made for each 1 per cent of moisture

nd Eastern Bituminous. — The standard is a ning not over 20 per cent volatile matter, 2 per t ash. A reduction of 1 per cent in the price will of volatile matter in excess of 25 per cent, and of t of ash and moisture in excess of the standard.

or western coals in which the volatile matter differs xygen, the above specification based on proximate tly accurate, and it is well to introduce the heat- her by a calorimeter or by calculation from the

ntaining not over 6 per cent moisture and 10 per ple, and having a heating value of 14,500 B.t.u. free from moisture and ash). For lower heating l, the price shall be reduced proportionally, and e in ash or moisture above the specified figures, be deducted.

ge. — **The space occupied by a ton of coal depends** e coal and the size of the lumps. A ton of 2240 size, or smaller, occupies a space of from 36 to 45 ounds of bituminous coal occupies a space of from nating the space required for storage, 45 cubic feet lly assumed.

nthracite coal when exposed to the weather under- xcept the oxidation of the sulphur content, which ntains a larger percentage of sulphur, the oxidation ent amount, may develop sufficient heat to cause me lignites are rapidly disintegrated when exposed carload lots of Illinois coal (*F. FURNACES, ELECTRIC, AND ELECTRIC FURNAC UCTS. — (*See also Electrochemical Processes, Industrial.*) Elect may be classified as follows:

Arc furnaces.
Induction furnaces.
Resistance furnaces.
a. Current conducted by the materials heated:
1. With electrolysis.
2. Without electrolysis.
b. Current conducted by a special resistor.

In the arc furnace the heat is produced by an electric arc (*see A* usually between carbon electrodes. The induction furnace is e static transformer (*see Transformers*) with the low-tension "windi by the material to be heated. In the resistance furnace the cur plied to the material to be heated (i.e., to the furnace "charge", special resistor, by connecting the charge or resistor directly to the s current supply. The heat developed in both the induction and res naces arises from the passage of the current through the resistanc the charge or special resistor.

The arc furnace may be considered a resistance furnace in which is a gas. Since the resistance of a gas at atmospheric pressure is g that of any solid resistor of the same dimensions as the arc, the amo that can be produced in a small space will be greatest with an arc f

TEMPERATURE AND DISTRIBUTION OF HEAT. — tage in electric heating is that a higher temperature can be produ using fuel, that the heat is produced inside the furnace where it is that the heat can be easily and accurately regulated. In the arc part of the positive carbon is estimated to be between 3900° C. a absolute. (*Waidner and Burgess, Bull. Bureau Stds., Vol. 1, p.* The temperature of the arc itself increases with the current. (*Ka buch der Spektroscopie, Vol. 1, pp. 154–160, 1900.*)

The electric energy delivered to the furnace as heat is used as to heat the charge to the desired temperature, which involves the furnace walls, if cold at the start. This energy is equal to the charge times the temperature rise times the specific heat. If t melted or vaporized in the furnace, additional heat must also This item may be reduced by delivering the charge to the furnace as in steel refining. (2) To supply the energy needed for the r energy so required cannot be reduced. (3) To supply the loss duction and radiation through the walls and electrodes, and the hea by hot gases. A part of the heat carried off by hot gases may be heating water in boilers, so that it is not a complete loss.

MAXIMUM SIZE OF ELECTRIC FURNACES. — The l able capacity of an open-arc single hearth with a compact bundle has been found in practice to be from 2500 to 3000 kilowatts at fro 40,000 amperes and from 75 to 90 volts. These large sizes are with the three-phase system, so that the maximum total power abs furnace is from 7500 to 9000 kilowatts. In carbide furnaces double furnaces are used with six electrodes, in place of three, in the sam the power absorbed is from 15,000 to 18,000 kilowatts. Great progr made in electric-furnace construction, by closing the furnace at the having special means of feeding in the charge, thereby avoiding t sance and protecting the workmen from the heat, as well as dist

DESIGN OF ELECTRODES FOR ELECTRIC FURNAC electrodes of an electric furnace should be so designed that the ene carried into the furnace with a minimum energy loss. The loss electrical resistance is directly proportional to the electrode's length; therefore be made as short as convenient. The loss due to electrica will be smaller the greater the cross-section of the electrode, but th from the furnace through the electrode will be directly proportic cross-section. It is therefore possible to find a cross-section of a giv which will give a minimum total loss for a given length. The cross-s would give the minimum loss on certain assumptions, only approxin is found from the equation

$$S = 0.346\, LI \sqrt{\frac{r}{k(t_2 - t_1)}},$$

and the loss itself, watts, is

$$h = 2.89\, I \sqrt{kr\,(t_2 - t_1)},$$

where S = cross-section of electrode, L = its length, I = the curr peres carried by the electrode, t_2 and t_1 the temperatures, in ° C., and cold ends of the electrode respectively, r = its mean electrica in ohms per unit cube and k = its mean heat conductivity for the perature $(t_1 + t_2)/2$. If S and L are in centimeters, r and k must b if S and L are in inches, r and k must be per in.^{2}.

The values of k and r for carbon and graphite are not known ac high temperatures. The following values have been computed fro ments of Hering (*Trans. Am. Electroch. Soc., Vol. 17, p. 166, 1910*).

Material	Temperature °C.		Thermal cond. g-cal. per cm.^{2} per °C. per sec.	E r ohn
	Hot end	Cold end

SMALL LABORATORY FURNACES. — A great variety of e naces have been devised. A few typical laboratory furnaces will b in this section. Some industrial furnaces are described in the next s

Moissan's Furnace (Fig. 1). — Moissan's work was carried out in consisting of two horizontal electrodes, mounted so that the distan the two ends could be adjusted longitudinally by a screw thread. An arc was formed between these electrodes in a cavity formed by some refractory material, such as lime. The substance to be heated was placed in a crucible under the arc as shown in Fig. 1. When the substance was not to be exposed to the gases of the arc, a furnace was made with a carbon tube passing through it at right angles to the electrodes and in below the arc. The substance to be heated was placed inside this tu

). — A type of furnace due to Borchers consists in wo larger electrodes. The charge is either packed ced under it. This type of temperature below that of the

High-pressure Furnaces. — The Arsem furnace may be of course the internal pressure above an atmosphere, but it is not designed for sures. A furnace for working up to 200 atmospheres has been de Hutton and Petavel. (*Phil. Trans., Series A, Vol. 207, p. 421, 1908, trochem. and Met. Ind., Vol. 6, p. 97.*) For a modified form see *Pring a* (*VIII Int. Cong. App. Chem., Vol. 21, p. 79, 1912*). For a furnace fo scopic work on gases at pressures up to 200 atmospheres, see *King, A. physical Journal, Vol. 28, p. 300, 1908.*

Heræus Furnace (Fig. 5). — A very useful type of furnace is c firm of Heræus. This consists in a tube wound in its middle portio electrical resistor. The ends of the tube are cooled by the air, or may be cooled by a coil of copper pipe through which water flows. The tube may be of some non-conducting substance, such as porcelain, in which case a ribbon of metal may be wound directly on the tube. Furnace tubes with grooves for winding with wire are now made by the Norton Company of Worcester, Mass., from fused alumina. These, however, and cannot be used for a vacuum furnace. Glazed German porcela heated up to 1180° C. and a vacuum maintained. At temperatures h this the glazing melts and air leaks into the tube. A nickel tube ma for higher temperatures.

Fig

The metallic winding for carrying the current may be of platinu nichrome, tungsten, molybdenum or any other suitable high-resistanc (*see Wires, Resistance*).

These furnaces are particularly useful when the temperature is t constant over a long period of time. For most purposes a constant c keep the temperature sufficiently constant. For greater constancy of regulator must be used (*see Bodenstein and Kranendieck, Z. f. Vol. 18, p. 417, 1912*). The Heræus type of furnace is usually more sa when homemade, as a greater choice of materials is then possible.

Hoskins Furnace. — A convenient furnace for heating rather large or masses of material is made by the Hoskins Manufacturing Co Detroit, Michigan. The heater consists of two rows of narrow, th plates which extend over two sides of the cavity which receives the su be heated. The contact resistance between the plates may be varied by This furnace of course requires a very large current at a low voltage.

Granular Carbon Furnace (Fig. 6). — A carbon or graphit may be easily heated by placing it in a trough surrounded by gra carbon; this conducts better than coke. The current is passed through the trough, into which it is conducted by carbon rods. Clay crucibles should not be used in this way for temperatures over 1000° C., as at a high temperature they are attacked by the carbon.

Fig

ELECTRIC-FURNACE PRODUCTS AND INDUSTRIAL FURNACES. — Some typical industrial furnaces and their products are described below.

Calcium Carbide. — Willson and Horry Furnaces. Calcium ca first made on a large scale by Willson in 1892 at Spray, N. C., by he and carbon in an arc furnace. The reaction that takes place is

$$CaO + 3\,C = CaC_2 + CO.$$

The furnace consisted of a carbon plate 3 by 2.5 feet with a carbon suspended above it. The whole was surrounded by brick walls. similar to this were at first used at Niagara Falls, with the lower

Digitized by Google

Acheson's theory of the formation of graphite is that the carbon first carbide, which decomposes at a higher temperature, leaving the carbo form of graphite. This theory is not confirmed by Arsem's experiment *Fitzgerald, Kunstlicher Graphit, Vol. 15 of the Engelhardt Monograph angewandte Electrochemie.*)

Carbon Bisulphide is made in a specially designed furnace by together sulphur and carbon. Most of the disagreeable features encoun the manufacture of this substance are thus avoided. (*Taylor, Tra Electroch. Soc., Vol. 1, p. 115, 1902; Vol. 2, p. 185, 1902.*)

Phosphorus is a substance the production of which the use of the furnace has much simplified. It is made in the Readman-Parker furnace ing to Wöhler's process:

$$Ca_3(PO_4)_2 + 3\ SiO_2 + 5\ C = 3\ CaSiO_3 + 5\ CO + 2\ P.$$

(*Min. Industry, Vol. 6, p. 537, 1897; Vol. 7, p. 557, 1898.*)

Alundum is the trade name of fused aluminum oxide, which is mad Norton Company of Worcester. Aluminum oxide is fused in an arc (*Min. Industry, Vol. 19, p. 28, 1910.*) Fused alumina is used as an a as a refractory substance for furnace linings, and porous crucibles of t stance are used in analytical laboratories.

Aluminum. — Hall and Héroult Processes. — Aluminum is now p by the electrolysis of a solution of alumina in fused cryolite ($AlF_3.3$ which other fluorides, such as those of aluminum and of sodium, are added factories. The aluminum sinks to the bottom of the crucible and is dr This process was discovered nearly simultaneously by C. M. Hall and The heat developed by the current in passing through the solution is s to keep the bath melted. The cathode is an iron trough lined with carb the anode consists of a number of carbon rods suspended over the crucibl Aluminum Company of America uses as anode for one crucible 48 carb 3 inches in diameter and 15 inches long. The electromotive force ap each crucible is 5.5 volts; the current is 10,000 amperes. The yield pounds of aluminum per horse-power day. For further information s *Industry, Vols. 6, 14, 15, 17, 20.*

Sodium, Potassium. — Castner Process. — Sodium and potassi obtained by the electrolysis of their fused hydrates, usually in the cell c by Castner (*U. S. Pat. 453,030, filed 1890; see also Becker, Die Elektromet der Alkalimetalle*). At Holcomb's Rock, Va., sodium is made by the elec of fused sodium chloride. (*Mineral Ind., Vol. 19, p. 614, 1910.*)

Calcium is made by the electrolysis of fused calcium chloride, to which fluoride is added to lower its melting point. Calcium is made at Ho Rock, Va., probably in a cell devised by Seward and Von Kügelgen (*U. 880,760, 1908; Min. Industry, Vol. 16, p. 131, 1907; Vol. 17, p. 99, 190* abroad by the method of Rathenau (*Z. f. Elektroch., Vol. 10, p. 508, 190* the Ratheneau method the cathode is an iron rod which just touches the of the melted calcium chloride. The calcium solidifies when deposited cathode by electrolysis. As the calcium grows the rod is withdrawn s rod of calcium is produced. (*Trans. Am. Electrochem. Soc., Apr., 1920.*

Zinc may be made by the electrolysis of fused zinc chloride. In th burne–Ashcroft process sodium chloride is added to zinc chloride in suc tity that the resulting mixture contains 28 per cent zinc. The cell is lined, sheet-iron vessel. The anode is carbon, the cathode, melted zinc vat takes 4.5 volts, with a cathode current density of 400 amperes pe The temperature of the fused salt is 450° C. (*Electroch. and Met. Ind., p. 65, 1905.*)

is one or more carbon rods suspended from above. The steel elec course melt several inches below the surface of the refractory lini crucible. The furnaces are sold by C. W. Leavitt and Co., 30 Ch New York, from whom the following data have been obtained.

These furnaces require from 65 to 70 volts at frequencies from 25 to The power factor is about 80 per cent and the duration of heat when is charged in the melted state is 1½ to 2½ hours. The number of are from 1 to 3, according to the capacity of the furnace. For a furnace 12 tons capacity, the maximum power required is 1200 kilowatts at the terminals of the electric generator; the energy consumption metal is charged cold is 900 kilowatt hours per ton of steel; with a melte from 150 to 250 kilowatt hours. The electrodes are so designed that th does not exceed 5 amperes per square inch of cross-section. The n consecutive heats possible without repairs is:

	Linings	Cover	Ele
With cold charge	30 to 40	20 to 30	
With melted charge	60 to 90	40 to 50	

To handle the furnace 6 persons are necessary: a melter, 2 assistant 2 workmen and a boy.

Other Arc Furnaces more or less similar to the Héroult furnace Keller furnace (*Trans. Am. Electroch. Soc., Vol. 15, p. 96, 1909*), the N furnace (*Met. and Chem. Eng., Vol. 10, p. 227, 1912*) and the Snyder (*Trans. Am. Electroch. Soc., Vol. 28, pp. 221–230, 1915*).

Brass Melting. — Electric furnaces are now used to a considerable brass melting. (*St. John., H. M., Electric Brass Melting, Elec. J Sept.*, 1919.) Some of the types of furnaces used are the Booth furnace (*Trans. Am. Electroch. Soc., Vol. 33, p. 247, 1918*); the furnace (*Met. and Chem. Eng., Vol. 12, p. 275, 1914; Trans. Am. Soc., Vol. 29, p. 407, 1916; Vol. 31, p. 87, 1917*); and the Helberg (*Met. and Chem. Eng., Vol. 12, p. 644, 1914*).

FIXATION OF ATMOSPHERIC NITROGEN. — One of important applications of the electric furnace is the fixation of at nitrogen. The various processes employed are described below.

Carbide Method. — In this method calcium carbide is heate nitrogen, forming calcium cyanamide according to the reversible rea

$$CaC_2 + N_2 \rightleftarrows CaCN_2 + C.$$

The carbide is heated in iron drums by a thin carbon conductor runnin the center of the drum. Heat is evolved by the reaction. The called "nitro-lime" or "lime-nitrogen," and contains 12 to 15 per cent (*Met. and Chem. Eng., Vol. 5, p. 78, 1907.*) It is used directly as a or may be converted into ammonia by superheated steam. The yiel gen by the carbide method is about 51.6 grams per kilowatt hour, incl manufacture of the carbide.

Direct-Oxidation Method. — In this method the nitrogen an in air are caused to combine in a high-voltage arc according to the reaction

$$N_2 + O_2 \rightleftarrows 2\,NO.$$

On cooling the NO is further oxidized to nitric dioxide. The nitric treatment with water gives nitric and nitrous acids:

$$2\,NO_2 + H_2O = HNO_3 + HNO_2.$$

Only about 1 to 3 per cent of the air treated is oxidized. The yield in land-Eyde furnace is 12.7 grams of nitrogen fixed per kilowatt hour. *Faraday Soc., Vol. 2, p. 98, 1906.*) Furnaces of three different de now in operation for oxidizing nitrogen: that of Birkeland and Eyd Schönherr, and that of H. and G. Pauling.

Direct Synthesis of Ammonia. — In this method, due to Haber, is formed directly from a mixture of nitrogen and hydrogen by passi catalyzer between 500° C. and 700° C. at 200 atmospheres, accordi reversible reaction

$$\tfrac{1}{2}\,N_2 + 3\tfrac{1}{2}\,H_2 \rightleftarrows NH_3.$$

(*Zeit. f. Elektroch., Vol. 16, p. 244, 1910; Vol. 19, p. 53, 1913.*) The of this process has not been made public.

Bucher Process. — This process was discovered in 1846 by Lewis (Bucher, *Am. Inst. Chem. Eng., Vol. 9, p. 335, 1916*) and is represent following reaction:

$$Na_2CO_3 + 5C + N_2 = 2NaCN + 3CO$$

which requires metallic iron as catalyzer. The temperature is betw and 1050° C. Many attempts have been made to use this process, but

FUSES. — (*See also Circuit Breakers; Wiring of Buildings.*) Meta wires which open electric circuits by melting or fusing when the curre a predetermined value are called fuses. They were used in the earlie plants to furnish automatic protection for feeder and generator circuit use is now confined largely to low-voltage distribution circuits ar protection of small pieces of apparatus such as motors and smal transformers.

All fuses have an inherent time-element feature due to the fact current must heat the fuse metal up to its melting temperature. This varies with the size and type of fuse, the large ones in general taking reach their fusing temperature than the smaller sizes, due to thei capacities. There are three designs of fuses in general use, namely, or link, the expulsion, and the enclosed or cartridge types. The choic depends upon the service for which the fuse is intended.

RATING OF A FUSE. — The rating of a fuse depends somewh type and general design. Fuses will, as a rule, carry their normal rate indefinitely but will blow at a certain overload varying from 10 per c enclosed fuse to about 80 per cent in an open fuse if the overload co sufficient length of time. For greater overloads the length of time re blowing diminishes rapidly.

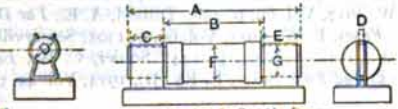
OPEN OR LINK FUSES were the original type of automatic p The early ones were small copper wires and had the drawback of formi globules and of possessing a high fusion temperature. In order to r temperature of the molten metal there were employed alloys of low fus made of lead, tin, or other metals. These fuses were soft and w damaged when tightening up the contact nuts. The next step was to fuses with copper tips, and these are still used to some extent.

As the price of aluminum was reduced this material was used l fuses as it has a high conductivity (thus reducing the amount of m fused), a fairly low melting point and almost complete vaporization of fused. By using wide strips of aluminum cut to form two or mor fairly reliable open fuses can be made up to 1200 amperes capacity.

Any metal strip which is exposed to drafts is apt to be very err behavior as a fuse. To protect link fuses from drafts, and also t the danger from molten metal which may be thrown at the time of b is desirable to install them in porcelain fuse boxes.

EXPULSION FUSES consist essentially of open fuse wires or stri in a holder, so designed that the expulsion of the gases formed by th of the fuse blows out the arc. The earliest designs of this type co removable fuse holder of lignum vitæ or similar tough, close-grain equipped with terminals which fitted into suitable blocks. Later ty the fuse placed in a fiber tube and arranged to blow out through on a bomb.

The fuses used for the protection of distributing transformers mo poles or houses are usually of the expulsion type. For such outdoor combination fuse and disconnecting switch is frequently used. Mod of the expulsion-type fuse were formerly used to advantage in railwa but in recent car equipments circuit breakers have practically repla and cut-outs.



INCLOSED OR CARTRIDGE FUSE. — This type of fuse consi tially of a fusible wire, strip or sets of wires and strips inclosed with or cartridge usually of fiber. The tube is filled with a material to ex

(*See also Gages, Sheet Metal.*) The sizes of wires having a ch are usually stated in terms of certain arbitrary scales ze or gage number of a solid wire refers to the cross- pendicular to its length; the size or gage number of a he total cross-section of the constituent wires, irrespec- spiraling. Larger wires are usually described in terms in circular mils. A circular mil is the area of a circle the area of any circle in circular mils is equal to the n mils. See *Units and Conversion Factors.*

f wire gages in use, the principal ones being the following.

ROWN AND SHARPE WIRE GAGE. — This gage used in the United States for copper, aluminum and age is designated by either of the abbreviations A. W. G.

G. or B. & S. Gage. — The diameter of wires having this gage are in the ratio of $\sqrt[39]{92}$ (= 1.1229 approx.) e has a diameter of 5 mils. No. 35 A. W. G., therefore, .1229 = 5.61 mils and so on until No. 0000 is reached, o mils.

roximately equal to $\sqrt[9]{2}$, which is 1.1225. This circum- e to have a group of wires of regular gage size with an nately equal to that of another regular gage size. imate relations are also useful:

he number increases the resistance 25 per cent.
he number increases the resistance 60 per cent.
he number increases the resistance 100 per cent.
he number increases the resistance 10 times.

pper wire has the following approximate characteristics:

et	1
	10,000
er 1000 feet	32

luminum wire has the following approximate character-

et	1.6
	10,000
er 1000 feet	9.5

ules it is easy to find the approximate size, resistance, e wire. For example, a No. 12 A.W.G. copper wire has per cent = 1.6 ohms per 1000 feet approximately. Its

ts resistance, is $\frac{10,000}{1.6}$ = 6250 circular mils; its diameter

) mils and its weight, $\frac{32}{1.6}$ = 20 pounds per 1000 feet.

E GAGE. — This gage, known also as the "Wash- ebling," "American Steel and Wire Co.'s" gage, is ed in the United States for steel and iron wire. It is "S. W. G.," but to avoid confusion with the British *e below*) it should be abbreviated "Stl. W. G." or "A.

Digitized by Google

BIRMINGHAM (OR STUBS') WIRE GAGE. — This gage used in the United States for some purposes, e.g., to designate the size wire, and is also employed to a limited extent in Great Britain. It is abbreviated "B. W. G." It is sometimes referred to as the "Stubs' but it should not be confused with the Stubs' Steel Wire Gage.

BRITISH STANDARD WIRE GAGE. — This gage, usually simply the "Standard Wire Gage," and abbreviated "S. W. G.," is also as the "New British Standard" (abbreviated "N. B. S."), the Englis Standard, or the Imperial Wire Gage, and is the legal standard of Great for all wires, as fixed by order in Council, August 23, 1883. It was con by modifying the Birmingham Wire Gage, so that the differences betwee sive diameters were the same for short ranges, i.e., so that a graph repr the diameters consists of a series of a few straight lines.

EDISON WIRE GAGE. — The size of a wire on this gage is its cross-sectional area in circular mils divided by 1000. For example wire 0.2 inch in diameter has the number $(200)^2/1000 = 40$. This gag rarely used.

OTHER GAGES. — In addition wire sizes are sometimes specified of the "Old English Wire Gage," known also as the "London Gage," "Stubs' Steel Wire Gage."

COMPARISON OF WIRE GAGES. — A comparison of the gages, in terms of the diameters (in mils or thousandths of an inch) wires corresponding to the various numbers, is given below. The cross in circular mils is the square of the diameter in mils.

COMPARISON OF WIRE GAGES

GALVANIZING FOR IRON OR STEEL, Specification for A
ance Test. — These specifications give in detail the test to be app
galvanized material, as recommended by the Electric Railway Engi
Association, the National Electric Light Association, etc. All specime
be capable of withstanding these tests.

(a) **Coating.** — The galvanizing shall consist of a continuous coating
zinc of uniform thickness, and so applied that it adheres firmly to the
of the iron or steel. The finished product shall be smooth.

(b) **Cleaning.** — The samples shall be cleaned before testing, firs
carbona, benzine or turpentine, and cotton waste (not with a brush), a
thoroughly rinsed in clean water and wiped dry with clean cotton waste.
The sample shall be clean and dry before each immersion in the solutio

(c) **Solution.** — The standard solution of copper sulphate shall co
commercial copper sulphate crystals dissolved in cold water, about in t
portion of 36 parts, by weight, of crystals to 100 parts, by weight, of
The solution shall be neutralized by the addition of an excess of che
pure cupric oxide (CuO). The presence of an excess of cupric oxide
shown by the sediment of this reagent at the bottom of the containing v
The neutralized solution shall be filtered before using by passing
filter paper. The filtered solution shall have a specific gravity of 1
65° F. (reading the scale at the level of the solution) at the beginning
test. In case the filtered solution is high in specific gravity, clean wat
be added to reduce the specific gravity to 1.186 at 65° F. In case the
solution is low in specific gravity, filtered solution of a higher specific
shall be added to make the specific gravity 1.186 at 65° F.
As soon as the stronger solution is taken from the vessel containing
filtered neutralized stock solution, additional crystals and water must be
to the stock solution. An excess of cupric oxide shall always be kept
unfiltered stock solution.

(d) **Quantity of Solution.** — Wire samples shall be tested in a glass j
least two (2) inches inside diameter. The jar without the wire samples
filled with standard solution to a depth of at least four (4) inches. Ha
samples shall be tested in a glass or earthenware jar containing at least
(½) pint of standard solution for each hardware sample. Solution sh
be used for more than one series of four immersions.

(e) **Samples.** — Not more than seven wires shall be simultaneously im
and not more than one sample of galvanized material other than wire
immersed in the specified quantity of solution.
The samples shall not be grouped or twisted together, but shall be we
rated so as to permit the action of the solution to be uniform upon all im
portions of the samples.

(f) **Test.** — Clean and dry samples shall be immersed in the required
tity of standard solution in accordance with the following cycle of imm
The temperature of the solution shall be maintained between 62° and
at all times during the following test.

First. Immerse for one minute, wash and wipe dry.
Second. Immerse for one minute, wash and wipe dry.
Third. Immerse for one minute, wash and wipe dry.
Fourth. Immerse for one minute, wash and wipe dry.

After each immersion the samples shall be immediately washed i
water having a temperature between 62° and 68° F., and wiped dry with
waste.

GALVANOMETERS. — (*See also Ammeters; Electrodynamomet meter; Voltmeters.*) The essential parts of a galvanometer are a p magnet (electromagnet in Einthoven String Galvanometer, see belo coil or wire designed to carry an electric current, the magnet and so mounted that the passage of the current through the coil causes tion of either the coil or the magnet, as a result of the mechan with which the current and magnet act on each other. See *Elect Magnetism, Principles of.* Ordinary direct-current ammeters and are operated on the same principle, but the term galvanometer is usuall for instruments designed for measuring relatively small currents, the being read either by means of a telescope and scale or by means of a scale. In portable test set galvanometers the deflection of a pointer

Moving-needle versus Moving-coil Galvanometers. — Galv in which the moving element is the permanent magnet, in the form needle, are called needle galvanometers, whereas those in which th element is the coil are called moving-coil galvanometers. The forme galvanometer is required when extreme sensitiveness is desired, but a rule be used in a commercial laboratory, on account of the disturb ences of the magnetic fields due to the lighting and power circuits in ratory and in neighboring buildings. Railway circuits, even though more away, may produce a disturbing field sufficient to render impo use of a sensitive needle galvanometer. For ordinary laboratory work, the moving-coil galvanometer can be made sufficiently sensitive, and permanent magnets used to produce the controlling field can be m strong, the effect of stray fields can be rendered relatively negligible.

Astatic Galvanometer. — The disturbing effect of stray magnetic a needle galvanometer can be partially prevented by the use of tw stationary coils and two needles, or the equivalent, the two needles arranged that any external field will produce opposing torques, and so connected that their torques are additive. The Broca galvanomete described below, is a modern type of astatic instrument.

Damping and Logarithmic Decrement. — Due to the mechanic to motion and the induced currents set up in the adjacent metal or co instrument as a result of the motion of the moving element, successi of the moving element when it is once set in motion decrease in a This effect is known as damping. Successive swings from the zero o rium position decrease approximately in geometric ratio. Hence of the logarithm of one swing to the logarithm of the next swing, to side of the zero, is approximately a constant. This constant, which is a of the damping, is called the logarithmic decrement of the instrument.

Ballistic Galvanometer. — A ballistic galvanometer is one in w moving element has a relatively long period and small damping. shown that when a quantity of electricity Q is discharged through su vanometer in an interval of time *very short* compared with the period o vanometer, then the first throw or swing of the moving element is appro proportional to the quantity of electricity Q. Such an instrument serves as a very convenient means of measuring the capacity of a (*see Capacity and Charging Current; Condensers, Electric*) as well as fo ing the quantity of electricity discharged through a circuit by transien electromotive forces (*see Magnetic Testing*).

Effect of External Resistance on Damping. — Since the da a galvanometer is due in part to the currents induced in the coils of th ment by the motion of the moving element, and since these currents dep

CHARACTERISTICS OF EINTHOVEN STRING GALVANOM

Material of string	Diameter of string	Resistance in ohms	Period in seconds	Magnifying power of microscope	Deflect mm
					Per microamp.
Silver wire.....	0.02 mm.	4.7	.....	500	4.4
Silvered quartz fiber.....	0.002 mm.	20,000	.....	500	62,500
	0.003 mm.	6,600	.....	650	333.000
	0.002 mm.	5,800	0.008	750	30
	0.002 mm.	3,890	0.005	750	9.7

* These are apparent deflections as observed through the microscope. Fo in the case of the galvanometer having the constants given in the third line, deflection is 333000/650 = 512 mm. per micro-ampere. An apparent deflectio ⅛ mm. can be detected by the eye, consequently with this particular galva current of $10^{-6}/3 \times 333000 = 10^{-12}$ amperes, approximately, may be detected

Vibration Galvanometer. — The Einthoven galvanometer may al as a vibration galvanometer for detecting an alternating current. I nating current is sent through the string and the tension on the latter i so that the free period of the string is the same as the period of the cur the string will be set in vibration, the amplitude of the vibration depen the strength of the current. Consequently when the instrument is th it may be used as a detector of extremely minute alternating current thus used the instrument is capable of detecting an alternating curren amperes, effective value.

A moving coil galvanometer may also be used as a vibration galv by providing means for adjusting the free period of the moving element to resonance with the period of the current to be measured. Fig. 4 shows such a galvanometer, the free period being adjusted by moving the movable bridge up or down.

Fig. 4. Vibrat nomet

Marine Galvanometers. — Any galvanometer that will give deflections that are not affected by the rolling of a ship and consequently can be used on shipboard may be called a marine galvanometer. A common form of marine galvonmeter is of the D'Arsonval type with the coil held by suspensions, both above and below, that are stretched under considerable tension.

The moving system of the galvanometer is carefully balanced, so that a 30-degree inclination will not cause a deflection of more than 3 mm. with the scale at 1 meter distance. It has a very stable zero and a sensitivity of 10 to 20 millimeters per micro-ampere with a 3-second period.

USE AND CALIBRATION OF GALVANOMETERS. — G eters, other than ballistic, are used in engineering work primarily a *detectors* in various bridge (q.v.) and potentiometer (q.v.) measurem

Combustion Engines; Gas Producers.) The word
means a substance which is capable of indefinite
o used in a restricted sense to mean any mixture
ation or for fuel. It is in this sense that the word

thousands of cubic feet, at 60° F. and at a pressure
he term " permanent " or " fixed " gas is used to
t precipitate any of its constituents when cooled.

addition to natural gas, which exists in limited
alities (in this country, chiefly in western Penn-
io, Indiana, Kansas, Texas and California), there
red gas. These various types all contain the same
ferent proportions, depending upon the process of
om which they are made. Gas may be made from
or liquid fuel, but coal is the fuel usually employed.

s given to the mixture of permanent gases resulting
l retorts of the volatile matter in coal. The heavy
mpurities are extracted by cooling and " washing "
gh purifiers containing hydrated lime or sesquioxide
n the retorts is coke; the condensed hydrocarbons
ulphur compounds and cyanogen are absorbed in
all these by-products are of value.
illumination, but in this country carburetted water-
tensively employed for this purpose. Coal-gas is
oses on account of its high manufacturing cost as
(see below), which, though unsuitable for illumina-
ory fuel for gas engines.

e is given to the mixture of permanent gases result-
take place when steam is passed through a body of
l to redness or beyond, the hot gas being condensed
me manner as coal-gas. The chief reaction in the
decomposition of the steam by the heated carbon,
monoxide, the reaction being $C + H_2O = CO + 2H$.
rocess, hence the production of water-gas is inter-
stages: (1) the " blowing up " or heating the fuel
ir into it, producing CO_2 by the reaction $C + 2O =$
of water-gas by blowing steam through the fuel,
een shut off. Water-gas is generally made from
not only hydrogen and carbon monoxide, but also
nitrogen and light hydrocarbons. Pure water-gas
ion, since it is deficient in the heavy hydrocarbons
od illuminant. This defect is readily supplied by
water-gas as it comes from the producer and super-
med; the naphtha vapor and the superheated steam
anent gases of the hydrocarbon group. Water-gas
etted water-gas " and forms an excellent illuminant.
reater proportion of illuminating gas is carburetted
or carburetted, is seldom used for power purposes,

ame is given to the mixture of permanent gases
reactions which take place when air is blown or
al. At the bottom of the bed, where the air is in
his is reduced on passing through the upper part of

the bed to CO by the reaction $CO_2 + C = 2\,CO$. The resulting gas al hydrogen, resulting from the reaction between the moisture in the co hot carbon, this reaction being the same as in the production of water- nitrogen of the air is also present in the gas, forming more than half i thereby making a very dilute or "lean" gas. This process has b seded by the producer-gas process described below.

Producer Gas. — This name is given to the mixture of perma resulting from the chemical reactions which take place when both ste are blown through a bed of hot coals. The gas is essentially a mixtur gas and Siemens gas. The process is a continuous one, enough air beir with the steam to maintain the producer bed at the proper tempera eliminating the "blowing up" operation in the water-gas process; a the presence of the steam and the reactions which take place between carbon, the proportion of hydrogen is increased and the proportion decreased, thus making a gas "richer" than Siemens gas. The exac tion of producer gas depends upon the kind of fuel used and the type o of which there are numerous forms (*see Gas Producers*). The gas m particular form of producer is frequently called by the name or type ducer, for example, "Mond gas," "Dowson gas," etc. Producer gas power plants employing large gas engines; it is also used for firing cer and metallurgical furnaces, and, to a limited extent, for firing steam

The thoroughness with which the gas must be cleaned depends upo pose for which it is to be used. For gas-engine work, it is particularly that no tar should be present. On this account, anthracite coal is used for the production of the gas for this purpose, in spite of the rela cost of such coal.

On the basis of the average figures from both the Bureau of Min Station and commercial plants, the following gas yield and heating va expected per ton (2000 pounds) of fuel as fired.

Fuel	Cubic feet of gas per ton of fuel as fired	B.t.u. per cubic foot of gas	B.t.u. per t as
Charcoal	160,000	135	21,
Anthracite	140,000	135	18,
Bituminous coal	135,000	150	20,
Lignite	72,000	155	11,
Peat	60,000	175	10,

Other Kinds of Gas. — "Oil-gas" is a mixture of gases resulting vaporization of crude oil and superheating the vapor; it is used to in illuminating qualities of water-gas. "Coke-oven gas" is the gas fo by-product in coke ovens. Its properties are intermediate betwee coal-gas and Siemens gas; the composition of the gas, however, varie kind of coal and with the time, changing from the beginning to the process. "Oil-water gas" is produced by the chemical reactions betw and oil heated to a high temperature in closed retorts. The cost of ma is low where oil is cheap. "Blast-furnace gas" is a waste produc furnaces, and is a mixture of CO, CO_2 and N, the latter being the la stituent. The relative proportions of CO and CO_2 vary with the of the furnace. An average analysis of blast-furnace gas cooled to at

), 10 per cent CO_2, 65 per cent N. Coke-oven gas, e gas are all suitable for use in gas engines.

NG VALUE. — The calorific or heating value (*see* of a given quantity of gas is the heat energy devel- tion. In this country, the calorific value of a gas per cubic foot, the volume being measured at 60° F. s of mercury. The total heating value of the gas ity of coal is less than that of the coal (or other In the case of coal-gas, the fixed carbon in the herefore, its calorific value contributes nothing to of water-gas and producer-gas, the carbon in the monoxide, but the heating value of carbon mon- carbon in it, since this carbon is already partially so required to distil the hydrocarbons in the coal sses due to radiation. The calorific value of pro- quantity of coal varies from 55 to 85 per cent of rom which it is made, depending upon the character oducer and the manner of operating it.

HEATING VALUE. — The discharge from a gas nsiderably greater than the boiling point of water, t heat of condensation of the water vapor in the ot available for the production of power, whereas on of the heating value of a gas this latent heat of he difference between the heating value, as deter- urement and the latent heat of condensation of ucts of combustion, is called the effective or net The net (or low) heating value of producer-gas is ver than the gross (or high) heating value. The n generally adopted in this country in reporting

FFERENT KINDS OF GAS. — The following nsidered the average composition (percentage by value of the different types of gases used for illumi- uld be noted, however, that the characteristics of considerably from the figures given in the table, of the coal used and the size and type of producer.

PERFORMANCE OF FLAME ILLUMINANTS. — Light from is due to minute incandescent carbon particles liberated from the gas The highest efficiency is obtained when the migration of these particle hence the pressure at the flame should not exceed two inches of wate flame should be set but little above the smoking point. The horizo distribution from flames is sensibly uniform. The spherical reducti ranges from 85 to 92.5 per cent, depending on the occlusion of light by ner. The batswing and fishtail burners used with ordinary gas should 90 per cent of the rated illuminating power of the gas when properly Acetylene is commonly burned in duplex burners with air holes givi pre-aeration. The usual one-foot acetylene burner gives 40 candle-po

INCANDESCENT MANTLES AND BURNERS. — The incand Welsbach mantle is the ashy residue of a woven structure of vegeta such as cotton, ramie or artificial silk, impregnated with oxides of ce thorium, with traces of other rare earths. The strength of mantle vari with the material and weave of the fibrous base. Its luminous prop pend on the purity and proportions of the oxides used. Mantles are quality chiefly by strength to resist shock, but the better grades ar superior in the maintenance of their candle-power.

The incandescent burner is made in two general types, upright and Each has a Bunsen tube with adjustable gas cock and air inlet. The a action and flame projection of the upright type is fairly self-regulat wide range of gas pressure and consumption. The inverted type ad narrow range of adjustment. The conditions required to obtain th efficiency from mantle burners are : (*a*) all gas and air ports must be adjusted to give the proper air-gas mixture and best projection pressu flame; (*b*) the flame should burn at the highest possible temperature mantle should be completely immersed in the hottest or outer zor flame.

Performance of Mantle Burners. — Candle-power and efficienc are based on lamps fitted with new mantles adjusted to the most efficie tions, this adjustment being, however, of such a character that any on into casual contact with gas lamps is quite competent to make it. Th performance of mantle burners in service is always somewhat below t values and depends to a marked degree on maintenance conditions. deterioration is due to (*a*) the fouling of the burner with dust, (*b*) the adjustment of air and gas ports, (*c*) the shrinkage of mantles and los active materials, and (*d*) the collection of dirt on glassware. Low-grad show very rapid deterioration, often amounting to 40 per cent in 5 R. F. Pierce (*Trans. Ill. Eng. Soc., Vol. VII, p. 686*) reports from relia under most unfavorable conditions, in an atmosphere charged with ir dust and so infested with insects that some of the burner tubes becam clogged the inherent deterioration in candle-power of well-adjusted lamps of the best grade to be as follows: Duration of test, 1000 hours; to mantle alone, 2.5 per cent; loss due to burner alone, 2.5 per cent; lo dirt on glassware, 10 per cent; total reduction in candle-power, 15 Tests of commercial installations receiving skilled maintenance show an performance from 15 to 25 per cent below the rated candle-power and e Without skilled maintenance the average performance is generally fr 50 per cent below rated candle-power and efficiency. (*Proc. Nat. El Assn., 1911, Vol. I, p. 809.*)

It is important to note that the principal sources of deterioration in candle power, as a general thing, are analogous to those operating in

Gas vs. Electricity. — For comparison with the above it may be r under initial laboratory performance conditions for given assumed l watt ratings the operating costs of 100-watt tungsten lamps with 5 cents and 10 cents per kw-hr. are respectively $0.75 and $1.40 pe lumen-hours. Corresponding costs for 250-watt lamps are $0.61 respectively. The advantages of electric lighting are chiefly co flexibility in the size and location of illuminants. The chief disadv electric lighting are danger of shock from abnormal voltages, the fi faulty wiring and the greater likelihood of service interruption. Th high-grade incandescent mantle lamps is a closer approach to daylight of the tungsten lamp, but is considered by many as less pleasing.

ERS. — The various forms of gas producers, of which
, differ chiefly in details of construction and in the
s parts of the apparatus. Two distinct processes of
in use—the up-draft process and the down-draft
purposes these processes are applied by different
ways resulting in the following four general types of

Digitized by Google

(*a*) Up-draft suction producers
(*b*) Up-draft pressure producers
(*c*) Down-draft producers
(*d*) Double-zone producers.

In the suction and down-draft types, the pressure in the gas generat that of the atmosphere. This is also true in at least one of the zo double-zone producer. In these types, the "suction" or draft th producer may be produced by an exhauster or directly by the suction engines which they supply.

In the pressure producer the air and steam are forced through th under a light positive pressure (usually equivalent to from 2 inches to water in the generator space above the fuel-bed).

The double-zone producer is, as its name implies, a combination draft and down-draft principles. Two incandescent zones are maint the gas is withdrawn at the center or waistline of the producer.

UTILIZATION OF BY-PRODUCTS. MOND PROCESS. — is about the only by-product of producer gas which has enough c value to justify the additional expense required to save it. This accomplished by the Mond process, which is the one in most general excess of steam is injected with the air, lowering the temperature an preventing the destruction of the ammonia in the coal. (The pro hydrogen and carbon dioxide in the gas is also increased and the pro nitrogen decreased.) The gas, after passing through a mechanical s caused to pass through a tower where it is thoroughly washed w sulphuric acid. The ammonia in the gas combines with the sulp forming ammonium sulphate. This acid solution of ammonium sul culates through the tower over and over again until it reaches a given saturation; then a certain amount of it is by-passed out of the s fresh acid is added. In this system, the heat energy lost by the gas is also used to preheat the air which is used in generating the gas a considerable increase in the economy of the process. From a t containing not less than 1.3 per cent nitrogen, it is possible to pro 90 pounds of sulphate of ammonia and from 140,000 to 160,000 140 B.t.u. gas.

RATING AND PERFORMANCE. — A gas producer is usuall horse-power, the rating being the number of horse-power which can be by gas engines supplied from the producer when the latter is gasi at a maximum rate. Such a rating is, of course, indefinite, as developed by the engines depends upon their design and the perc load which they are carrying, and the rate of gasification depends quality of coal and the care taken in firing. The following dat results of a series of tests on bituminous coal and lignites mad U. S. Geological Survey at St. Louis on a 250-horse-power Taylor and a three-cylinder vertical Westinghouse 235-horse-power ga These tests are summarised in a paper by R. H. Fernald in the *J Soc. Eng., 1907, Vol. 12, p. 551.* The table on page 625 is derived curves there given.

All items in this table affected by load factor are given only for loa from 90 to 100 per cent of full load (235 brake horse-power). The wei per horse-power-hour does not include the coal required to produce injected into the fuel bed. The efficiency is based on calorimetric meas no deduction being made for the latent heat of condensation of the w in the products of combustion of the gas.

COSTS (Pre-war figures). — The following approximate formu of producer-plant equipments have been derived from a large numb installations. They include the purchase price of generators, eva the necessary scrubbers and filters, but do not include erection, foundations; P is the horse-power rating of the producer.

Up to 250 horse-power..... $\$500 + 10 \times P$
250 to 1000 horse-power... $20P - \$2000$

The cost of such plants erected including producer equipment, and foundations averages from \$80 to \$110 per rated horse-power, buildings, for plants up to 250 horsepower. Plants from 1000 to power average about \$70 per horse-power, including buildings.

Gas holders..... $\$1000 + \$0.26 \times$

Detailed manufacturers' estimates of investment cost and cost of twenty-six producer plants are given in the paper by Mr. Fernald *Soc. Wes. Eng., 1907, Vol. 12, p.551.*

contact will be twice as great as in an ordinary gear, which will inc strength of the gear and its smoothness of action.

Twisted Teeth. — If a great number of very thin gears were placed one slightly in advance of the other, they would still act as a step Continuing the subdivision until the thickness of each separate gear tesimal, the faces of the teeth instead of being in steps take the form or twisted surface, and we have a twisted gear. The twist may take a and if it is in one direction for half the width of the gear and in the direction for the other half, we have what is known as the herring double helical tooth. This form of tooth is much used in heavy m practice, where great strength and resistance to shocks are necessar are frequently made of steel castings. The angle of the tooth with a lin to the axis of the gear is usually 30 degrees.

Spiral or Helical Gears. — If a twisted gear has a uniform twist i what is commonly called a spiral gear (properly a helical gear). Th which the pitch surface intersects the face of the tooth is part of a he on the pitch surface.

Pitch Angle. — The pitch angle of a helical gear is the angle the center line of the tooth and a line perpendicular to the axis of the

Screw or Worm. — A spiral wheel may be made with only one hel wrapped around the cylinder several times, in which it becomes a worm. If it has two or three teeth so wrapped, it is a double- or triple screw or worm.

Worm-Gearing. — When the axes of two spiral gears are at rig and a wheel of one, two or three threads works with a larger wheel threads, it becomes a worm gear, or endless screw, the smaller wheel being called the worm, and the larger, or driven wheel, the worm whe this arrangement a high velocity ratio may be obtained with a sing wheels. For a one-threaded wheel the velocity ratio is equal to th of teeth in the worm wheel. The worm and wheel are commonly so co that the worm will drive the wheel, but the wheel will not drive the wo

Differential Gearing. — Various forms of differential gears are us object is to devise a motion such that the velocity ratio is equal to th the number of teeth in one gear wheel to the *difference* between the of teeth in this gear wheel and the number of teeth in the other wheel form of differential gearing one wheel meshes with a set of teeth on of a second wheel. The second wheel is so arranged that it cannot tu its own axis but its center is caused to move in a circle concentric with wheel.

But for the limitation that the difference between the wheels mu too small, the possible ratio of speed might be increased almost ind and one pair of differential gears made to do the service of a whole train If the problem is properly worked out with bevel gears this limitation completely set aside, and external and internal bevel gears, differing single tooth if need be, made to mesh perfectly with each other.

DESIGN OF GEARS. — In order that the teeth of wheels an may run together smoothly and with a constant relative velocity, it is that their working faces shall be formed of certain curves called c The essential property of these curves is that when two teeth are in co common normal to the tooth curves at their point of contact must pas the pitch point, or point of contact of the two pitch circles. Two su are in common use — the cycloid and the involute.

TERNATING-CURRENT. — (*See also Alternat-d Magnetism, Principles of; Generators, Direct-Current; Rules.*) In all dynamo-electric machines of the usual polar) the electromotive force induced in any one con-ue and alternates in direction. If the terminals of any rought out to an external circuit by means of revolving an alternating current will flow in the circuit. In order uous current it is necessary to add a commutato. or rec-le and elementary form of electric generator is an alter-nd the direct-current generator is a special form adapted nutator to give a continuous or unidirectional current.

– Alternating-current generators may be classified erent distinguishing characteristics. The following se characteristics in the order of their prominence.

ors. — In the synchronous type the action of inducing sults from the relative motion of the armature con-nagnetic field produced by exciting coils in which a nt flows. The frequency of the alternating electro-ectly on the number of field poles and the angular part.

. — In the induction type the magnetic field is of the and is produced by polyphase alternating currents gs with the load current. The mechanical construc-nduction motor with a short-circuited polyphase wind-per. The frequency depends upon the characteristics n practice the frequency is determined or "set" by a er generator or motor, in the external circuit. This ssary to supply the exciting current of the induction eans of the frequency setter the power factor of the qual the inherent power factor of the generator.

Disadvantages of Induction Type. — A minority of be of the induction type with advantage as they will ts in case of a short circuit on the system. Their current is less. A certain number of the units must pe to "set" the frequency and supply the exciting machines. Consequently, if there is a large propor-s the synchronous machines operate at a poor power capacity effect in the load system, such as synchronous

Revolving-armature Types. — In the revolving-e type there are two, or some multiple of two, poles, coil for the direct-current excitation, and the flux in and purposes constant in value. The relative move-nductors causes the variation in flux interlinkages nsity.

re constructed with an armature revolving inside a s and voltages increased it was found that a more rial could be obtained by making the armature the at the insulation of the high-voltage member was ember was kept stationary.

enerators of large capacity (500 kilowatts and greater) volts and up) are made of the revolving-field type.

the inductor type the direct-current excitation is con-stationary) coil and the variation in magnetic flux is

Digitized by Google

obtained by revolving a spider with bare projecting poles which a reluctance of the magnetic path. Thus the flux-threading any armature coil is always in the same direction, but varies in intensity o

Comparison of the Inductor Type with Revolving Field or R Armature Type. — There are no windings or insulation on the moving of the inductor type, which is therefore adapted to high speeds. Th variation in the reluctance of the main magnetic path and the consequ tion in magnetic densities in the field structure of the inductor causes eddy currents, hence the construction of this type has been aband machines of large power. It is still used for radio work however. S *Communication*.

Single Phase, Two Phase or Quarter Phase and Three P The single-phase generator is usually about 30 per cent heavier and mo than a polyphase generator of the same rating. By changing the armature connections a polyphase machine may frequently be recon be a three-, two- or single-phase machine.

As transmission by three-phase currents is more economical of cop by two-phase or single-phase currents, all power transmission lines a phase. Consequently unless there is some local condition requiring two phase, the three-phase generator is preferable.

Two-phase and three-phase generators of the same capacity and strain are of practically the same dimensions, weight and cost.

Trade Terms. — It has become almost universally the custom t an alternating-current generator as *ASB*, *AQB* and *ATB;* the *A* sta alternator, *S* for single phase, *Q* for quarter phase, *T* for three phase a revolving field.

Separately-excited and Self-excited Types. — For years it was a to develop a satisfactory and simple self-excited alternator and some v sucessful but not simple. The object was to obtain a constant voltag load by means of automatic self-excitation. However, with the perf the automatic voltage regulator the need for automatic self-regulatio and there is now very little demand for self-excited alternators.

METHODS OF RATING. — All a-c. generators are rated in amperes (kv-a.) and unless otherwise specifically stated are rated at t which they will give continuously with a rise in temperature not excee tain values depending upon the character of the insulating materials *Standardization Rules A.I.E.E.*

Machines, or those parts of machines, insulated with mica, asbestos heat resisting material are allowed a rise in temperature of 70° C. as by thermometer, or 75° if measured by resistance. This includes mo alternators, both armature and field, and the fields of many other alte

Machines, or those parts of machines insulated with varnished ca impregnated cotton or linen, are allowed a rise of 50° C. as measured mometer, or 55° if measured by resistance. This includes the arm most slow and moderate speed machines.

Most machines have their fields designed sufficiently liberally to ena to give their rated kv-a. at 80 per cent power factor with rated volt this is stated in the specifications. It should be noted that the heati *armature* depends upon the kv-a. and not upon the kilowatt load. T the power factor of the load connected to the alternator, the gre heating of the *field coils* for the same kv-a. output.

VOLTAGE. — Alternators are now built to generate voltages up t and 15,000 volts between lines, either single phase or polyphase. Al

T POLE GENERATORS. — The procedure in
rrent generaotr for a given power output, voltage
n requirements regarding regulation, efficiency, etc.,
tly empirical. The data of four specific designs are

Digitized by Google

given below in the section on *Examples of Design and Performance*. Th of procedure is to lay out a preliminary design from rough calculations, the performance of this design, modify the preliminary design where t lation indicates, recalculate the performances, etc., until a design is a which meets the given requirements.

Definitions. — The following terminology is used in the discussi design of generators:

Pole Arc. — The arc subtended by one pole face, measured periphery of the armature; in the following discussion it will be exp inches.

Pole Pitch. — The arc measured along the periphery of the from the center of one field pole (N-pole, say) to the center of the pole (S-pole); in the following discussion it will be expressed in inches.

Ampere Conductors per Inch of Armature Periphery. — T uct of the number of conductors per inch measured along the periphe armature by the effective amperes flowing in each conductor.

Slot Pitch. — The distance in inches measured along the periphery between the centers of two adjacent slots. The slot pitch to the pole pitch divided by the number of slots per pole.

Coil Pitch. — The number of slots spanned by a coil; that is, has one side in slot number 1, and the other side in slot number 7, the the coil is $7 - 1 = 6$. A coil which spans a distance exactly equal to pitch is said to have a "full pitch," but if it spans a lesser distance to have a "fractional pitch." For example, if there are six slots per a coil has one side in slot number 1, and the other side in slot numbe said to have a fractional pitch of $\frac{5}{6}$ or $\frac{4}{6}$.

Leakage Factor. — The ratio of the flux per pole which enters t ture core to the total flux (including the leakage flux) which would be p by the field winding.

Preliminary Calculation of Main Dimensions. — *Let*

P_0 = output in kilovolt amperes (kv-a),
ρ = ratio; pole arc divided by pole pitch,
B = average magnetic flux density per square inch in air gap,
σ = ampere-conductors per inch of periphery,
V = peripheral velocity in feet per minute at gap,
D = diameter of armature in inches,
L = length of armature along shaft in inches,
N = revolutions per minute,
p = number of poles,
f = frequency in cycles per second,
$A = D + p$.

Then the following relation holds for either a single-phase or a p machine, other than turbo-alternators:

$$P_0 = \frac{\rho\sigma BVDLk_2k_3}{144 \times 10^9},$$

Five of the six design constants in the right-hand member of this equa subject to choice; the equation then fixes the sixth constant. The c the values of the various constants should be based upon modern prac idea of which is given below in the following paragraphs. For values constants k_2 and k_3 see the section below on *Predetermination of Perform*

For turbo-generators see section below on *Design of Turbo-alternators*.

number of field poles is related to revolutions per minute N and the f by the formula

$$f = \frac{Np}{120}, \quad \text{or} \quad p = \frac{120f}{N}.$$

Hence when the frequency and speed are both given, the numb is fixed. When N is not given, but L is assumed approximately eq as above, the number of poles is found, when D has been determi the relation

$$p = \frac{D}{A}.$$

A value of A must of course be chosen such that p is an even num speed N is then obtained from the relation

$$N = \frac{120f}{p}.$$

Armature Windings. — While there are many forms of armature which may be used, there are practically only two forms that are i use in this country. These are the "Chain Winding" and the "Lap W

Chain Winding (Fig. 1). — This winding is characterized by number of coils equal to half the number of slots; that is, there is only of a coil in each slot. The coils may be either form wound and insulated, in which case slots with open faces are required; or they may be wound by hand in place, in which case partly or entirely closed slots may be used.

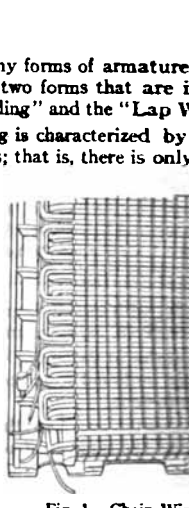

Fig. 1. Chain Win

There are at least two kinds of coils in each machine. These are characterized by the shape of their end connections, as these end connections lie some in one plane and some in another. If there is more than one slot per pole per phase, there must be four different shapes of coils, having two different pitches; the coils of any one phase per pole are placed concentrically. The chain winding is most generally used in high-voltage machines, 2000 volts or higher.

Lap Winding (Fig. 2). — This winding contains a much larger number of coils, all of the same form and size may be two, four, six, etc., sides of coils in each slot, the coils being placed side by side two coils deep. This winding is similar to the multiple-drum winding of a direct-current armature. With two coil sides per slot the slots must be open, but with more than two coil sides per slot the slots may be partly closed. This type of winding is satisfactory for low voltages and very convenient if there are a large number of slots per pole.

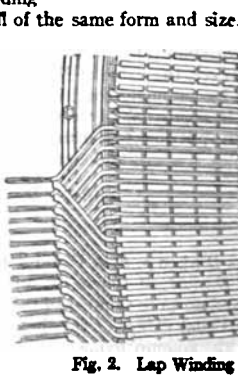

Fig. 2. Lap Winding

The coils are connected in groups of 2, 3, etc., per pole per phase, depending upon the slots per pole per phase. Successive groups or poles of the same phase are connected in series or multiple by "pole connections."

Preliminary Dimensions of Magnetic Circuit. — The diameter of the armature and the axial length of the pole face for the preliminary design are fixed by the above calculations There remain to be determined the air gap, the dimensions of the armature teeth, the length and radial depth of the iron, the dimensions of the field poles, and the dimensions of the fi Preliminary values for these quantities may be arrived at as indicat

Air Gap. — The minimum clearance between armature core and field poles in modern generators is given in the accompanying table. The average length of the air gap, due to the chamfer on the poles, is about 25 per cent greater.

Armature Diameter, in.	M air
40	
80	
120	
160	
200	
240	

Armature Teeth. — The dimensions of the armature teeth depend upon the number and dimensions of the slots, which in turn must be such as to contain the necessary conductors. Another important limitation to the width of the teeth, however, is the value of the magnetic flux density therein. Let s = pitch of slots, a = pole arc, g = average radial depth of air gap. Then the effective numbe under each pole is $(a + 2g) \div s$. The effective width of the tooth is its a section one-third the distance from its minimum width towards its width. The effective axial length of the teeth is approximately equ of the axial length of the pole face L determined above. From t the effective cross section of the teeth perpendicular to the flux determined, and this divided into the total flux per pole ϕ gives th flux density in the teeth. The value of ϕ from the preliminary ca above is $\pi\rho LDB \div p$, where ρ = ratio of pole arc to pole pitch, D = di armature at gap, B = average magnetic flux density in gap, and p = poles. The average flux density in the teeth in modern alternatin generators ranges from 90,000 to 110,000 lines per square inch.

Armature Core. — The axial length of the armature core slightly greater than the axial length of the pole face. A fair all twice the radial depth of the air gap. The core is usually built up steel punchings, 14 mils thick, the punchings having received pre thin coat of varnish. Ventilating ducts from ⅜ to ½ inch in width (along the shaft) are usually provided, these ducts dividing the core tions from 2.5 to 3 inches thick (measured along the shaft). The axial length of the armature iron is therefore the total length of the core less the space occupied by the air ducts and insulation between p This latter is about 10 per cent of the net length after deducting occupied by the air ducts.

After the excitation in ampere turns per pole required for various power factors desired (according to the specifications or the service re the generator) has been determined, that condition of operation whicl the greatest number of ampere-turns F is selected. A field winding v give this excitation and a margin for safety, with the exciter voltage is then designed. Using this value of F and a current density of 1000 per square inch, the cross section of the field winding is $1.4\,F + 1000$ w of insulated wire, or $1.15\,F + 1000$ when made of insulated strip. The the coil will be $c - 0.75$ (see Fig. 3), allowing $\frac{5}{8}$ inch at each end for and insulation. Therefore the depth of winding will be for wire $\delta = 1.4$ $(c - 0.75)$ + thickness of spool on which the wire is wound, or $\delta = 1.15$ $(c - 0.75)$ + thickness of spool. The spool is usually 0.25 inch thick.

The radiating surface of the coil is then

$$A = 2\,c\,(f + b + 4\,\delta).$$

Resistance and Temperature Rise of Field Winding. — in temperature per watt radiated per square inch of surface of a fiel pends on the peripheral speed of the revolving field or revolving armature. The accompanying table gives the temperature rise in degrees centigrade per watt radiated per square inch. For other rates of radiation the temperature rise is proportional. Let w = watts radiated per square inch for the assumed temperature rise (usually 45° C.), A = area of radiating surface, then the allowable loss per pole is wA; and the field current is then $I_f = wA + v$, where v = volts per pole. The volts per pole should be taken as 80 per cent of the exciter voltage divided by the number of poles (all field spools in series), allowing 20 per cent for emergencies (low speed, etc.). The number of field turns per pole is then $t = F + I_f + 0.5$, the half turn being a convenience in connecting up. The proper resistance (r) of the field w then $wA + I_f^2$, and the necessary cross section (q) of the conductor i inches is

ntering the armature is

$$\phi = \frac{E \times 10^8}{4.44\, k_1 k_2 k_3 f S}.$$

(k_1). — This constant is proportional to the form
n around the periphery of the armature. In all
s are so shaped that this distribution is practically
= 1. This is usually done by making the air gap
t the center of the pole.

Digitized by Google

One method of doing this is to make the outline of the pole face a
circle of such a radius (less than the radius of the armature in rev
machines) that the gap at the tips is twice the gap at the center.

For very accurate predeterminations the distribution of the flux
calculated. (*See S. P. Thompson, Dynamo Electric Machinery, Vol.
C. A. Adams, Trans. A.I.E.E., Vol. 33.*)

Winding Distribution Constant (k_2). — This constant all
fact that if there is more than one slot per pole per phase, the co
the various slots of one phase under a pole do not generate e.m.f.'s
the same phase. Since the slots pass under the pole consecutively
of the conductors reach a maximum consecutively. These e.m.f.'s
fore be combined vectorially and not merely added together. k_2
in single-phase, two-phase and three-phase machines.

The following table gives the values of k_2 for uniformly distribute
with equally spaced slots.

Slots per pole	Value of k_2		
	1 phase	2 phase	3 phase
1	1.000	.....	.....
2	0.707	1.000	.....

18	0.64	0.90	0.960
24	0.635	0.90	0.958
∞	0.632	0.90	0.958

These constants apply to a winding uniformly distributed around
ture periphery. This is always the condition in a two- or three-pha
A single-phase machine usually has its working winding irregularly
so the above constants are only of theoretical interest. (*See special
single-phase machines below.*)

Pitch Constant (k_3). — It is sometimes desirable to use coi
fractional pitch, particularly in machines of large pole pitch, in or
copper and I^2R loss, and also in any machine to give a particularly
shape. When this is done each turn connects in series two conductors generating e.m.f.'s which are not in phase and their resultant is therefore not as great as their arithmetic sum. The constant k_3 is the ratio of this resultant or vector sum to the arithmetic sum of the two e.m.f.'s. The relation between k_3 and winding pitch expressed as a percentage of the pole pitch is given in the accompanying table.

Prepare a table like the following:

Part	Flux	Cross section, A	Flux density = flux/A	Ampere turns per inch, m *	Length of path, λ
Field yoke....	$0.5\ v\phi$	de	.....	.....	i
Field pole.....	$v\phi$	$0.95\ bf$	.....	.....	c
Air gap.....	ϕ	af	.....	.....	See below
Arm. teeth....	ϕ	See below	.....	.....	n
Arm. core.....	$0.5\ \phi$	kl	.....	.....	k

* The value of m is found from the B–H curves in the article on *Magneti* when the flux density has been calculated.

Field Yoke. — The field yoke carries only half as much flux piece, as the flux divides at this point. The material is usually cast i steel. Find the magnetic density as indicated and refer to the proper tion curve to find the ampere-turns magnetizing force per inch for t (see Fig. 4). The length of path is one-half the distance from th one pole to the center of the adjacent pole and is shown by i in Fig the total ampere turns as indicated.

Field Pole or Magnet Core. — This carries all the flux. T is usually sheet steel of high permeability, but sometimes solid steel The factor 0.95 is used for laminated steel poles; for solid poles this course unity. The length of this path is usually taken as c, the le space for the field spool. This is not strictly accurate, but the den pole shoe (c_2) is so low that the excitation required for this part is n

Air Gap. — All the flux in the pole piece does not cross the ga leaks across the interpolar space. The value of the flux in the gap is same as the useful flux in the armature. For the area of gap sectio tection (af) of the pole shoe is taken. The length of the path in the taken as the mean of the gap length. As the maximum length (a tips) is usually made twice the minimum, and the outline of the p made the arc of a circle, the average length is usually 1.25 times the The ampere turns per inch are $0.313 \times$ (density per square inch).

The total ampere turns calculated as above indicated is sometimes by a constant (0.9 to 1.1), to allow for the spreading of the flux into t

Armature Teeth. — The flux is confined at any one time t portion of the teeth per pole known as "teeth under one pole." Sin spreads somewhat on leaving the pole piece it is logical to assume th up a peripheral length equal to the pole arc plus twice the length of t If, therefore, this length is divided by the pitch of teeth at the periph armature, the quotient is the average number of teeth carrying fl given instant. This figure may quite properly contain a fractional teeth. The teeth being wedge shaped or sectors of a circle, that cr (not the mean cross section) which will give the average excitation must since saturation increases more rapidly than the cross section decrease approximate value is found at a point one-third the distance from the width towards the maximum width.

The effective cross section of the teeth is then equal to this width by the product of the effective length of the core by the number of

The corresponding reactance is $2\pi fL$, where f is the frequency in second.

There are several paths for this so-called armature leakage flux surrounding one or more slots, namely, the path around each slo around a group of slots of one phase, the path around the end The effect of the flux of one phase on the conductors of another (m tance) must also be considered.

The slots lying under a pole have a path of greater permeance lying opposite the interpolar space or between poles, as the form completely surrounded by iron.

With the exception of the path around the end connections, the of each path is readily calculated by the same process as used above ing the leakage factor. The path around the end connections is and the permeance so small compared with that in the core proper, that it is convenient and sufficiently accurate to add a percentage for this flux. This is done by allowing for every inch of the projecting length of the end connections one-tenth as much flux or inductance as for an inch of the embedded portion of the conductors.

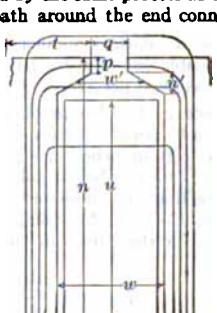

FIG. 4. Leakage Flux

In calculating the permeance of the various paths only the length of the path in air is considered, as the reluctance of the path in iron is so small compared to the path in air as to be negligible.

Let l = effective length of armature core; l' = length of end conn end); P_1 = the total permeance of all the leakage paths for a slot u piece; P_2 = the total permeance of all the leakage paths for a slot tween two poles, and the other quantities as in Fig. 4. Then

$$P_1 = \left(\frac{u}{3w} + \frac{n'}{w'} + \frac{p}{q} + \frac{t}{2g}\right)\left(l + 0.1\,l'\right)$$

$$P_2 = \left(\frac{u}{3w} + \frac{n'}{w'} + \frac{p}{q} + \frac{t}{t+q}\right)\left(l + 0.1\,l'\right)$$

In addition to the above symbols, let f = frequency in cycles per se the slots per pole per phase; s' = slots in series per phase; c = eff ductors per slot = 2 × (turns per phase)/slots per phase; k_2 = "pitch (*see above*). Then the effective reactance in ohms per phase corres the permeance P_1 is

$$x_1 = 20.1 f p' c^2 s' k_2 P_1 \times 10^{-8},$$

and corresponding to the permeance P_2 is

$$x_2 = 20.1 f p' c^2 s' k_2 P_2 \times 10^{-8}.$$

For reactance of turbo-generators see p. 658.

Reactance Drop.— For preliminary or approximate calcula better and more conservative to use the value found for the induct slots "under the poles," as this gives a greater reactance and voltag as the poles usually cover about two-thirds of the armature periph

gulation.

Digitized by Google

A reasonable value for armature reaction would be between 150 ampere turns per pole for a 25 cycle machine and between 1000 and 60 cycle machine.

Synchronous Reactance. — The effect of the armature leakag and armature reaction upon the terminal voltage of a generator at excitation are of like character, since the voltage induced in the armat each of these causes is in quadrature with the current. The "s reactance" of a generator is the equivalent reactance which would same effect as the armature leakage reactance and armature reactio

The synchronous reactance may be predetermined by finding th ampere-turns (from magnetization curve) corresponding to a volta the drop due to leakage reactance and adding to these ampere turns ture reaction ampere turns. The voltage from the magnetization c sponding to this sum divided by the armature current per phase synchronous reactance per phase. In the calculation of regulat "magnetomotive force method" (see below), however, it is more co express the synchronous reactance in terms of the excitation ampe overcome it.

Regulation. — The regulation of a generator machine is defined of the difference in terminal voltage at no load and at full load to t voltage, the field excitation being kept constant at its full-load value. as a percentage the regulation is $100(V_0 - V) \div V$ where V is t terminal voltage and V_0 the no-load terminal voltage at full-load field

Two different methods have been employed for the calculation of one known as the "magnetomotive-force" method, and the other a tromotive-force" method. Both are approximations, the first giv lower than the actual value, and the second a value higher than value. More accurate methods are given in the *Standardisation R A.I.E.E.*, which see.

Magnetomotive-force Method. — One way in which this been applied is the following: Let V = terminal voltage per phase a R = alternating-current resistance per phase in ohms (= 1.15 ti current resistance); I = full load amperes per phase; $\cos\theta$ = powe the load; X = leakage reactance per phase in ohms. Calculate

$$V' = \sqrt{(V\cos\theta + RI)^2 + (V\sin\theta + XI)^2} \quad \text{and} \quad \theta' = \tan^{-1}\left[\frac{V\sin}{V\cos}\right.$$

taking θ' positive for I lagging behind V'. From magnetization cur excitation ampere turns corresponding to V' and let n = armature reac turns per pole for current I (see p. 635). The total field ampere-tu

$$F = \sqrt{m^2 + n^2 + 2mn\sin\theta'}.$$

Let V_0 = voltage per phase from the magnetization curve correspon excitation F; then the regulation is

$$100\,\frac{V_0 - V}{V}.$$

The difference between V' and V and between θ' and θ is usually and in preliminary calculations m may be taken as the excitation ar corresponding to V, and θ' may be taken equal to θ.

Electromotive-force Method. — Let V = terminal voltage at full load; R = alternating-current resistance per phase in ohm ceding paragraph); XI = volts per phase from magnetization curve

equired to send full-load current through armature
ent; I = full-load amperes per phase; $\cos\theta$ = power

flux is set up which will cause eddy currents in these conductors, if th well subdivided, and in the surrounding iron; as well as a hysteresis surrounding iron. The loss due to this load flux is called the "load l

The load loss is a function of the leakage flux and the subdivision ductors. A large number of turns of fine wire will involve a very If the conductors must be large, they may be made of stranded cab to shape. It is almost impossible to calculate this loss, and very measure it. A rough method is to assume the resistance per phase in 15 per cent, as this loss. like the true copper loss, is proportional to the the armature current. The total amount of the loss is less than 1 p the input in well-constructed machines.

Efficiency. — Let P = total output in kilowatts; R_a = resistance of armature; I_a = armature amperes per phase; R_f = resistance p field winding; I_f = field current; q = number of phases; p = numbe C = total core loss in kilowatts; and F = friction and windage loss in Then the per-cent efficiency is

$$\frac{100\,P}{P+C+F+(1.15\,R_a q I^2_a + p R_f I^2_f)\times 10^{-3}}.$$

This assumes the load loss equivalent to increasing the armature (as calculated or measured by direct current) by 15 per cent. If th is determined from the short-circuit core loss the formula for efficien

$$\frac{100\,P}{P+C+F+L+(R_a q I^2_a + p R_f I^2_f)\times 10^{-3}},$$

where L is the load loss in kilowatts.

The efficiency is a maximum for that load at which the constant equal to the variable losses.

Customary values for the efficiency at full load and each of the los load for various sizes of generators are given in the following tabl values are merely indications and vary with the frequency, voltage, sp factor, etc. A 60-cycle low-voltage machine will be likely to have a ciency than a machine of the same rating for 25 cycles or high voltage

EFFICIENCY AND LOSSES, USUAL VALUES

Rating, kv-a.	Efficiency, per cent	Friction, per cent	Excitation, per cent	Core, per cent	Ar

10,000	97.2	0.5	0.35	1.5	

* Copper and load loss.

Heating. — The rise in temperature of the field coils is ascertai incidental step in the calculation of the field winding as explained

The rise in temperature of the armature is best determined by given by Arnold (*see Wechselstromteknik, Vol. IV, p. 141*). In thi tion the losses in the projecting portions of the end windings are assu

ated by the end windings while the core loss and copper loss in that portion the winding embedded in the slots are radiated by the surface of the armature core. Let L = length of armature iron in inches; λ = mean length of nature turn in inches (*see Armature Resistance, below*); R_a = armature resistce per phase in ohms; I_a = armature amperes per phase; D_1 = outside diter of armature punchings in inches; D = inside diameter of armature chings; s = number of ventilating ducts; q = number of phases; t = rise in perature in degrees centigrade per watt radiated per square inch of surface. he the watts to be radiated are

$$P = \text{core loss} + \frac{2LqR_aI^2_a}{\lambda},$$

d the radiating surface, including only one-half the area in the air ducts, as e sides of the air ducts are not as effective as the rest of the surface, is

$$A = \pi L(D_1 + D) + \frac{\pi}{4}(D_1^2 - D^2)(2 + s).$$

e rise in temperature by resistance in degrees centigrade is then

$$T = \frac{Pt}{A}.$$

e value of t for a well-ventilated stationary armature ranges from 30 to 40, pending upon the thickness of coil insulation, and the peripheral speed of e field. For a stationary field and revolving armature the value of t given ve for the rise in a revolving field may be used.

Checking Calculations. — Substitution in the following formula gives an ellent check on the above calculations:

$$\frac{DL_f}{Q} = \frac{KA \times 10^8}{fB_g na},$$

here D = diameter of rotor at gap in inches; L_f = length of pole face parallel shaft; Q = total kv-a. of generator; f = frequency in cycle per second; = armature-reaction ampere turns; a = pole arc in inches; A = diameter pole in inches; B_g = flux density, lines per sq. in. in air gap; and K = 22.5 single-phase and 15.9 for two-phase or three-phase generators.

SINGLE-PHASE GENERATOR. — Single-phase generators do not make effective use of the material as do polyphase generators, for the reason that e armature winding can occupy effectively only about one-half of the peripheral surface of the armature; if it occupies more than this there will be voltes generated in the windings which are so out of phase with each other that e resultant voltage is only from 63 to 70 per cent of the sum of all the voltages nerated.

Therefore, if a polyphase generator is used as a single-phase machine with the ame magnetic densities and the same copper densities, the output will be much ss on account of the lesser voltage available. It is, therefore, customary to verload the magnetic elements of the machine somewhat to raise the voltage nd thus reduce the overload on the copper which would be necessary to get he desired output. However, if both the iron and copper densities are increased until the machine gives as much output single phase as it is intended to ive polyphase, there will be an increased heating. Thus, for the same heating, btained by a readjustment of the iron and copper losses, a machine of a given irst cost will give about 75 per cent as much output single phase as may be btained polyphase.

In addition to the disadvantage of a single-phase generator that it cannot

make use of all the periphery of the armature, it also labors under t vantage that its armature reaction is pulsating instead of constant, introduces an additional loss in the form of eddy currents.

By using two phases in series of a three-phase machine, or one phase phase machine, a fairly good single-phase machine is obtained. By the winding slightly differently the same number and arrangement of (or coil sides) can be connected up to give a simpler winding requiring ings of coils, that is, a winding "in one plane."

The formula for the calculation of the e.m.f. of a single-phase ge $E = 4.44\, k_2 k_3 f S \phi\, 10^{-8}$, where the symbols, with the exception of k_2, same significance as in the formula for polyphase machines, p. 629. The value of k_2 depends upon the portion of the armature periphery (including the teeth between slots) occupied by the main winding. Let A = this fraction of the armature surface, then the corresponding values of k_2 are given in the accompanying table. The value of A corresponding to a uniformly distributed winding is unity.

A	
1	
¾	
⅔	
½	
⅓	

The average value of the armature-reaction ampere turns per pole of a single-phase machine is SI/p, where S = the number of turns, I = the armature current per phase, and p = the number of poles, but this pulsates between 0 and twice the above value. The evil effects of sating may be reduced by employing a short-circuited winding havi at 90 degrees to the main field winding. A squirrel cage or "am winding in the pole faces is frequently employed for this purpose.

Due to this pulsating action the load losses are greater and this taken into account in calculating the efficiency and regulation by c the effective armature resistance as 1.15 to 1.5 times the direct-curr ance.

The leakage reactance of a single-phase machine pulsates betwee equal to that obtained by the formula above in the paragraph on *Leakage Reactance*, and a value two-thirds as great. Satisfactory r obtained by multiplying the value obtained from the formula by 0. effective single-phase value. In this case the whole winding is con one phase.

DESIGN OF TURBO-GENERATORS. — In turbine-driven the steam turbine is usually built by the same company that build erator, and the two machines are practically one unit. The steam t developed to such an extent that for a given capacity in power it weigh a reciprocating engine, occupies much less space, costs less and is more cal of steam and fuel. Good economy in steam turbines, however, i only with high angular velocities. This has made it difficult to appl bine to useful purposes. The electric generator has shown itself to b suitable device to absorb the power of the turbine and make it availa divided form and at convenient speeds for general application. H required many years of experience to develop an electric generator wh operate successfully at the high angular velocities suitable for direct to the steam turbine. The principal difficulty was the design of a co which would withstand the enormous stresses in the revolving mem resulted from the centrifugal force. Thus the design of the machine is largely a question of the type and construction of the rotor, wh field.

d. Laminated pole pieces attached to a spider by keys. (These are being built although there are a large number in service.)

In these revolving fields the length is about the same as the diamet large machines the length is greater than the diameter. The air ga one to two inches. A uniform air gap is necessary to prevent noise an

Construction of Stator. — Since the pole pitch is large, a large n slots per pole is used (12 to 24) and this gives a low armature self in and high short-circuit current. Due to the long pole pitch the end co are long and subjected to considerable mechanical forces, as a resu leakage flux. They must, therefore, be held securely in place by non supports. For armature reaction in ampere-turns per pole values of f to 20,000 are common, and the field winding is usually of a capacity times the armature ampere-turns. The regulation is poor (20 to 30 This defect is readily overcome by the use of automatic voltage regul *Regulators*). The current density in the copper (2000 amperes per squ is lower than in slow speed machines, while the constant "ampere co per inch periphery" has high values, viz., 600 to 1500.

Provision for Ventilation. — The ventilation of these machines is similar to that of air-blast transformers. Thus there must be provi sufficient air to carry off the heat generated with a reasonable rise in ten of the machine and the air; (*b*) Ample duct capacity to prevent too hig of the air; (*c*) Proper spacing of the ducts so that there is no part very an air duct; (*d*) Proper precautions to prevent the air from carrying moisture into the machine.

One hundred cubic feet of air per minute at 20° C. will carry off 1 k rise in the temperature of the air of 18° C. Velocities of the air of fro 6000 feet per minute are common in the machine proper. The surfa will give off 4 or 5 watts per square inch with a rise of 35 to 45° C. a cooling air.

There are two methods of ventilation, the "radial" and the "ax Figs. 7 and 8. In the radial method air enters the air gap at both ends

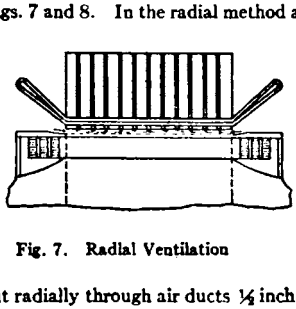

Fig. 7. Radial Ventilation

Preliminary Calculation of Main Dimensions. — Equation (1), page 634, applies, but customary values of some of the constants are quite different for reasons stated above.

ρ is usually unity with distributed windings.

B, the average density in air gap varies from 25,000 lines per square inch in 60-cycle machines to 32,000 in 25-cycle machines. Maximum density is 1.57 times the average.

V, the peripheral velocity, varies from 15,000 feet per minute in small, low frequency machines to 27,000 in large machines, figured at the surface of the revolving field.

σ, the ampere conductors of the armature per inch periphery of the field, must be figured on the same diameter as V in order for the equation to check. σ has values as in Table I.

Digitized by Google

D = outer diameter of field, in inches.
L = total length of field parallel to shaft, in inches.
k_2 and k_1 the same as on page 634.

Connection of armature winding may be single-phase, two-phas phase Y, or three-phase delta. For all three-phase machines for m 6600 volts, the Y-connection is usually employed, for the reasons given 642.

Number of Turns in Series per Phase (S) is found as on page preliminary value.

Armature Reaction Ampere Turns (n) per pole is found as per fo page 647, and is an important criterion of design in turbo-generators very close to the values given in Table I.

Number of Slots and Conductors per Slot are determined by t the turns in series by the relation

$$2QS = cs,$$

where Q is the number of phases, S the turn in series, c the conductor and s the total number of slots. With values of $2QS$ set, values of 1, 2, 4 and any other even number are tried until the combination w most nearly satisfy the equation is found. s must be divisible by the of poles and the number of phases, in order to make a conventional Usual values for s are given in Table I.

Size of Armature Conductor. — For preliminary purposes, a curren of 2000 amp. per square inch may be assumed, which divided into th per phase gives the cross-section of one "effective" conductor in squa By "effective conductor" is meant the conductor which carries t current per phase. On account of the large currents in large mach frequently advisable to divide the winding into multiple paths, two multiple for instance, then each conductor carries half the phase cur is called half an effective conductor. To reduce eddy currents and bending, the conductors are usually made up of from 4 to 30 strands angular wire laid parallel and insulated from each other. This makes i to build up a conductor of convenient shape, but necessarily reduces factor.

Size of Armature Slots is determined, first, by the space necessary ductors and insulation, and, second, by the depth which is best suite diameter of armature. The slot factor is low for machines of this size reasons: (1) high voltage is customary, (2) a considerable part of th left vacant to serve as a passage for ventilating air, (3) the winding deep in the slot to give sufficient reactance to limit the instantaneo circuit current. A typical slot would be 6 inches deep by 1 inch wide winding and wedge occupying only 5 inches of the depth. Custom factors are given in Table II, usual depths in Table I and space all insulation and air in Table II. The dimensions given for insulation in the insulation on both sides of the coil, that is, an allowance of 0.30 in 0.15 inch on each side. The area of the slot is equal to the cross-secti copper divided by the slot factor and the width of slot is equal to t section divided by a suitable depth as judged from values in Table I.

The Armature Winding is usually a double layer barrel with as m as slots and one, two or three turns per coil. The coils usually hav two-thirds that of a pole in order to shorten the end connections, sav and space, and reduce the copper loss. It is of the lap winding type Fig. 2. There may be as many circuits in multiple in each phase

FACTOR AND SLOT INSULATION

Slot Factor	Insulation, inches	
	Depth	Width

0.35	1.50	0.25
0.33	1.50	0.32
0.30	2.00	0.46
0.27	2.00	0.55

the amount of current per circuit. Each turn is hat it lies near the top of the slot on one side and side.

robable armature resistance is figured at this point he armature does not exceed that which may be s figured as on page 645, except that the straight s 1 or 2 inches beyond the core, adding 7 to 8 turn. It is customary to figure the resistance of n temperature the resistance of 1000 feet of copper 07 ohm. The total I^2R loss should be from 0.2 per erate size machines; less in large machines. See

n Armature is found as given on page 641, and has Table I. This is because the output per pole is so nt runs quite uniformly from 1.1 to 1.15 and is low h and distributed field winding.

adjusted so that the magnetic densities are about stator and rotor teeth and in the air gap the density naximum density (in the center of a field pole) is e density (see *Induction Motors, Polyphase*). For a may be assumed.

those given in Table I is selected, say 36 for a 2-pole machine, and t spaced as if there were 54 slots, but two groups of 9 each are omitted at rically placed positions, thus forming the pole centers. This will give per pole, in which will be placed 9 coils per pole, each of a different p all concentric with the pole center.

For each diameter there is a certain number and depth of slots wh the best proportion between amount of copper and strength of tooth may be judged from Table I. The width of a slot is made approxim to 0.66 of the pitch on the circle at the bottom of the slots.

The Length of Air Gap is much influenced by its function in tion. For the electrical characteristic of the machine it is found des have the length such that the ampere-turns excitation expended in at no load and normal voltage are about equal to the armature re rated load.

No Load Magnetization Curve. — This is calculated as for i motors (q.v.) on account of the distributed field winding and the pe of flux. The average densities are figured on a basis of full pitch pole all stator teeth per pole carrying flux. The maximum density in ga teeth and rotor teeth is obtained by multiplying the average density for a sine wave. With saturation in the teeth (over 110,000) or with wide pole centers, this constant becomes 1.5 or 1.4 respectively.

On account of the long air gap (long compared to slot openings widths) the effect of slots in contracting the flux in the gap is not ma that the density in the air gap may be taken the same as at the surfa rotor. Investigation shows that the increase in density in the air to the slots is only from 2 to 4 per cent and this is balanced by figu density at the surface of rotor instead of at the mean gap diamet section of rotor teeth is figured at a point one-third the distance f bottom of the slots and the total section includes the one large cent and several smaller teeth.

The average length of the path of the magnetic flux in the two core siderably less than one-half the pole pitch on account of the distribu It is usually about 100 to 120 magnetic degrees.

The materials used are generally silicon steel for the stator and for for the rotor. The tendency of the flux to pass through the slots inste teeth is not so great in these machines as in other types because, in t the flux can spread out with saturation, and in the stator, because sities are not very high. A magnetization curve between no load volts terminals and ampere-turns per pole is usually plotted up to a voltage cent of rated voltage.

Armature Leakage Reactance. — The formula used for slow-spe nators will not apply because of the large number of slots per pole and connections and the formula used for induction motors is not suited b the long air gap.

Arnold (*Vol. IV, p. 8*) gives a formula and proof which has been found very well to present day turbo-generators. Referring to Fig. 4, all di in inches, let P_s be the effective leakage flux per ampere-conductor in then

$$P_s = 3.2L\left(\frac{u}{3w} + \frac{u'}{w'} + \frac{p}{q}\right),$$

where L = total length of core in inches.

Let P_t be the leakage flux per ampere-conductor from tooth tip to t set up by the belt of s_1 slots per pole per phase, then

Digitized by Google

$$P_t = L\left(2.36 \log_{10} \frac{\pi s}{2q} + A\right),$$

ere s = pitch of teeth at face and "A" has values as follows:

q =	1	2	3	4	5	6	7	8	9	12	15
A =	0	.3	.6	1	1.7	2.1	2.7	3.2	3.8	4.8	5.5

Let P_c be the leakage flux per ampere-conductor around the end connections, ing up by and interlinking the whole belt of s_1 coils, then

$$P_c = l_c\left(1.18\, s_1 \log_{10} \frac{2\, l_c}{U_c}\right),$$

here l_c = length of end connection at one end = $\left(\frac{1.8\,\gamma D}{2p}\right)$ as in the calculation mean length of turn.

U_c = perimeter of a belt of coils = $u + 2s_1 w$ in a double layer winding (see g. 4).

Then the total reactance in ohms per phase is

$$x = 2\pi f p s_1 c^2 k_2 k_3 (P_2 + P_t + P_c) 10^{-8},$$

here f = frequency;

p = number of poles;

c = effective conductors per slot = $\frac{2S}{ps_1}$.

The reactance drop in volts is "x" times the current per phase, and this drop ded by the rated voltage is the per cent reactance, or per cent reactance drop, ch is usually from 8 to 16 per cent.

Excitation at Rated Kv-a. — This is figured as on p. 648, Magneto-tive Force Method, giving conservative values, or as recommended in the dardization Rules of the A. I. E. E. The excitation required in ampere ns per pole is found for full kv-a. output at 100 per cent and 80 per cent wer factor.

Design of Field Coils. — These are usually designed to give the excitation quired at 80 per cent power factor with about 80 per cent of rated exciter ltage, that is at 200 volts d-c. impressed across the field circuit terminals.

The suitable cross-section (sq. in.) of field conductor is found by the relation

$$a = \frac{0.0115 \times (m l t) \times F \times p}{E_x \times 12{,}000},$$

here $(m\,l\,t)$ = mean length of field turn (ins.) figured as for the armature turn cept as to pitch diameter (at center of slots) and as to pitch of end connections, ually 67 per cent, and

F = required ampere-turns *per pole*;

p = number of poles;

E_x = Assumed voltage across field;

0.0115 = resistance per square inch per 1000 feet of copper at 125° C., the temperature commonly assumed for field copper.

Digitized by Google

This section, a, is definite for the conditions assumed and is indepe
the number of turns. The number of turns depends upon the allow
or heating. The more turns (more copper) the less the loss.

The working field current I_f is found (a) by assuming 1500 amp. pe
inch in this section of conductor for the excitation for 100 per cent pow
or (b) by assuming a definite loss for excitation and dividing this los
assumed voltage on the field. The number of field turns per pole
$t = F + I_f$ and these turns are distributed equally in the available
should be noted that each turn lies in two slots. The field slot factor h
from 0.4 to 0.6, the lower value applying where much space must be
to ventilating air. Field coils made up with mica and asbestos insulat
ate successfully with a specific loss of 0.90 watt per square inch of coil
giving a rise of about 50° C.

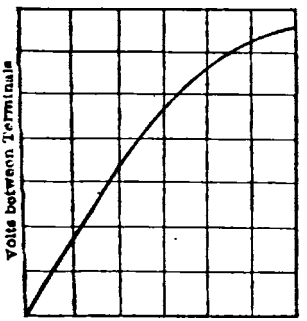
Efficiency and Losses. — The losses are friction, excitation, core-lo
ture I^2R and load loss. The last two are usually combined and re
as the "armature copper loss." The principal friction is that due to
and is a function of the ventilation. The excitation loss is treated abo
core-loss is best calculated on the basis of the loss per cubic inch at
maximum densities as discussed in the article on *Magnetic Properti*
material used is usually 14 mils thick, having a hysteresis coefficient η
and eddy current coefficient $\epsilon = 0.00007$. In turbo-alternators the
by test usually comes out very close to the calculated value, thereby
from some other machines in which a factor greater than unity must
for practical results.

The armature copper loss is greater than the true ohmic loss by fr
50 per cent on account of the load losses.

TABLE IV. — USUAL EFFICIENCIES AND LOSSES

Kv-a	Per cent efficiency	Per cent friction	Per cent excitation	Per cent core-loss	Pe ar
2,000	96	1.50	0.70	1.20	
5,000	97	1.20	0.45	1.00	
10,000	97.5	1.00	0.35	0.90	
20,000	98	0.80	0.25	0.77	
30,000	98.2	0.70	0.20	0.75	

Heating of Armature and Field may be estimated by means of
given under the section above on *Ventilation;* 100 cubic feet of air pe
is provided for each kilowatt of loss. The rise in the armature coils
100° C. per watt per square inch of coil surface and in the field coils abou
per watt per square inch.



Synchronous Impedance is very high on these machines and th
short-circuit current correspondingly small. It is frequently the case t
excitation for rated voltage and no load, the short-circuit current is
the rated load current. Thus voltage regulation by external means
lutely necessary, the inherent regulation being from 20 per cent to 30
at unity power factor and rated load.

the current in the field. Fig. 10 shows the connections for making
On account of the existence of the hysteresis loop (*see article on Magn
erties of Iron*), it is necessary, in running this test, to increase the
rent gradually from point to point and never reduce the value at
until the highest excitation has been obtained. The curve differs
from the magnetization curve of a closed sample of iron because the
circuit of the alternator contains a considerable air gap, the magn
curve of which is a straight line. Therefore, if the saturation cu
machine contains a portion which is very straight, the indications
the air gap is of considerable magnitude. If the machine is op
very high magnetic densities, this is indicated by the fact that the
responding to rated voltage is found at a point on the curve where it
horizontal.

Some machines obtain good regulation by operating at high satur
this is a cheaper method than by using a low value of armature rea
leakage reactance.

The magnetization curve is usually plotted in terms of the volts between terminals. In comparing the observed and calculated magnetization curve it should be noted that the calculations are expressed in terms of the volts per phase.

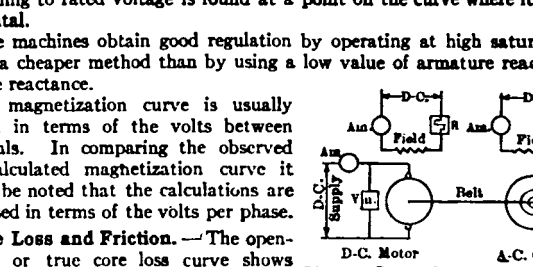

Fig. 10. Connections for Mag
Curve, Core Loss and Friction

Core Loss and Friction. — The open-circuit, or true core loss curve shows the core loss in watts for each value of the no-load terminal voltage. It is made by driving the generator at rated speed by means of a small m
efficiency of which is known, and varying the generator excitation
shows the connections for this test. The voltage and mechanical
(= input to motor multiplied by its efficiency) required for each value
tion are noted. The power P_0 for zero excitation is the friction lo
machine. The core loss for any excitation is $P - P_0$. The no-load s
curve can be made at the same time as the core-loss test.

Synchronous Impedance. — The synchronous-impedance curve s
relation between various values of field current, or excitation ampere t
the current that flows in the armature on short circuit. It is made
circuiting the armature through ammeters and operating at full frequency with various values of field current. Fig. 11 shows the connections for this test. Of course only fractional values of normal excitation are used, or the current in the armature would be so great as to cause damage.

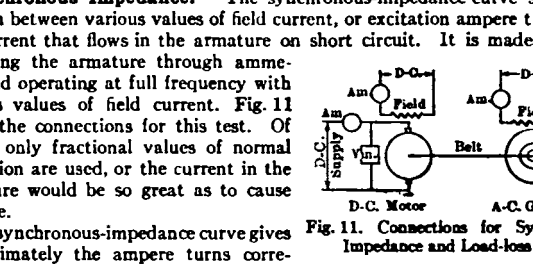

Fig. 11. Connections for Sy
Impedance and Load-loss

The synchronous-impedance curve gives approximately the ampere turns corresponding to armature reaction and the leakage reactance drop in t
ture combined, i.e., the ampere turns corresponding to the synchron
ance. The approximation arises from the effect of the armature
and the low saturation or magnetization of the magnetic circuit under
circuit conditions.

Stray Load-losses. — These include iron losses, and eddy-current losses in r copper, due to fluxes varying with load and also to saturation.
The following is quoted from the *Standardization Rules of the A. I. E. E.:* Stray d-losses shall be determined by operating the machine on short circuit and rated-load current. This, after deductiug the windage and friction and R loss, gives the stray load-loss for polyphase generators and motors. These es in single-phase machines are large; but the Institute is not yet prepared specify a method for measuring them.

Resistance Measurements must be made when all parts of the machine are some known temperature. They are also made after the heat run, when the achine is hot, to check the temperature as measured by thermometers (*see ticle on Resistance and Conductance*).

Field Resistance is measured by the simple voltmeter-ammeter method *rticle on Resistance and Conductance*).

Armature Resistance. — The armature resistance between terminals is also measured by the simple voltmeter-ammeter method, by connecting two of the terminals to a sorce of direct current (the other terminal being free), the rotor (field or armature of course being at rest). In the case of a single-phase or two-phase machine the resistance as thus measured is the resistance per phase. In the case of a three-phase machine, let R_t = the resistance as thus measured and R_p = the resistance per phase. Then for a Y-connected armature $R_p = R_t \div 2$, and for a Δ-connected armature $R_p = 3R_t \div 2$. If the connection is not known, the calculation of the resistance drop and copper loss may be figured correctly assuming it either Y or Δ connected, provided the resistance per phase and current per phase are both calculated on the same assumption regarding the connection. In the case of a two-phase machine the resistance between terminals A and B and between B and C (B being the common terminal) should each be measured, and the average taken. In the case of a three-phase machine the resistance between A and B, B and C, and A and C should be measured and the average taken.

Calculation of Regulation and Efficiency from Tests. — From the results of the preceding observations, the regulation and efficiency of the machine at various loads may be calculated by the methods given above, in the discussion of *Predetermination of Performance*, using the test data instead of the calculated quantities. The synchronous-reactance ampere turns may be taken as equal to the synchronous-impedance ampere turns, since the resistance drop in the armature on short circuit and reduced excitation is seldom over 10 per cent of the synchronous-reactance drop, and as the two are in general rature the synchronous-impedance drop differs from the synchronous reactance drop by less than one per cent. In using the magnetization curve and the synchronous-impedance curve one must keep in mind whether they are plotted in terms of voltage and current per phase or in terms of volts between lines and line current.

Full-load Saturation Curve. — This curve shows the relation between the terminal voltage and field current with full-load current in the armature. It may be plotted from tests or calculated from the magnetization curve and the synchronous impedance in the same manner as the regulation is calculated.

Armature Leakage Reactance. — There are three methods by which the leakage reactance may be determined:

(1) **Synchronous-impedance Method.** — This gives only approximate results but is very generally used as a synchronous-impedance test is made on every generator. Let n be the field ampere turns per pole required to force full-load current through the short-circuited armature. Let a be the calculated

Digitized by Google

armature-reaction ampere turns per pole (see above), with rated
Then $n - a$ is the excitation necessary to induce the leakage reactanc
(IX) in the armature. From the open-circuit saturation curve find th
corresponding to $(n - a)$ ampere turns. Reducing to volts per
necessary, and dividing by the current per phase, the result is the
reactance X per phase in ohms.

(2) **Full-load Characteristic Method.** — This method is also
mate. Let the excitation in ampere turns per pole required to give rate
at full non-inductive load be q. Let the ampere turns to give rate
without load be m. Then $n = \sqrt{q^2 - m^2}$ is taken as the synchronous-i
ampere turns, and the leakage reactance is calculated as described in
ceding paragraph.

(3) **Inductance-measurement Method.** — This method giv
values, but is not very often employed. From an external source o
frequency, full-load current is sent through the armature of the mach
tested, with the fields excited to the normal value but not rotati
voltage drop across the armature terminals is measured for several
positions of the coils with respect to the poles, ranging through an arc
one-half the pole pitch. Let Z = the voltage per phase divided by the
R = the resistance per phase corrected for load loss (i.e., the effective r
as determined from the short-circuit core-loss curve), then the leakage r
per phase is $X = \sqrt{Z^2 - R^2}$. This reactance will vary with the po
the coils and the maximum and minimum may be found by making
culation for the different positions of the coils with respect to the fields.

Heat runs are made at rated load and various other specified loa
parts in which the rise in temperature is of interest are:

Armature core surface;
Armature core ventilating ducts;
Armature conductors;
Collector rings;
Both pole tips;
Field winding;
Bearings;
Frame;
Room.

The temperature of the field and armature winding should be measu
by thermometers and by the resistance method. In taking the tempe
a hot surface by thermometer a small pad of waste should be placed
bulb after the thermometer is put in place. The pad should not be t
or it will prevent the normal radiation from the surface.

With large machines it is inconvenient and expensive to test under
conditions. For determining the heating without actually developing
power of the machine there are several methods available.

Reversed-field Method. — The field circuit may be tapped
full-load field current sent through a portion of the field coils in a
opposed to that for normal operation. For example, in a 24-pole mac
current in 8 of the field coils may be directed in such a manner that
reversed with respect to the remaining 16. The armature winding will
generate a voltage due to the 8 poles that are not neutralized and the
approximately one-third rated value. If the armature is short circuit
rent will flow due to this reduced voltage, and this current can be mad
proximate closely the full-load value by making a proper division of t
If the machine is operated under these conditions the friction, excitat

Digitized by Google

s and armature copper loss will be very nearly equal to their value under rmal operating conditions, yet to drive the machine only an amount of power proximately equal to the sum of the losses is required.

Synchronous-motor Loading. — If two machines are available they y be connected up as a generator and synchronous motor and the field excita- n of the motor adjusted so that a current of full-load value, but having a ge reactive component, will flow in the armature, the power factor being arly zero. The power required to drive the generator at full-load excitation t full-load current will then be small.

Direct-current Loading. — Full-load losses may be simulated on a e-phase generator by connecting the three phases in delta and leaving the open at one point, to which a direct-current ammeter and a source of direct rrent may be connected in series. The delta is first closed through an alter- ating-current ammeter and the triple-frequency current in the delta (*see lternating Currents*) is measured. The direct-current ammeter and source direct current are then connected in series with the delta and the direct rrent increased until the sum of the squares of the local current of triple equency and the direct current is equal to the square of the rated current per hase.

Open-circuit Short-circuit Method. — Another ingenious method, ad- cated by Hobart, consists in alternating open-circuit and short-circuit tests, ch under exaggerated conditions, so that at the end of each hour the total att hours lost in each part are equal to the watt hours that would be lost in rmal operation. For example, let the core and field copper loss be 4 kilowatts, d armature copper loss 1 kilowatt. If, now, the machine is operated for minutes with armature short circuited and the excitation adjusted to give kilowatts copper loss, and for 40 minutes on open circuit with excitation djusted to give 6 kilowatts core and field copper loss, then the loss per hour the armature copper is 1 kw.- hr., and in the field winding and core 4 kw.- hr., the same as under normal conditions. For an exact division of the time between he open-circuit and short-circuit conditions, the core and field copper loss uring the short-circuit run must be taken into consideration. After several hours of this relaying the machine will have reached a temperature correspond- ing to full-load operation.

Insulation Tests. — The insulation of a machine is usually tested by apply- ing a given voltage between the conductors and the part of the machine from which they are insulated. An insulation resistance test is also made.

Voltage Tests. — During manufacture the coils are tested separately, and after the machine is assembled a voltage test between the completed windings and frame is made. After the heat run, while the machine is still warm, a third test of the insulation between windings and frame is made.

For this third test an alternating voltage is applied between armature and frame, according to the ***Standardization Rules of the A.I.E.E.*** (q.v.)

The voltage should be increased gradually and the final value should be applied for one minute. In this test the machine acts as a condenser and therefore care should be taken that the frequency is not so high or the inductance of the supply circuit so great as to set up resonance. It is advisable to have considerable resistance in the supply circuit.

To prevent an uneven distribution of voltage, all the terminals of the winding should be connected together by fine wires and one terminal of the high-potential circuit connected to the common connection. The high potential should be measured by a spark gap connected in shunt to the machine.

Insulation Resistance. — The insulation resistance is measured by connect- ing one terminal of a 500-volt direct-current supply to the windings of the ma-

chine through a voltmeter with a 500 scale, and connecting the othe terminal to the frame. If the resistance of the voltmeter is R_v ohm voltmeter deflection x, the insulation resistance is $R = \frac{R_v}{x}(500 - x)$.

EXAMPLES OF DESIGN AND PERFORMANCE. — In the pp. 667 and 668 will be found the essential data both of the mechanica trical features of four representative alternators. The list of items wil useful as a guide in collecting data on various machines. Perform are deduced from tests.

OPERATION. — In the operation of an alternating-current gen following factors should be considered:

Phase Connections and Grounding. — When a third harmonic in the e.m.f. wave of a three-phase generator, the triple frequency e.m three phases (or windings) are additive when the three phases are co Δ, that is, the Δ forms a short circuit to the third harmonic e.m.f.'s, a triple frequency current may therefore be set up in the windings irres the load on the machine. On this account, large three-phase gene usually Y-connected, since with this connection the third harmon between any two terminals of the machine neutralize each other. when two or more Y-connected machines are operated in parallel neutrals grounded, a triple frequency cross-current of considerable may be set up between the machines, unless the wave form of the e.m various generators are exactly the same, which is practically never the prevent such cross-currents with Y-connected machines with grounde it is the usual practice to ground the neutral of but one generator Provision must of course be made to shift this ground connection fro chine to any other, so that a ground connection can always be maint spective of which machine or group of machines may be running.

The advantages and disadvantages of grounding the neutral are di the article on *Grounding of Electric Circuits*.

Division of Load between Alternators in Parallel. — The divisi between two or more alternators operating in parallel cannot be c altering their field excitation, as is the case with direct-current g Changes in the load taken by any alternator of a group can be effecte admitting more or less steam to the driving engine or turbine (or v water-wheel). In order that the various alternators shall share the load properly, it is therefore necessary that the governors on the sev movers give the same speed-load characteristics.

Although the field excitation has no effect on the distribution of the lo the alternators, it does affect the power factor of the load delivere machine. The excitation of each alternator should be so adjusted t livers its load at the same power factor as the others.

Starting a Single Generator. — Before a generator is started up it must be inspected and cleaned and filled with oil if necessary. The r then brought up to the proper speed and the bearings again inspected the oil-rings are running properly. The exciters or excitation circuit i in readiness and the rheostat in the alternator field circuit adjusted for resistance. Before exciting the field the armature insulation must be t dry. If it is not the armature is short-circuited through an ammete for several hours at a partial excitation to give about rated current in circuited armature. When the insulation is thoroughly dry the short removed and the excitation adjusted to give rated voltage at the terminals with correct speed. To shut down the machine the loa

removed by opening the circuit breaker; then the field rheostat is maximum resistance as is also the rheostat in the exciter field if t individual exciter. Then the field circuit is opened.

Paralleling of Generators. — Before connecting a generator to b which one or more other generators are connected, the following must be satisfied:

1. The frequency of the generator must be the same as that of the
2. The frequency of the generator, and therefore its speed, must be for an appreciable interval of time.
3. The voltage of the generator must be the same as the voltage bars.
4. The generator and bus-bar voltage must be in phase.

If the two machines have not the same frequency or if the freque constant, a condition will occur intermittently in which the two ve 180° apart or the two machines are in series on a short circuit, and a current will flow. If the voltages are not equal, a large "wattless" current may flow, and if the two voltages are not in phase, a large rent will flow which will cause a mechanical shock. To indicate w conditions are fulfilled any one of several "synchronizing" device employed, as described in the article on *Synchronizers and Synchrosco*

Synchronizing with Lamps. — The simplest method of syn small machines is to use incandescent lamps as shown in Fig. 12. In the connections are such that the lamps remain dark when the above are satisfied, while in Fig. 12B they will remain bright under these c If the frequencies are wrong the lamps will flicker (the slower the nearer the two frequencies). If the voltages are wrong the lamps in

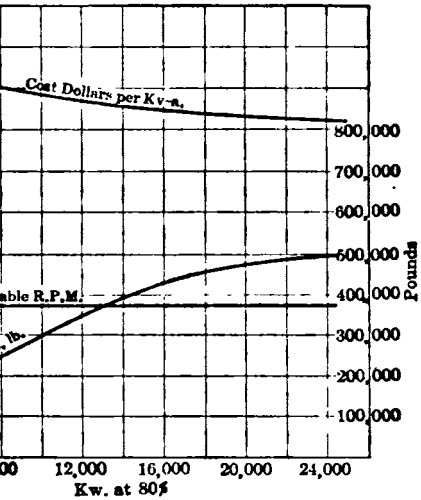
SPECIFICATION FOR A-C. GENERATOR. — The followi
randa are intended to assist in writing specifications. See also article
fications.

Principal Characteristics and Conditions of Service. — Service
generator is to be used, such as a-c. lighting, single-phase railwa
operating railway or lighting synchronous converters, etc. Voltage an
of phases. Rated output in kilowatts or kilovolt amperes at stat
factor. Frequency and speed.

Style and Description; Details of Construction. — Type of
revolving field, induction type, etc. Details of speed, governing
mover, and how generator is connected to prime mover, e.g., direct
driven by steam turbine, reciprocating engine, water wheel, water tu
engine, oil engine, etc., with vertical or horizontal shaft. Whether
sated. Whether exciter is to be supplied; if so, its characteristics.
rheostat is to be supplied, its characteristics, including the effect
generator voltage of each step and of all steps; whether to be cont
hand or automatically. Restriction of excitation current and voltag
quirements respecting carrying capacity of slip rings. Accessibility of
Whether embedded thermometer coils shall be furnished. Windings
clamped securely to prevent any vibration of overhanging parts. M
protection of armature conductors if exposed. If belt driven, speci
details; whether bed plate is desired.

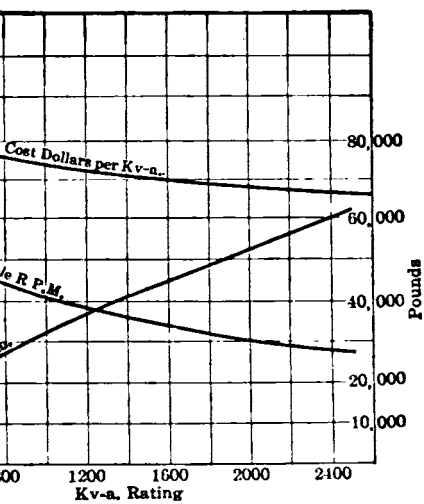
Work to be Done by Other Contractors.—Whether Contract
furnish and install the following. Main wiring, field wiring, field rheo
dial plate and chains. Point of division between engine and gener
tracts.

Performance and Tests. — (*See Standardization Rules of the*
Temperature rises upon which ratings are to be based. Details of
capacity. Efficiency at 25, 50, 75, 100, and 125 per cent load. Hi
tial tests of insulation. Requirements regarding effects of moist
insulation. Requirements for parallel operation, i.e., whether the m
to operate in parallel with similar machines or different ones. It is
specify that the terminal voltage shall vary according to a sine law. R
with 100 per cent power factor and normal speed; the load may
from zero to 150 per cent of rated load without causing more than
variation of voltage, the exciter field being kept constant.



DIMENSIONS, WEIGHT AND COST (1922 prices). — While g
vary widely in their specific weights and costs, that is weight per kv
and cost per kv-a. rating, they may be divided into classes in which thes
teristics are fairly definite.

The conditions primarily affecting the specific weight are: method
speed, frequency, voltage and size. In addition there are the peripbe
and mechanical construction which cannot be easily classified. The m
rating is fundamental. For purposes of comparison the rating may
as the output in kv-a. which each machine will give continuously wi
in temperature not exceeding 50° C. On this basis the specific weight
as the speed, frequency or capacity increases, and increases with in
voltage. The cost per pound decreases as the frequency decreases
the capacity increases. The cost per pound increases as the voltage
ipheral speed increase.



Alternating-current generators may be divided into three classes a
to their speeds and purposes:

High speed, as turbine-driven generators.

Digitized by Google

nd Suitable Speed for 60-cycle Turbo-generator Sets, Including Turbine.

d Suitable Speed of Water-wheel driven 60-cycle A-C Generator.

Digitized by Google

Medium speed, as belt-driven and water-wheel-driven.
Slow speed, as engine-driven generators.

Approximate weights, costs per kv-a. and suitable speeds are i
Fig. 13 for turbo-generators and in Fig. 14 for water-wheel-driven 60-c
volt, polyphase machines. The weight and cost of 25-cycle gen
from 10 to 20 per cent greater than for 60-cycle generators. T
machines for less than 2300 volts is practically the same as for 2300-
ment. Two-phase generators weigh and cost practically the sam
phase. Single-phase generators weigh and cost from 25 to 30 per
These data are of course suitable only for preliminary estimates;
particularly, are subject to large variations due to changes in comm
ditions from year to year. For final estimates exact dimensions and
should be obtained from the manufacturers.

Commutating Pole or Interpole Machines. — These ma
small auxiliary poles alternately placed with respect to the ma
excited by a few turns in series with the load. The effect of thes
improve the operation of the machine in the matter of commutation

Bi-polar Machines. — Small continuous-current machines are u
bi-polar or two-pole type with a more or less inclosed frame of cylin

Multi-polar Machines. — Large direct-current machines are c
polar type, that is, have a large number of radial pole pieces.

Belt-driven and Direct-connected Types. — Direct-curren
may be of either the "belt-driven" or the "direct-connected" ty
mined by the method of connecting to the driving unit. Belt-drive
are characterized by a higher angular velocity than direct-connecte

RATINGS. — It has been common practice (up to 1914) to rate d
machines on the basis of the output in kilowatts which they will g
ously with a maximum rise in temperature by thermometer of 50°
surrounding air at 25° C. See however the recent recommenda
A.I.E.E. in the article on *Standardisation Rules*.

VOLTAGE. — The standard voltages for which continuous-curr
are built are:

80 volts for use on shipboard.
110–125 volts for lighting purposes and incidental small power
motors, cooking utensils.
220 volts for three-wire systems with lighting and power combine
500–600 volts for power alone and particularly for railway service
1200–2400 volts for special railway service and heavy traction.
2000–6000 volts for series-arc-light circuits fed by series machines

ELECTROMOTIVE FORCE INDUCED IN ARMATUR

Z = total number of armature conductors
p = number of field poles.
m = number of parallel conducting paths between the positiv
tive brush sets; that is $\frac{Z}{m}$ is the number of armatur
in series between positive and negative brush sets.
under Armature Windings.)
ϕ = total useful magnetic flux per pole.
N = revolutions of armature per minute.
f = frequency in cycles per second.

If a coil of wire be revolved about an axis in a magnetic fie
in Fig. 3, each length of conductor, or side of the coil, will pass en
the armature in $\frac{60}{N}$ seconds. The time taken for a con-
ductor to pass through the magnetic field under each
pole, or from a to b, is $\frac{60}{Np}$. Hence the average value
of the electromotive force induced in each armature
conductor as it passes under each pole is $\frac{Np\phi}{60 \times 10^8}$ volts,
since a cutting of 10^8 lines per second gives one
volt. Since in an actual machine the conductors are uniformly
around the surface of the armature, this is also the average volt
ductor in each of the conductors between a and b at any ins

where

C = total number of coil-sides or bars,

p = number of poles,

z = average pitch* = $\frac{\text{front pitch} + \text{back pitch}}{2}$,

s = total number of slots,

b = number of coil-sides or bars per slot.

The total number of sides (C) is double the number of coils, has two sides. C must be a multiple of the number of slots (s number of poles (p).

The average pitch (z) must be an even number so that the fro pitches may be different and odd ($z - 1$) and ($z + 1$), respectively always two layers of coil-sides, top and bottom. One side of each c top layer in one slot and in the bottom layer in another slot. The and back pitches of a coil are always odd because they are made fro in the top layer (odd numbers) to one in the lower layer (even nu Fig. 6. Here the pitch is $14 - 1 = 13$.

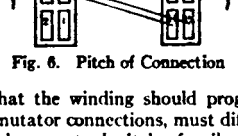

Fig. 6. Pitch of Connection

Fig. 7. Lap Win

In order that the winding should progress continuously the fr pitch of commutator connections, must differ by one coil (or two coi the back pitch, or actual pitch of coils. The actual spread of a (Fig. 7) is the same front and back and is equal to the "back pit

The total number of coils $Q = C/2$ is equal to the number of segments and must be a multiple of the number of slots. In gen common multiple of the number of poles and the number of slots drum winding is possible. It is sometimes desirable that the nu should not be a multiple of the number of poles. In order to gr in poly-coils z should be a multiple of the coil-sides per slot.

Series-drum or Wave Windings, Simplex. — This type of wi in direct-current armatures where the ordinary multiple drum woul too low a voltage or require too many turns of fine wire in each coil. Its advantage is that it gives an armature that is better balanced magnetically and that only two brush studs are necessary. A greater number of studs may, however, be used. There are always two circuits in multiple, regardless of the number of poles. The characteristic reverse bends of its face conductors are shown in Fig. 5. The characteristic form of the coils is represented in Fig. 8.

Fig. 8. Wa

Conditions for Wave Winding. — The conditions to b laying out a series-drum winding are expressed in the formula

$$C = pz \pm 2 = sb,$$

* Let the coil-sides be numbered consecutively from slot to slot, a travel through the conductors in the order in which they are connected starting at conductor No. 1, say, passes through the point or commutat to conductor No. 8 and thus through the back connection to No. 3, t pitch is $8 - 1 = 7$ and the back pitch is $8 - 3 = 5$, and the average pitch

The multiplicity and complexity may be carried to a very extr (*See under Armature Windings in any standard textbook.*) These windings are hardly ever used in the United States and England occasionally in Germany and France.

ARMATURE REACTION (OR ARMATURE INTERFERE

The armature reaction of a d-c. machine has a very important influe commutation and regulation of both generators and motors. It is of the magnetomotive force of the current in the armature conduct magnetic field set up by the field coils.

Separate Fluxes by Field and Armature Currents. — When cur in the field coils and no current flows in the armature, a flux is set up a path directly across the armature from pole to pole as in Fig. 9. On hand when current flows in the armature and there is no current in flux is set up in the armature across the axis of the poles, as in Fig.

Fig. 9. Field Flux

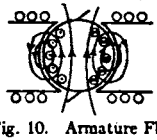

Fig. 10. Armature Flux

Fig. 11. Dis

Resultant Flux. — As a result of this action the flux is shifted arou one tip of each pole has its density increased and one tip has the d creased as in Fig. 11. If the brushes are at the geometrical neutral t longer on an axis at right angles to the flux; that is, they are no lon neutral point with respect to the resultant flux. With the brush position the coil underneath a brush is cutting flux and generating which is short-circuited by the brush and causes sparking. The brus therefore, be moved a small angle in the direction of rotation in a ge the opposite direction in a motor) until they are on the neutral axis. of the brushes aggravates the conditions, but nevertheless, unless the strength is too great, a position can be found in which a brush short coil that is in the real neutral position and is inactive.

Relations Shown Vectorially. — In Fig. 12 F_1 and A_1 are the m.m field and armature with the brushes on the geometrical or apparent ne

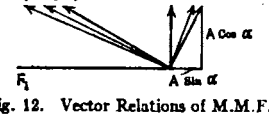

Fig. 12. Vector Relations of M.M.F.'s

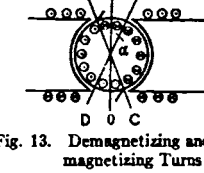

Fig. 13. Demagnetizing an magnetizing Turns

R_1 is the resultant of these. The brushes which are in line with A_1 right angles to R_1. If the brushes are moved to an axis at right angl at A_2, then the resultant becomes R_2 and the desired conditions have

brushes still further to A_3 giving the resultant R_3 d A_3 at right angles to each other. The stronger the to the field flux the greater will be the angle through e moved.

moved through an angle α to the position A_2 there is nature m.m.f., $A \sin \alpha$, directly opposed to the field nt, $A \cos \alpha$, is at right angles to the field m.m.f. This eference to Fig. 13.

and Cross-magnetizing Action. — Let the move- to A_2 be represented in Fig. 13 by the movement from le α. Then the conductors in the angle 2α, between d D, carry currents whose m.m.f. directly opposes the eld coils; these are known as back or demagnetizing ler of the armature conductors, in A–C and B–D, a m.m.f. at right angles to the field and cause a dis- re known as cross-magnetizing conductors.

while all the conductors in the sections A–B and C–D onstitute back ampere-turns, these are opposed to the hen we come to our quantitative treatment in which we make use of the turns of 2α as the back ampere-

n Armature Reaction.* — The demagnetizing effect be almost entirely overcome by placing the brushes To prevent sparking under these conditions inter- use of interpoles does not in itself prevent armature le sparkless commutation when the brushes are set luce armature demagnetization to a minimum.

CTANCE. — Eacn coil of the armature carries a ction as it travels from a positive brush to a negative direction as the coil travels from a negative to a posi- rection of the current in each coil reverses during bars to which the coil is connected pass under the urrent in any circuit it is necessary to take out the rm of magnetic flux linked with the circuit, and put esented by a flux in the opposite direction. In doing e circuit a voltage which is proportional to the time and which opposes any change in the value of the he e.m.f. of self-inductance of the coil.

; Commutation. — To minimize the voltage of self- to keep the number of ampere-turns in each coil as e the reversal to take place as slowly as possible. It voltage of self-inductance by introducing an opposing ished in practical machines by giving the brushes a nterpoles.

Brushes. — The brushes are moved in the direction (opposite direction in a motor) away from the true rgoing reversal is moving in a flux coming from an density that it induces by rotation in that particular and neutralizes the voltage of self-inductance.

es on Commutation. — Interpoles or commutating he main poles over the neutral space. These poles

* See *Motors, Direct-current.*

Digitized by Google

are excited by the load current until they give a flux of the proper dire value to induce the desired neutralizing voltage. (*See also above unc ture Reaction.*)

Increasing Resistance in Path of Short-circuit Current commutation. This changes the time constant of this circuit, that i the stored energy of the magnetism is dissipated in I^2R loss in this instead of in sparking at the brush. The usual method of accompli is to use carbon brushes which have a higher resistance of contact t brushes. Another method is to introduce a high resistance in the c between the winding and the commutator segment.

DESIGN. — The steps in the systematic procedure in the design machine of given voltage and power rating are given below. Simplex are assumed.

1. Statement of problem.
2. Suitable speed.
3. Number of poles.
4. Diameter and length of armature.
5. Length of air gap.
6. Number and size of slots.
7. Total flux, preliminary.
8. Number of turns on armature, preliminary.
9. Armature reaction, ampere-turns.
10. Number of conductors per slot.
11. Form of armature winding.
12. Size of armature conductors.
13. Exact size of slots.
14. Armature resistance and heating.
15. Design of commutator and brushes.
16. Reactance voltage.
17. Exact value of flux.
18. Cross-section of magnetic path; usual flux densities.
19. Excitation; calculation of magnetic circuit.
20. Stability factor.
21. Armature reaction or interference.
22. Field winding, series, shunt.
23. Interpoles or commutating poles.

The performance of the machine should then be calculated from liminary design to determine whether the design meets the imposed and such modifications as are necessary should then be made. Th calculating the performance are the calculations of:

24. Core-loss.
25. Friction.
26. Excitation loss.
27. Armature circuit loss.
28. Efficiency.
29. Regulation.
30. Heating.

Symbols. — The following notation is employed uniformly t this article; other symbols, and the same symbols with primes or subs defined in the paragraphs in which they are used.

(AR) = armature reaction ampere-turns per pole.
B = flux density in air gap, lines per sq. inch.
b = number of coil sides per slot.

100–300	6	6	8
300–500	6	8	10
500 and greater	..	..	12 and more

Usual Values of the Constants in the formula at bottom c are:

Magnetic Density in Air Gap (B) has values from 40,000 lines per s in small machines, 55,000 in medium and 70, 000 in large machines. the density in the air gap is taken the same as the density at the pol

Ampere-Conductors per Inch of Periphery, or the Specific Loading product of the total conductors around the armature times the curre divided by the periphery of the armature. The usual values for σ a accompanying table.

Ratio of Pole Arc to Pole Pitch (ρ) varies from 0.6 to 0.85 with an average value of 0.7.

Kw. rating	σ-amp.-co inch of p
	For continuous rating
0–150	250–400
150–400	400–600
400 and greater	600–900

Determination of D and L. — Having found D^2L the two factors may be separated by two methods. Assuming a square pole face (a desirable proportion for economy of armature and field copper), then

$$L = \frac{\pi \rho D}{p},$$

and substituting in D^2L we can solve for D.

Another method of determining separate values for D and L is by a tion of the peripheral speed. The peripheral speed is fairly unifo machines, having values of from 3000 to 5000 feet per minute. average value near 4000. The diameter of armature is given by the

$$D = \frac{(\text{Peripheral speed}) \times 12}{\pi N}.$$

5. Length of Air Gap in inches for a given diameter has a v approximately by the table in the next paragraph. This gives a for preliminary work but it may be found advisable to change it l design.

6. Number and Size of Armature Slots. — A rough approx practice gives the number of slots as four times the diameter in inc eral practice is shown in the following table.

Digitized by Google

Air gap, in.	No. of slots	Depth of slots, in.
0.08	25- 40	0.6
0.10	30- 60	0.75
0.12	40- 80	1.00
0.125	60-100	1.25
0.15	80-150	1.50
0.19	100-200	1.75
0.25	150-300	2.50
0.35	200-400	3.25

Armature (ϕ) is fixed by the assumed gap density B eter D of the armature:

$$\phi = \frac{\pi \rho L D B}{p}.$$

in Series (S) between brushes is

$$S = \frac{E \times 10^8}{4 f \phi}.$$

Ampere-Turns per Pole are

$$(AR) = \frac{IS}{p}.$$

mpere-turns per pole (AR) should not exceed certain check as explained in the accompanying table.

Kw. rating	Armature reactive ampere turns per pole (AR)
0-100	1500-3500
100-300	3500-6000
300-500	6000-8000

higher than advisable it he value of the flux by

ctors per Slot (c). — If ots on the armature, the tors per slot (c) must are sometimes antag- olution is a compromise. ling:

$$c = \frac{2 p S}{s}.$$

g:

$$c = \frac{2 \pi \sigma D}{Is} \quad \text{and} \quad c = \frac{4 S}{s}.$$

per and give a number of conductors which can be slot having a depth of from 3 to 4 times its width. r a multiple winding we then choose a series winding. **Winding** (for general discussion of forms of wind-

inding. — If the number of conductors per slot (c) a multiple-drum winding, we choose an arrangement coil sides per slot and assume the conductors per slot

at a value the nearest multiple of the coil sides per slot, thus gro conductors into coils.

Series-drum Winding. — If a series-drum winding is indica For a four-pole machine choose a number of conductors per slot (by 6 and a number of slots (s) in the series 29, 33, 37, etc., endeavorin that value of $\frac{sc}{4}$ that comes nearest to our preliminary value of S, t of turns in series between brushes. Or for a four-pole machine choose of conductors divisible by 10 and a number of slots in the series 27, 3 gives a value of $\frac{sc}{4}$ the nearest the preliminary value of S.

For a six-pole machine choose a value of c divisible by 4 and a slots (s) in the series 26, 32, 38, that gives a value of $\frac{sc}{4}$ nearest the de of S.

The preceding values of s give the best winding arrangement but other combinations giving unequal front and back pitches and longer co

Revised Value of Turns in Series (S). — Having chosen values for s and c to fit the form of winding desired we must revise our p assumption for the turns in series, S, to accord with the actual windi for a multiple drum $S = \frac{sc}{2p}$, and for a series drum $S = \frac{sc}{4}$.

12. Size of Armature Conductors. — The current in each conduct to the line current I divided by the number of poles in a multiple-dru and to $I/2$ in a series-drum winding of the simple type. The cross each conductor is equal to the current per conductor divided by the amperes per square inch, which varies from 3000 in small machines and 2000 in intermediate size machines to 1500 in large machines.

Kw. rating	Slot f
	For 125 volts
0– 10	0.28
10– 50	0.35
50– 100	0.40
100– 400	0 50
400–1000	0.60

13. Exact Size of Slots, Slot Factor. — The total number of slots is definitely set by the style of winding. The maximum allowable depth depends upon the diameter of the armature. The width of each slot should be from 0.4 to 0.6 of the pitch of the slots, which is the quotient of the periphery of the armature divided by the number of slots. The ratio of the total cross-section of copper in a slot to the cross-section of the slot is known as the slot factor and has more or less consistent values.

Type of slot	No. of bars or coil-sides per slot	Allowance for coil and slot insulation, in.

Part	Material	Lines per sq. in.
Field yoke	Steel	70,000–100,000
Field yoke	Cast iron	35,000– 70,000
Pole core	Steel	70,000–100,000
Air gap	Air	40,000– 70,000
Armature teeth	Steel laminations	90,000–125,000
Armature core	Steel laminations	60,000– 90,000

The proper cross-section of each part is found by dividing the flux in by an assumed density. (*See also following paragraph.*) In most dimension, as the length along the shaft, is known and the other is th

19. Excitation. — Calculation of Magnetic Circuit. — It is ac calculate the densities and excitation for a value of flux corresponding t at the speed at full load, as this is the most important condition. It practice to assume a loss of voltage of 5 per cent at full load instead of predetermining the value.

Values of Flux in Different Parts of Magnetic Circuit. — mature teeth and air gap the total flux is equal to the calculated value ful flux. In the armature core the flux divides and we have one-half flux in each branch. The field flux or flux in pole cores is greater useful flux and is equal to the useful flux multiplied by the leakage (ν). (*See section 17.*) In the yoke the flux divides and each branc one-half as much as the pole core.

Ampere-Turns. — The number of ampere-turns required for is best calculated by the assistance of a tabulation like the following the symbols refer to the dimensions shown in Fig. 15.

20. Stability Factor. — It is necessary at this point in the design the relations to see if the machine is liable to be unstable or require an shift of the brushes. If interpoles are to be used this is not importa interpoles are not to be used certain conditions must be fulfilled. The of these conditions is the "stability factor" which is the quotient of ampere-turns required for gap and teeth divided by the armature turns beneath the pole.

The ampere-turns beneath the pole are equal to

$$\frac{\text{(Armature reaction ampere-turns)} \times \text{(Pole arc)}}{\text{Pole pitch}}.$$

The conditions to be filled are that at maximum current in the arm armature ampere-turns beneath the pole shall not exceed the field amp required for gap and teeth. This is covered by the custom of making th factor at full load have a value of from 1.3 to 1.5 in generators and 1 motors.

21. Armature Reaction or Interference. — The current in the conductors sets up a magnetomotive force which reacts on the magne force of the field coils and prevents them from setting up as much flux there is no current in the armature. It is, therefore, necessary to have strength at any load greater than at no load by an amount sufficient come or neutralize the armature reaction, or to provide special auxili for the purpose. There are four methods of estimating the effect of interference and overcoming it.

(*a*) It is common practice in the manufacture of d-c. machines to field coil of such ample capacity that it is sure to be more than suf overcome armature interference and set up the flux desired. This fie adjusted in practice by putting an adjustable resistance in series with field and a suitable resistance in multiple with the series field. For thi It is usual to provide a total number of field ampere-turns per pole (F) the net ampere-turns per pole at full load required for flux, as calculat item No. 19, plus a number of field ampere-turns equal to 40 per ce armature reaction ampere-turns as calculated under item No. 9.

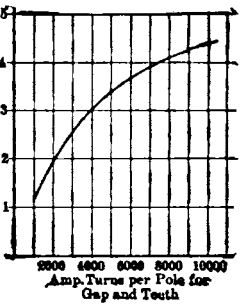
(*b*) The effect of armature reaction is divided into back ampere-t cross ampere-turns. The excitation ampere-turns per pole to over back ampere-turns (caused by shifting the brushes) is

$$A' = \frac{\text{(Armature reaction)} \times \text{(Brush shift in segments)} \times 2p}{\text{Total commutator segments}}$$

The excitation to overcome the effect of the cross ampere-turns upon many variables but in machines designed in accordance with practice it bears a fairly uniform relation to the cross ampere-t pending upon the value of the ampere-turns in gap and teeth, as foll

Cross ampere-turns = (armature reaction ampere-turns) − back turns).

Field ampere-turns to compensate for cross ampere-turns is then (cross ampere-turns).



Where K has values as shown in Fig. 16 (*given by Cramp, see Bibli*

Thus the total field ampere-turns at full load is then equal to

$$F = \text{(Net ampere-turns for flux, section 19)} + A' + B'.$$

used as described in section 23.

arious Loads. — At no load the excitation required essary to produce a flux corresponding to the rated y load corresponding to a current I the excitation in al to the sum of: (1) that required to produce a flux where R is the total resistance of the armature between ance and the resistance of the series field; (2) that back ampere-turns caused by I, and (3) that required mpere-turns due to I. The process of calculation 0 and 21 for full-load conditions is, therefore, repeated

If the machine has a series field this should be laid ld coils are sometimes placed outside of, and concentric

For a compound-wound machine the ampere-turns d are equal to the difference between the full-load -load ampere-turns. As it is usual to shunt about through a shunt resistance the number of series turns

$$t_1 = \frac{\text{Ampere-turns required}}{0.75 \times \text{Load current}}.$$

h turn in square inches is taken equal to the full-load

with an extra odd half turn to facilitate connection, g is

ness + 0.016 for insulation) $(t_1 + 1)$.

Digitized by Google

Allowance for a layer of insulation inside and outside adds about o. to the depth of winding.

The mean length of turn l_f' is (see Fig. 15):

For square pole $l_f' =$ (periphery of pole) + 4 (depth of winding).

For round pole $l_f' = \pi\,(f +$ depth of winding).

The resistance per spool is

$$r_1 = \frac{0.0093\, l_f' f'}{12{,}000\, q_1},$$

where q_1 is the cross-section of a turn.

The total drop in voltage in the series field is $0.75\, r_1 I$ which should be 0.5 per cent and 1 per cent of the rated voltage.

Shunt Field. — The shunt field is required to give a certain nu ampere-turns, usually equal to the no-load ampere-turns. Let this nu ampere-turns per pole be F. At 1000 amperes per square inch the cros of copper in a coil would be $F/1000$. The total cross-section of the coil, i insulation, is determined by means of the space factor f'. Then the cros

of the coil $= \frac{F}{1000 f'}$, where f' has a value of 0.5 if No. 18 B. & S. wire 0.55 for No. 12, 0.60 for No. 6, and from 0.6 to 0.8 where copper r used. Where very small wires are used f' becomes as small as 0.25 (*cle on Electromagnet Windings*).

The depth of winding will be

$$b_2 = \frac{F}{1000 f' c_2},$$

where c_2 = length of coil (*see Fig. 17*).

The superficial area will be (see Fig. 17) $A_2 = 2\,(f + b + 4\, b_2) c_2$.

The rise in temperature in ° C. of the coil will be from 60° to 80° per square inch of A_2; thus for 40° rise on the spool the watts (w_2) per spoo be from $0.5\, A_2$ to $0.6\, A_2$ depending upon the ventilating effect of the armature.

Voltage per spool under normal conditions, allowing 25 per cent to spare for rheostat, will be

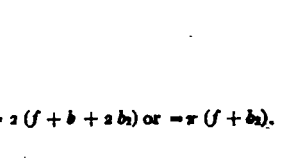

Fig. 17. Dimensions of Field C

$$e_2 = \frac{0.75\, E}{p}.$$

Current in shunt field $= i = \frac{w_2}{e_2}$.

Turns per spool $= t_2 = \frac{F}{i}$.

Mean length of turn, in in. $= l_f = 2\,(f + b + 2\, b_2)$ or $= \pi\,(f + b_2)$.

Resistance per spool $= r_2 = \frac{e_2}{i}$.

N OF PERFORMANCE FROM DESIGN. —
etermining what will be the performance of a given

Digitized by Google

24. Core-loss. — The core-loss consists of hysteresis and eddy cu in the armature teeth and core. It is best calculated by taking from in the article on *Magnetic Properties of Iron* the hysteresis loss per at one cycle per second for the proper density and the eddy loss per at one cycle per second for the proper density and thickness of sh values are substituted in the following formulæ.

Total loss in core $= V_c C_h f + V_c C_e f^2$,
Total loss in teeth $= V_t C_h f + V_t C_e f^2$,

where

V_c and V_t = volume in cubic inches of core and teeth respectively,
C_h = constant from hysteresis loss curve for proper density,
C_e = constant from eddy loss curve for proper density, and thickn
f = frequency.

A rough value for V_c and V_t can be conveniently obtained from in the table for the calculation of the excitation, section 19. Then

$V_t = p \times$ (area path) $\times$ (length of path),
$V_c = 2p \times$ (area path) $\times$ (length of path).

The calculation of the core-loss is one of the most unreliable and uns steps in the design, as the value calculated by theoretical principle multiplied by a factor having a value between 1.5 and 3 to obtain t the core-loss that will be found in the finished machine, on account o tions of flux caused by the teeth. This factor is obtained in commerc from tests on machines similar to the one being designed.

25. Friction and Windage can be calculated by formula for any line of similar machines but no method applicable in general can Machines are designed so that the value of the friction loss very close mates those given in the table in section 28. The true friction vari as the speed, and the windage as the square of the speed. In shunt the speed does not change much with the load so this loss may be ass stant in this class of machines (*see Motors, Direct-current*).

Stray Power Loss. — This term is sometimes used to includ core-loss and friction and windage.

26. Excitation Loss or RI^2 in Shunt Field. — Since in a s machine the loss in the field rheostat is charged against the machin loss is equal to the terminal voltage multiplied by the current in the s The loss is usually constant and only subject to the arbitrary variati hand regulation.

27. RI^2 Loss in Armature Circuit, including the brushes, series connections, varies as the square of the armature current, and, therefor mately as the square of the load, and also irregularly to a small ext the variation of brush contact resistance with the value of the curr temperature of the copper must also be considered. (*See Resis Conductance.*)

28. Efficiency. — The efficiency is the ratio of the output to the output and all losses. It is predetermined by estimating the value o for the particular condition of load under consideration, as descril preceding paragraphs.

If P = the output in watts and the symbols A, B, C and D re spectively the values in *watts* of the various losses described in s 25, 26 and 27 for the load P, then

$$\text{Per cent efficiency} = \frac{100 \times P}{P + A + B + C + D}.$$

Digitized by Google

num for that load at which the variable loss D is equal losses $A + B + C$. Hence the desirability of making n a machine which is to be operated most of the time

s and Losses. — An idea of a reasonable value for the s of various sizes and the distribution of the losses is ble. It must be remembered that the efficiency of a e may vary throughout a wide range depending upon

Friction (total), per cent	Excitation, per cent	Core-loss, per cent	Arm. RI^2, per cent

of a shunt generator may be predetermined as follows: e the total excitation in ampere-turns per pole to erminals at full load. C is made up of the m.m.f. to nd the m.m.f. to overcome armature reaction. Let ld for an excitation C as shown by the no-load satura-

$$\text{cent regulation} = 100\,\frac{E_0 - E}{E}.$$

se in temperature of the field coils was found in section ure of the armature conductors was roughly checked essary to determine more accurately the probable rise mature conductors as the heat due to the core-loss ture of the armature windings. The following method account all the variables in this complex problem and onstants gives very reliable results.

icated in Fig. 18.

ature core itself is taken as the sum rface, the two annular surfaces at he annular surfaces in the air ducts. n the ducts is used since this surface external surfaces. It is assumed by this surface consists of the core- he armature $R_a I^2$ which occurs in tors embedded in the slots.

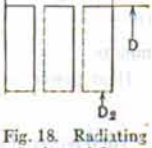

Fig. 18. Radiating Surface of Core

Digitized by Google

A part of the heat due to $R_a I^2$ in the conductors flows from the copp the slot insulation to the iron, if the temperature of the copper is h that of the iron. Sometimes, however, at light loads for instance, th ture of the iron is greater than that of the copper and the flow of heat This condition is taken care of in the following method.

The remainder of the heat due to $R_a I^2$ is dissipated through the in the end connections to the surrounding air which is in motion due t pheral speed of the armature.

Power in watts dissipated by surface of armature core is

$$P_1 = \text{core-loss} + R_a I^2 \left(\frac{2L}{l}\right),$$

I = full-load current; R_a = resistance of armature winding; L = t of core; l = mean length of armature turns.

Effective radiating surface of armature core in square inches is

$$A_i = \pi DL + \frac{\pi}{4}(D^2 - D_2^2)(2 + d).$$

D = outside diameter of armature (Fig. 15); D_2 = inside diameter of d = number of air ducts.

Rise in temperature in ° C. of armature core above air is

$$T_i = \frac{P_1}{A_i} t.$$

t = 30 for narrow, or high-speed armature; = 40 for long or armature.

Permeance of heat path from copper to iron through slot is

$$M = \frac{U_s L s}{k_1 d_1},$$

where

U_s = perimeter of slot insulation; s = total number of slots; k_1 = d_1 = thickness of insulation in slot; L = length of core.

Heat power in watts transferred from copper to iron or vice versa is

$$Q_1 = M(T_c - T_i),$$

where

T_c = rise in temperature of copper above air

Permeance of heat path from copper to air at end connections is

$$N = \frac{U_c l_c Z}{k_2 d_2 + k_3},$$

where

U_c = perimeter of end connection; l_c = length of end connection; number of bars or coil sides; k_2 = 400 to 500; d_2 = thickness of insulati connection; $k_3 = \frac{170}{1 + 0.00025\,V}$; V = periphery speed of armature minute.

Heat power in watts transferred from copper to air by end connecti

$$Q_2 = NT_c.$$

Total power of $R_a I^2$ in armature winding is

$$P_2 = Q_1 + Q_2 = M(T_c - T_i) + NT_c.$$

2. **Saturation Curve.** — The saturation curve is not of immedia in determining the quality of a machine but is more particularly of the designing engineer. It is made by driving the armature at speed and supplying current to the shunt fields from a separate sourc tial. As the current in the shunt field increases the potential generated by the armature varies and this is measured by a voltmeter.

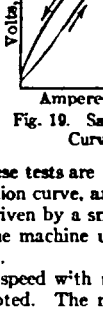

Fig. 19. Sa Curv

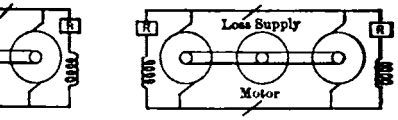
On account of the existence of the hysteresis loop (*see Magnetic Properties of Iron*) it is necessary to increase the field current gradually and never to reduce the value at any step until the maximum value has been reached. The curve is plotted with volts as ordinates, and field current or ampere turns as abscissæ and shows the typical knee curve of all saturation curves. Different curves are obtained with increasing and decreasing excitation as shown in Fig. 19.

3. **Core-Loss and Friction, or Stray Power.** — These tests are the same arrangement as used in determining the saturation curve, a made at the same time. The machine to be tested is driven by a sm having a capacity about 10 per cent of the rating of the machine u All the losses and constants of this motor must be known.

First the machine under test is driven at the desired speed with in the fields and the power taken by the driving motor noted. The output of the driving motor is calculated and this gives the friction large machine.

Then the large machine is excited and the power to drive it is de This power represents the core-loss plus the friction loss. Dedu friction loss already determined, the values of the core-loss for vari of excitation are found. See also *Magnetic Properties of Iron*.

The combined core-loss and friction loss constitute the stray powe



4. **Load Runs.** — The machine is run and the excitation adjust the proper voltage at no load. The load is then added and the termin noted. If E_0 = voltage at no load and E = voltage at full load, the is $\frac{E_0 - E}{E}$.

If the machine has not commutating poles it is necessary to ma liminary test in order to set the brushes at that position which give compromise in sparking at no load and full load. Commutation is observing the action of the brushes at full load and 150 per cent l conclusions are a matter of judgment and experience, although sparking have been arbitrarily agreed upon and are represented in series of pictures.

5. **Heat Runs** are made by operating the machine at full load fo of time until the temperatures of the various parts that can be not operation have become constant. The greater the capacity of the m longer will be the time necessary.

Dead-load and Pumping-back Methods. — Heat runs may either by the "Dead Load" method in which a resistance load, such a rheostat, is connected to the terminals and full rated load power is r drive the machine; or by the Hopkinson or "Pumping-back" method two machines having similar characteristics are run together, one a generator to supply electrical power to the motor which in turn drive by means of a belt or similar mechanical connection. For this tes supply" is required which may consist of a source of either electrical

ount of power required is from 10 to 20 per cent nachines. The connections are shown in Fig. 20, Fig. 21 for mechanical loss supply.

these data are included all the factors necessary to determine the eff
lation, commutation and heating of the machines. Dimensions a
and weights in pounds. Performance data are deduced from tests.

SERIES ARC-LIGHT GENERATORS. — These machines
to give a constant value of current in the external circuit irrespe
resistance or counter e.m.f. in that circuit. This is accomplished
the voltage impressed on the external circuit to decrease whenev
tendency of the current to increase. The load usually consists
(20 to 50) of arc lamps connected in series, each taking about 40
lamp requires the same value of current and the total voltage is pr
the number of lamps in use. If a lamp is no longer needed it is sh
by a switch and the current in the remainder of the lamps remai
because the generator automatically reduces the voltage supplied.
lation of the current is obtained by two or more of the following m
high armature reaction which tends to weaken the field whenever
increases; (2) movable brushes to vary the number of turns in se
brushes; (3) a series field arranged so that turns may be shunted, sh
or cut out; and (4) a high degree of saturation in the magnetic circui
so that the flux changes very slightly for considerable change of m.

The pole face density is usually quite high and the path of the flu
is of high reluctance, whereas the path of the armature flux is of low
thus there is much field distortion. The machines are usually wou
to 4000 volts. The distorting effect of armature reaction is usually
to take care of sudden and small variations of the load, and large
variations of the load are taken care of either by moving the brushe
position giving either a lower or higher voltage, or by commutating
some of the turns of the series field.

Brush Arc Machine. — This was the first arc-light machine to

Compound Generators, Equalizer Connection. — In order t compound-wound machines in parallel it is necessary to provide an connection which makes a common connection on all the machines at between the armature and the series field as shown in Fig. 24.

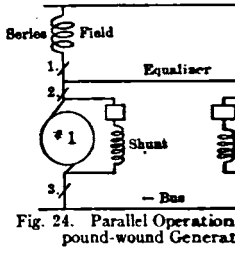

Fig. 24. Parallel Operation pound-wound Generat

The function of the equalizer is to divide the load current at all times in the proper proportion between the series fields of the different generators. This prevents the machines from acting as series generators or differential motors which would cause short-circuits.

For compound-wound machines to operate successfully in multiple all machines connected to one set of bus-bars must have the same amount of compounding as well as the same voltage at no load. Due to saturation in the circuit it is not always possible to make the compounding curve a stra i.e., the increase in voltage directly proportional to the load. It is, necessary to investigate the compounding curves of machines before operated in parallel. With unlike compounding curves one machine come overloaded while another is under-loaded, unless the field curre machine is adjusted.

In connecting a machine in parallel with those in operation it is ne see that it has the proper polarity and voltage, that the equalizer circui

ENERATORS, STATIC. — (*See also Generators, Alternating-current; Elyt.*) In electro-therapeutic and X-ray work a unidirectional high-frequency current is desired and is often obtained by a kind of electric generator led a static generator. There are two types of static generators available r the purpose, the frictional machine and the influence machine.

Frictional Machine. — In the frictional machine two dissimilar substances e rubbed together in some form rotating apparatus as shown in g. 1. A rotating glass plate *A* ubbed on both sides at *BB* by o pieces of leather which are ased and covered with the amal- m 1 Zn, 1 Sn, 2 Hg. The glass s electrified positively and the harge is drawn off by the metal oints *CC* which almost touch the lass. Two silk aprons *DD* cover he glass between the rubbers and he metal points, to prevent the ssage of the charge into the air. he rubbers are connected to ground remove the negative charge which cumulates upon them.

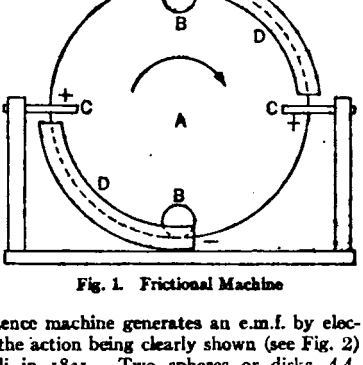

Fig. 1. Frictional Machine

Influence Machine. — The influence machine generates an e.m.f. by electrostatic induction, the principle of the action being clearly shown (see Fig. 2) in a machine invented by G. Belli in 1831. Two spheres or disks *AA*. called carriers and normally insulated from each other, are rotated about the shaft *B*. The two fixed plates *CC* are charged initially from some external source. When the carriers *AA* take the position shown in the figure, a momentary connection is made to the neutralizing wire *EE* at the spring contacts *DD*. As a result of this connection between *A* and *A*, the carriers are charged by induction, the charge on each being opposite to that of the adjacent plate. When the carriers rotate still further, the connections at *DD* are broken and the charges induced on the carriers become isolated. When the carriers are rotated through half a revolution from the position shown, they strike the prongs *FF* and add their charges to the field plates *CC*.

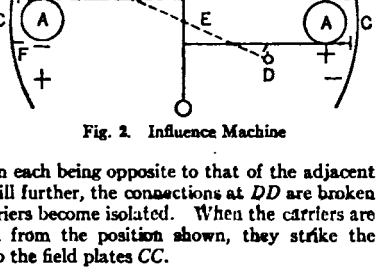

Fig. 2. Influence Machine

Wimshurst Machine. — Many forms of influence machines based upon the above principles have been devised. The most successful designs were made by Voepler, Holtz and Wimshurst. The Wimshurst machine, shown in Fig. 3, has superseded most of the other forms because of its self-exciting powers and suitability for work in all conditions of atmosphere. Two glass disks, *A* and *B*, are rotated close together and in opposite directions. A certain number of tin-foil carriers *CCC*, are mounted upon the outside surface of each plate. Neutralizing conductors *DD* for each disk are placed at right angles to each other. The collecting combs *EE* are connected to a condenser *F* and a spark gap G across which the discharge takes place. If two diametrically opposite

carriers on the back plate are charged positively and negatively re
opposite charges will be induced upon the adjacent carriers on the f
if they are connected by the neutralizing wire. The induced charges are isolated when this connection is broken and are drawn off at the collecting combs *EE*. In the Wimshurst machine induced charges in moving from the point of electrification to the collecting combs also serve to induce other charges on the back plate.

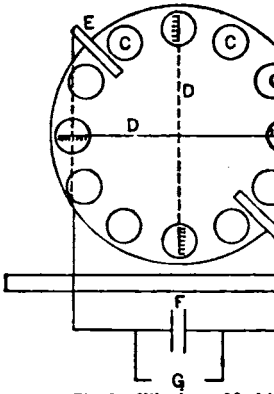

Fig. 3. Wimshurst Machi

After a few revolutions of the disks, half of the carriers on each plate are charged negatively and half positively, giving a machine of reliable service and high power. Unlike the Holtz machine the Wimshurst machine does not reverse its polarity when the distance between the terminals is made greater than the sparking distance. Large influence machines are constructed with several plates revolving in opposite directions and connected in pa whole being contained in a glass case to protect the plates from dust. plate Wimshurst machine gives a spark of eight inches and a twelve-plat will give a spark of 13⅝ inches. The plates in these machines ar mately 30 inches in diameter and the machines give 6 sparks for each of the disks.

OUND CONNECTIONS. — (*See also Grounding of Electric Circuits.*) ound connection is a conductor buried in the earth and connected by uctors to other conductors or apparatus which are to be maintained at h potential, irrespective of the current which may flow through it. Usually cuit is not grounded except at such points that under normal conditions peration no appreciable current flows to ground. A current may, however, stablished through a ground connection due (1) to a lightning discharge, to an accidental grounding of a live wire of a grounded circuit, and (3) a cross between the grounded circuit and a high voltage ungrounded circuit; the last instance the current through the ground connection is only the tively small charging current between the other wires of the high voltage tem and the ground (*see Capacity and Charging Current*).

SE OF GROUND CONNECTIONS. — Ground connections are used the following purposes: (1) for lightning arresters, to afford a path to ground the lightning; (2) for lightning rods on buildings, for the same purpose; steel transmission poles to give the current a short circuit to ground in se of insulator failure. Also as a lightning protection; (4) to bring the ural points of circuits to ground potential and thus reduce the potential sses of the system and minimize the danger of accident from shock; (5) to ing transformer cases, instrument cases, conduits, etc. to ground potential d thereby reduce the danger from shock; (6) to obtain an earth return for egraph circuits; (7) for wireless telegraph systems to obtain the use of the rth's electrostatic capacity.

GROUNDING TO CONDUCTORS USED FOR OTHER PURPOSES. — Where an extensive system of water pipes buried in the earth is ailable, a satisfactory ground connection can be made directly to the pipes. as pipes are not suitable for ground connections, as in case of broken joints he resulting arc might ignite the escaping gas. Steam heat pipes are ot insulated (and therefore partially electrically insulated) from the earth. here there are two ground connections, one to an electric railway track and he other to a water pipe, there is danger that railway current may thereby be troduced into the water piping system and produce electrolysis. Sheaths of ables are not good ground as the cables might be injured by the currents in heir sheaths, either from electrolysis or unforseen heating. In fact, cable heaths, like other buried conductors, have a tendency to collect stray currents from electric railways and special ground connections sometimes have to e made to permit these currents to escape without producing electrolysis. teel frames of buildings present only a limited surface to ground at the foundations and are therefore only good when the current to be discharged will be proportionally small.

Connections to Piping System. — The National Electrical Code contains he following requirements:

Size of Ground Wires. — Not to be smaller than No. 6 A.W.G. copper for ightning arresters and must be large enough to carry current caused by or following discharge of arrester (Rule 15*A*l); not to be smaller than No. 8 A.W.G. for irect-current systems and must have at least one-fifth the carrying capacity f the grounded conductor, and not to be smaller than No. 8 A.W.G. for alternating-current systems but must have at least one-fifth the carrying capacity f the wire to which it is attached, except that it need not be larger than No. 0 A.W.G. (Rule *Ak*).

Method of Making Ground Connections.—In connecting a ground wire to a piping system, the wire should be sweated into a lug attached to an approved clamp, and the clamp firmly bolted to the water pipe after all rust and scale

have been removed; or be soldered into a brass plug and the plug scre
a pipe or pipe fitting.

GROUNDING TO SPECIAL PLATES, PIPES, ETC. — When
buried conductors are not already available, direct connection to th
may be made (1) by burying a plate in the earth, (2) by burying a wir
bon in the earth, or (3) by driving a pipe vertically into the earth.
form of ground connection is now generally accepted as the best. Th
methods of direct grounding are described in detail in the section below o

Factors Affecting the Impedance of Ground Connection. The
impedance opposing the flow of current into the ground through a gro
nection depends (1) upon the extent of metal surface in contact with t
(2) the thoroughness of this contact, (3) the wetness of the earth, (4) the
between this ground connection and the ground connections (if any *)
the current leaves the earth.

The effect of the distance upon the impedance between the electro
important one, but is frequently overlooked. If the electrodes are
gether, the impedance will be low on account of the shortness of th
path. If the distance between electrodes be increased, the impedanc
increased until a certain point is reached, after which it will steadily
on account of the increase in the cross-sectional area of the earth
experiments by the Cunliffes (*Jour. I.E.E., 1909, Vol. 43, p. 449*) the
ance" (probably meaning impedance) reached a maximum when th
plates were about 25 feet apart, the decrease in "resistance" being c
den for smaller or greater distances, as shown in Fig. 1. A curve by
Creighton (*G. E. Rev., 1912, Vol. 15, p. 60*) shows the resistance betw
grounds at various distances apart, the maximum resistance being
tained at 25 feet.

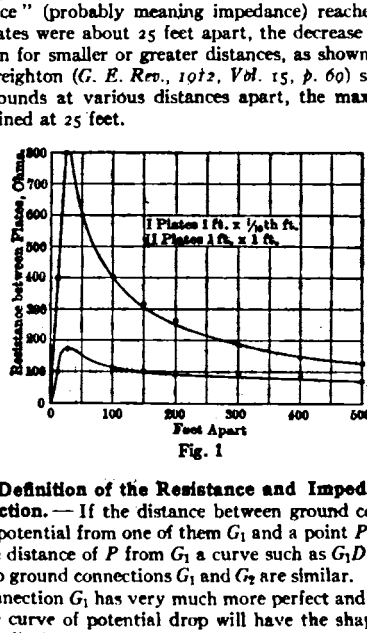

Fig. 1

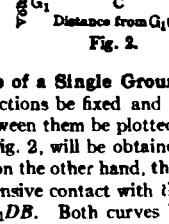

Fig. 2.

**Definition of the Resistance and Impedance of a Single Grou
nection.** — If the distance between ground connections be fixed and
of potential from one of them G_1 and a point P between them be plotte
the distance of P from G_1 a curve such as G_1DA, Fig. 2, will be obtain
two ground connections G_1 and G_2 are similar. If, on the other hand, th
connection G_1 has very much more perfect and extensive contact with t
the curve of potential drop will have the shape G_1DB. Both curves
peculiarity of being steep near the electrodes and of becoming flat betwe
indicating that the greater part of the resistance occurs near the el

* The circuit may be completed by a displacement current, through the air,
surface of the earth.

Digitized by Google

the current is restricted to a limited area, practically no drop occurring ere the current spreads out.

The impedance of the ground connection G_1 is then defined as the ratio of the ential drop CD, to the current entering the ground at G_1, and similarly for ground connection G_2. The resistance may be approximated by measuring impedance at different frequencies, and by extrapolation, finding the impedce at zero frequency. This will be the resistance.

Resistance of Some Typical Ground Connections. — The resistance of ound connections varies so greatly with the condition and nature of the soil, at data on resistance have only local application. The following tests are sented merely to give a general idea of the results which are obtained in ctice.

Authority	Time of year	Description of soil	Type of ground connection	Dimensions	Depth	Ohms
					ft.	
Horie.....	Feb.–June	Surface loam	Plate	1 ft.×1 ft.	..	1940

Hayden...	June–July	Clay loam	Pipe	2½ in.	3.1	35.4
	Mch.–Apr.	Clay loam	Pipe	2½ in.	3.1	240

E. F. Creighton (*G. E. Review, 1912, Vol 15, p. 67*) says: "If an iron pipe inch in diameter is driven into normally moist earth to a depth of 6 or feet, it will usually have a resistance of about 15 ohms. Eight ohms may be sidered unusually low, while dry soils may give a resistance of 56 ohms and wards." Creighton also states that after a depth of several feet in the conting stratum has been reached, each additional foot decreases the total sistance by the factor $d/2$ where d is the depth in feet.

DESIGN OF GROUND CONNECTIONS. — It is as a rule impracticable to install a ground connection of sufficiently low conductivity to allow the assage of the maximum current it may have to carry without producing a siderable rise of voltage. The conductivity which a ground connection ould have is therefore largely a matter of experience and judgment rather an a matter of exact calculation. Cheapness and durability usually determine the material, usually iron or copper, and the thickness.

Copper Plates. — Formerly the most common form of ground connection sisted of a copper plate embedded in charcoal or coke in moist earth. The e of coke is questionable, for the reason that the sulphur in the coke is likely corrode the copper plate and thus increase its resistance. Some engineers e of the opinion that neither charcoal nor coke is of any particular use in conection with a ground plate. The corrosion of copper ground plates is greatly duced by coating with tin. As the conductance of a ground connection is

not proportional to the area of the metal plate, the use of a single la is an uneconomical method of obtaining a low resistance.

Copper Wire or Ribbon. — The wire or ribbon has the advantage resistance than a plate for the same area. The wire has the further a that no special material or connection is required. The wire may b in a straight line or coiled with turns wide apart into a plane spiral. form is sometimes made by wrapping a number of turns of wire a butt of a pole before setting it.

Pipes Driven into the Ground. — The driven pipe or rod is pro best of all forms of direct ground connections. The pipe is usually an often galvanized or sherardized, from ¾ inch to 2 inches in nominal si 6 feet or more into the moistest ground available. The diameter of a little effect upon its earth resistance; thus a pipe 2 inches in diame resistance only 6 to 12 per cent less than a pipe 1 inch in diameter Creighton, *G. E. Rev., 1912, Vol. 15, p. 14*). To facilitate driving, t sometimes provided with a pointed casting at the lower end and c upper end. The pipe has the advantage that it is cheap to install, as dug, and being driven vertically, it can tap any conducting stratum of which is practically accessible. It is highly efficient as regards cor per square foot of surface exposed to the earth, and while the resist single pipe will exceed that of a large plate, a higher and more perma ductivity can be obtained from several pipes driven at some dista and connected in multiple, than from an equal expenditure in mo single large ground plate. Ground pipes or plates in multiple shou less than 6 feet, and preferably 10 feet, apart, in order to avoid supe two zones of high current density.

If the ground available is naturally dry the conductivity may be by cupping out the soil around the pipe at the surface and adding a fe of salt and water. A neater form of earth unit is shown in Fig. 3. A of metal or earthenware of any available diameter is set around the pipe at the surface of the ground and covered by a lid. This receptacle will hold the salt. Its advantages lie in the easy construction of the connection and protection of surrounding vegetation from the saline water.

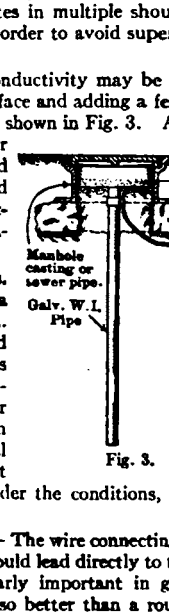

Fig. 3.

Pipe Grounds for Lightning Arresters. — The General Electric Company recommends a large number of grounds at each installation. These numerous ground connections are joined together by a copper connection. It sometimes happens that a good ground cannot be conveniently made near the arrester, or that a better one can be made at a more distant point. In this case it is recommended that the principal ground be made at the more distant point, but that a ground of some sort, the best possible under the conditions, directly underneath the arrester.

Connections to Ground Plates and Pipes. — The wire connectin paratus to be grounded to the buried conductor should lead directly to with as few bends as possible; this is particularly important in g lightning arresters, in which case a flat strip is also better than a rou All exposed joints and those buried in the ground should be made in su that they will not rust off. The buried connection from a ground pla surface should be so protected that it will not rust off or be cut off w

nections are made for other purposes. It is also necessary that the connections be protected from mechanical injury and theft, from the surface of the ground above the level at which it can be reached. To insure reliability, connections should as far as possible be made so that their continuity can be determined by inspection.

TESTS OF GROUND CONNECTIONS. — Ground connections should frequently tested to determine their continuity and occasionally to determine their impedance. Alternating current should be used, in order to avoid the effects of polarization. In order to pass a current through a ground connection it is necessary to have a second connection in order to complete the circuit. Where a large water-piping system is available for the return connection, an approximate measure of the resistance can be obtained by passing a current from the ground connection to an accessible part of the piping, say a hydrant, and computing the resistance by dividing the volts by the amperes. The resistance thus obtained includes both the resistance to be measured and that of the connection through the piping system. As the latter is probably much smaller and may be insignificant, the result gives an approximate idea of the resistance and locates a discontinuity as an infinite resistance, that is, no current flowing. Where there are two similar grounds, current may be passed from one to another and the sum of the two resistances, or the average resistance, obtained.

When a more accurate determination of the individual resistances of two or more ground connections is desired, the connections shown in Fig. 4 may be employed and a curve obtained by test, similar to that shown in Fig. 2. The apparatus required comprises a source of alternating current, a rod P which may be driven into the earth, a high resistance wire BD stretched between the two ground connections G_1 and G_2, an ammeter A and a telephone receiver T. The contact C is slid along the resistance wire until the telephone receiver is silent. The drop of potential between G_1 and the rod is then the same as between G_1 and the contact C. The drop between G_1 and P is therefore equal to

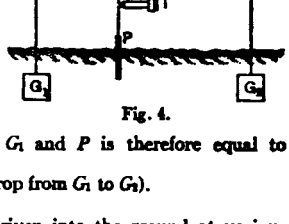

Fig. 4.

$$\frac{\text{(length of wire } BC)}{\text{(length of wire } BD)} \times \text{(total drop from } G_1 \text{ to } G_2).$$

By taking a series of observations with P driven into the ground at various points the curve of potential drop is readily plotted and the resistance of each ground connection, as defined above, readily obtained.

CARE OF GROUND PLATES AND PIPES. — The greatest trouble with ground plates and pipes arises from electrolysis, and periodic resistance measurements should be made as described above. When a ground connection shows an abnormally high resistance, it is usual to supplement it with a new ground connection, as it seldom pays to remove the old ones. Ground connections deteriorate rapidly if equipped with salt boxes; but even under the worst conditions they are likely to last many years. Practically no accurate measurements of the resistance of ground connections were made until quite recently, so that little is known about their life performance. J. L. R. Hayden cites the case of some pipe grounds which maintained the same average resistance for three years.

SPECIFICATIONS FOR GROUND PIPES AND PLATES. — (*See also* Article on *Specifications.*) In the case of ground plates, the following data

should be specified: Material of plate (usually copper); size of plat thickness; depth at which the plate shall be buried; amount of cha and above it; method of connecting the plate to its cable or wire (u dered and bolted); whether the plate shall also be connected to the and if so, how.

In the case of pipe ground connections, the following data should b Diameter of pipe; whether galvanized, sherardized, etc.; depth to pipe shall be driven; method of finishing the top of the pipe; heigh shall project above the ground; whether the pipe shall be connec track rails and if so, how.

GROUND DETECTORS AND ARCING-GROUND SUPPRESSORS. — A ground detector is a device for indicating an accidental ground on a transmission line; an arcing-ground suppressor is an arrangement of switches and relays by means of which an arc tending to maintain an accidental ground is automatically extinguished

GROUND DETECTORS FOR NORMALLY UNGROUNDED SYSTEMS. — On ungrounded two-wire direct-current systems a voltmeter of the central-zero type connected between the ground and the middle point of a resistance joining the two line wires serves as a satisfactory ground detector. The direction of the deflection will indicate on which wire the ground has taken place, and the magnitude will indicate the nature of the ground. For alternating-current circuits, this method is unsatisfactory on account of capacity effects and also because of the higher voltages commonly involved.

Electrostatic Ground Detectors. — For single-phase ungrounded systems the simplest form of ground detector consists of two electrostatic voltmeters, each connected between one line wire and the earth. A ground on either wire causes an inequality in the readings of the two meters.

The more common form of ground detector operates as an electrostatic differential voltmeter. Fig. 1 shows diagrammatically the arrangement for a single-phase instrument. The movable vane V is connected to the earth, the fixed plates S_1 and S_2 are connected one to each of the two mains. Vane V will be equally attracted by the two plates unless the insulation resistances of the two line wires to ground are not equal, but will deflect from its normal position to one side or the other when a ground occurs.

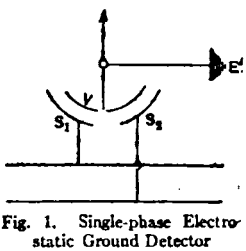

Fig. 1. Single-phase Electrostatic Ground Detector

The three-phase electrostatic ground detector for ungrounded circuits is made in two principal forms. One form consists of three separate elements, each similar to that used in the single-phase instrument, all three elements being in one case but having individual scales. Another form consists of a movable spherical vane, connected to the earth, and three fixed vanes, each of which is connected to one line wire. The movable vane in its normal position is equally distant from each one of the fixed vanes, but, in case of a ground on one line wire, it moves away from the fixed vane which is connected to the line wire on which the ground occurs. The principal parts of this instrument are clearly visible through the glass front of the instrument cover; hence no pointer and scale are needed. Two single-phase detectors will work satisfactorily on three-phase circuits, if the junction point of the two instruments is connected through a condenser to the third line wire.

Voltage Range. — Commercial sizes of electrostatic ground detectors range from 650 volts to 22,000 volts for single-phase circuits, and from 1150 volts to 22,000 volts for three-phase circuits.

Connections. — Electrostatic ground detectors are usually not connected directly to the line wires, especially if the voltage is above 3300. Some types are furnished with special terminal studs containing high-resistance rods of graphite through which the instrument is connected to the line wires. Other types are connected to the circuit through condensers, commonly of tubular form. Although, in this case, the condensers practically insulate the instrument from the line, the leads connecting the detector and the condensers must be treated as high-tension conductors, i.e., they should be properly separated and

far enough from neighboring metal in order that disturbing capacity effe not be introduced. Therefore, the leads should be fairly short and must enclosed in metal conduit.

GROUND DETECTORS FOR NORMALLY GROUNDED TEMS. — The methods outlined above, depending on the variable p difference between mains and earth, do not apply to earthed systen three-wire circuits with grounded neutral, or four-wire, three-phase circu grounded neutral. The most usual method for earthed circuits is nect an ammeter in the earth circuit between the earth plate and t tem; hence any leakage current will have to pass through the amme low-range instrument is desired if slight grounds are to be detected. I to protect the instrument from excessive currents, an arrangement may by which the instrument is short-circuited as soon as the current reache tain value, or a resistance may be inserted in the circuit to reduce the to a safe value. By the second method a short-circuit due to a ground be suppressed without interruption of service on the line in question. same time, however, the pressure on the other line wires with respect t would be raised to a higher value.
